The cases of laboratory-acquired SARS coronavirus infection and the subsequent transmission of disease to others after one such case reinforce the importance of strict attention to safe laboratory practices. Because the reemergence of SARS could lead to global spread, the local, national, and global public health and health care communities must be alerted quickly and updated regularly about new cases and the status of transmission.

375 MEASLES

MARTIN WEISSE AND MARK PAPANIA

DEFINITION

Measles (synonyms: rubeola, red measles, hard measles, 7-day measles) is a highly contagious systemic viral disease characterized by generalized maculopapular rash, fever, cough, coryza (rhinitis), and conjunctivitis. The measles virus is a negative-stranded RNA virus of the genus *Morbillivirus*, family Paramyxoviridae, with only one serotype and 23 genotypes.

EPIDEMIOLOGY

In the pre-vaccine era, measles was a nearly universal rite of childhood, affecting almost every child by 15 years of age. As a result of high vaccination coverage, measles has not been endemic in the United States for more than a decade (incidence <1 case/million people). However, a limited number of measles cases occur annually in the United States from the international importation of the virus. Many other countries have eliminated endemic measles, including all countries in the Americas. Unfortunately, measles is still endemic in many developed and developing countries and still causes an estimated 164,000 annual deaths worldwide.

Measles, which is one of the most contagious diseases, infects more than 90% of susceptible people who come into close contact with an infectious patient. The measles virus is transmitted mainly by direct contact with large respiratory droplets, but airborne spread is also possible. Persons with measles are considered infectious from 4 days before the onset of the rash until 4 days after its onset. Immunocompromised patients may shed virus for a prolonged time and should be considered infectious as long as they have catarrhal symptoms.

Measles infection confers lifelong immunity, as does measles vaccination. Maternal measles antibody, which is transferred through the placenta, protects infants of immune mothers during the first months of life. More than 90 to 95% of a population must be immune to sustain interruption of measles transmission.

PATHOBIOLOGY

Measles infection usually occurs through inhalation of infectious droplets into the respiratory epithelium or direct inoculation onto the conjunctiva. The virus attaches to host cells by its hemagglutinin protein, and its fusion protein allows viral entry and facilitates spread between cells. The virus initially replicates in the respiratory epithelial tissues or the adjacent lymph nodes. A primary viremia disseminates the virus to the reticuloendothelial tissues of the tonsils, lungs, gastrointestinal tract, spleen, and distant lymph nodes. Several days later, the onset of prodromal symptoms heralds a secondary viremia that results in further spread of the virus to the skin, viscera, kidney, and bladder. Histologic changes in the skin and mucous membranes consist of epithelial giant cells with surrounding mononuclear infiltrates and edema. Koplik spots, which are inflammatory lesions of the buccal submucous glands, have similar histologic features.

The development of IgM antibody coincides with the appearance of the rash; during the next week, IgG antibodies appear and persist for life. Cell-mediated immunity is also critical for resolution of acute infection. Measles virus infection causes a significant immunosuppression that predisposes infected patients to secondary bacterial and viral infections, which increase the mortality rate of measles. The exact mechanisms of immunosuppression are unknown.

CLINICAL MANIFESTATIONS

The incubation period of measles is usually 8 to 12 days after exposure until the development of the first symptoms. The well-known description of the prodrome of measles is fever associated with cough, coryza, conjunctivitis, and Koplik spots, often accompanied by malaise, myalgia, and headache. Fever increases with the severity of catarrhal symptoms and peaks at the onset of the exanthem; it frequently reaches 40° or 41° C and may persist for 6 days. Koplik spots, an enanthem of small bluish white spots on a red background on the buccal mucosa lateral to the molar teeth (Fig. 375-1), are pathognomonic for measles. Koplik spots precede the rash by 1 day and are no longer evident 2 days into the rash.

FIGURE 375-1. Typical Koplik spots.

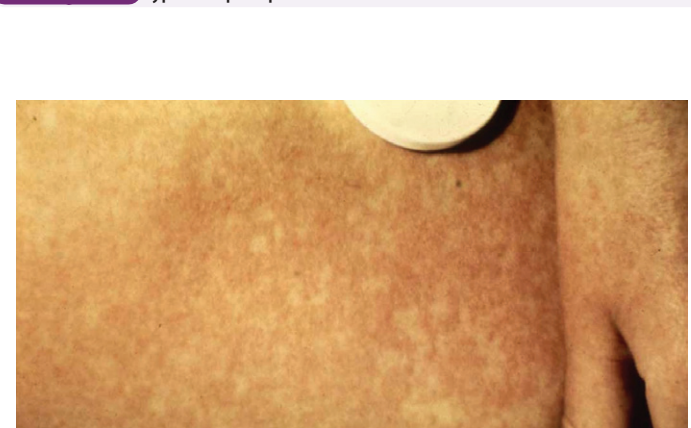

FIGURE 375-2. Typical morbilliform eruption of measles, with broad areas of confluent red maculopapular lesions interspersed with islands of normal skin.

The measles rash (Fig. 375-2) typically arises 2 to 6 days after the onset of the catarrhal symptoms. It begins on the face or behind the ears as individual red macules that blanch with pressure. During 12 to 24 hours, the macules become papular and tend to coalesce. The rash progresses from head to trunk to extremities and maintains the same pattern of progression from macules to coalescing papules. By the fourth day of the rash, the entire body is typically involved, although the hands and feet may be spared. The rash fades in the same head-to-toe order in which it appeared and often peels with a brawny desquamation during the subsequent weeks. In darkly pigmented individuals, the erythema may be difficult to appreciate, and the rash may be better felt than seen.

Important variations in the classic presentation of measles include "modified measles" in patients who have received immune globulin prophylaxis and "mild measles" in previously vaccinated persons. In both variations, any of the classic symptoms may be attenuated or absent. Such cases are extremely difficult to diagnose in the absence of known exposure to measles. Also, immunocompromised patients can have severe measles pneumonia without rash. Measles should be considered in any immunocompromised patient with pneumonia of unknown etiology.

TABLE 375-1 A GUIDE TO THE DIFFERENTIAL DIAGNOSIS OF MEASLES

	CONJUNCTIVITIS	RHINITIS	SORE THROAT	ENANTHEM	LEUKOCYTOSIS	DIAGNOSTIC TESTS AVAILABLE
Measles	++	++	0	+	0	Yes
Rubella	±	0	0	0	0	Yes
Exanthem subitum	0	0	0	0	0	Yes
Enterovirus infection	0	0	±	±	0	Yes
Adenovirus infection	+	+	+	0	0	Yes
Scarlet fever	0	0	++	+	+	Yes
Infectious mononucleosis	0	0	++	+	±	Yes
Drug rash	0	0	0	0	0	No

0 = not usually present or no test available; ± = variable in occurrence; + = present: test available (virus or bacterial culture, serology); ++ = present and severe.
Modified from Brunell PA. Measles. In: Ausiello D, Goldman L, eds. *Cecil Textbook of Medicine,* 23rd ed. Philadelphia: Saunders Elsevier; 2008:2477.

Complications

The most common complications of measles are diarrhea, otitis media, and pneumonia. Diarrhea occurs early in the disease and is probably the result of intestinal measles virus infection. Measles-associated diarrhea significantly contributes to morbidity and mortality in malnourished patients. Pneumonia is the most severe common complication and is responsible for the majority of deaths associated with measles. Measles-associated pneumonia may be a giant cell pneumonitis consistent with direct infection by measles virus or be caused by a secondary bacterial pathogen, most often *Staphylococcus aureus* (Chapter 296) or *Streptococcus pneumoniae* (Chapter 297).

Overall, children younger than 5 years and adults older than 20 years have the highest complication rates. Complication rates do not vary substantially by sex except that pregnant women are at high risk. Measles is especially hazardous during the first trimester, often leading to fetal demise. Later in pregnancy, the rate of prematurity is high, as is maternal pneumonia.

Malnutrition is associated with increased fatality rates, and children with vitamin A deficiency are at high risk for severe keratoconjunctivitis, which can lead to blindness. Immunocompromised patients (e.g., those with human immunodeficiency virus [HIV] infections, with cancer, or receiving chemotherapy or immunosuppressive drugs such as steroids) are at higher risk for severe measles complications. Interstitial pneumonia occurs 1 to 2 weeks after the onset of measles and is the most common cause of measles-related death in immunocompromised patients. Measles inclusion body encephalitis occurs in immunocompromised patients 1 to 6 months after acute measles and is usually fatal.

Postinfectious encephalomyelitis occurs in 1 in 1000 measles cases. Patients present during the 2 weeks after the onset of the rash with headache, recurrence of fever, vomiting, and stiff neck. Up to 25% of patients die, and 33% of survivors suffer neurologic sequelae. Elevated IgG and IgM can be found in cerebrospinal fluid, but measles virus cannot be isolated, thereby suggesting an autoimmune pathologic process. A rare late central nervous system complication of measles is subacute sclerosing panencephalitis (Chapter 378), a degenerative demyelinating disease due to chronic infection. Subacute sclerosing panencephalitis occurs years after the acute measles infection and is almost universally fatal.

DIAGNOSIS

In many countries, measles has become such a rare disease that most physicians have never seen a patient. One key to making the diagnosis is to consider measles in any patient with a generalized maculopapular rash and fever. The index of suspicion should be raised if cough, coryza, and conjunctivitis are present and if measles virus transmission is occurring in the area or if the patient has traveled internationally or had any association with international travelers. Although Koplik spots are pathognomonic, the absence of Koplik spots does not exclude the diagnosis. The lack of vaccination should increase the level of suspicion, but measles can occur despite two documented doses of measles vaccine.

The standard laboratory test for measles is an IgM measles antibody assay on a single serum specimen. However, during the first 3 days of rash, up to 25% of cases may not have IgM; the test can be repeated if the rash and fever persist for 3 days. Acute and convalescent sera to test for a rise in IgG antibody are sometimes useful. Urine, throat swabs, or blood specimens can be sent for viral culture or for detection of viral RNA by reverse transcription–polymerase chain reaction. Genotype sequence analysis aids in tracking the source of the virus, monitoring transmission patterns, and distinguishing a mild case of measles from a vaccine reaction in patients who have recently received measles vaccine.

Differential Diagnosis (Table 375-1)

Other viral infections that may be confused with measles are rubella (Chapter 376), human herpesvirus 6 and 7 infection (Chapter 382), infectious mononucleosis (Chapter 385), and parvovirus B19 infection (erythema infectiosum, Chapter 379). In general, these infections have a milder course. Bacterial infections that may mimic measles include secondary syphilis (Chapter 327), scarlet fever (Chapter 298), streptococcal or staphylococcal toxic shock syndrome (Chapter 447), and leptospirosis (Chapter 331). Drug eruptions (Chapter 448) and Kawasaki disease (Chapter 278) must also be considered. It can be extremely difficult to distinguish measles vaccine reactions, which may include fever and rash, from a mild case of measles. In highly vaccinated populations, measles is rare and clinical symptoms may be attenuated; serologic and virologic assays are critical in distinguishing measles from other diseases and conditions.

TREATMENT Rx

Vitamin A treatment (100,000 IU orally for children 6 to 12 months of age, 200,000 IU orally for children 1 year of age and older) on 2 consecutive days is recommended for children 6 months to 2 years of age who are hospitalized with measles and for any child older than 6 months who has evidence of immune deficiency, clinical evidence of vitamin A deficiency, impaired intestinal absorption, or moderate to severe malnutrition or who comes from communities where vitamin A deficiency is common or measles case-fatality rates are 1% or higher. In these settings, vitamin A can reduce blindness due to severe keratoconjunctivitis and decrease mortality by as much as 50%. For patients with ophthalmologic evidence of vitamin A deficiency, the dose should be repeated once 4 weeks later.

No specific antiviral or other therapies are recommended for measles. Ribavirin, isoprinosine, and interferon alfa have demonstrated modest benefit in small clinical trials, but no controlled trials have been conducted. For most patients, treatment of measles consists of symptomatic therapy with antipyretics and analgesics and encouraging fluids to maintain hydration.

PREVENTION

Vaccination

Live attenuated measles virus vaccines are the best means of preventing measles. Although the vaccine virus strains vary from different manufacturers, all provide equivalent protection. Measles vaccine is typically given as a component of the combination measles-mumps-rubella (MMR) vaccine or the measles-mumps-rubella-varicella (MMRV) vaccine. Measles-containing vaccines can be given at the same time as other live or killed vaccines.

Infants with known or suspected HIV infection also should be vaccinated at 6 months and then again at 9 months if they are at risk of exposure to measles. The first dose of vaccine is given at 9 months of age in countries where transmission is widespread and mortality is high, and it can be given as early as 6 months of age in U.S. infants at high risk of exposure. In the United States, the first dose of measles vaccine is usually given at 12 to 15 months of age (Chapter 17).

In the United States, a second dose of measles vaccine is given when a child enrolls in school at 4 to 6 years of age. Many other countries also recommend a routine second dose at various ages or provide a second opportunity for vaccination in mass campaigns to ensure protection. However, a high rate of first-dose coverage should always be the top priority.

Contraindications to measles vaccination include pregnancy, immunodeficiency, leukemia and other immunosuppressive diseases, administration of immunosuppressive drugs such as systemic corticosteroids or antimetabolites, and untreated active tuberculosis. Extreme caution should be used in considering vaccination in patients with severe allergies to gelatin, neomycin, or other vaccine components or a history of thrombocytopenic purpura. Persons with HIV infection should be vaccinated against measles unless they have signs of severe immunosuppression.

Common adverse events after vaccination with measles vaccine include transient fever and mild rash, each of which occurs in roughly 5% of vaccine recipients. More serious adverse events are very rare.

Prevention of Measles Virus Transmission

To prevent transmission of measles, contact should be minimized between persons with suspected or confirmed measles and all persons who might be susceptible to measles; isolation and airborne precautions are indicated for hospitalized patients. When a case of measles is suspected, the local health department should be contacted immediately to assist with measures to prevent virus transmission.

Postexposure Prophylaxis

If susceptible persons 6 months of age or older are identified within 72 hours of exposure to measles, vaccination is recommended (if it is not contraindicated) as it may prevent or alter the course of the disease. Susceptible household contacts of measles cases should be given immune globulin within 6 days of exposure, especially those who have contraindications to measles vaccination, such as pregnancy or immunodeficiency, and those who were not identified within 72 hours of exposure. Immune globulin may prevent measles or result in a less severe case of measles.

PROGNOSIS

In well-nourished populations with access to modern medical care, the case-fatality rate is typically 1 to 3 deaths/1000 cases, but case-fatality rates as high as 20% are seen in some developing countries as a result of malnutrition, limited access to health care, and immunodeficiency. Most measles deaths are associated with pneumonia or encephalitis. Antimicrobial treatment of secondary infections, especially pneumonias, can significantly reduce measles deaths. Vitamin A deficiency is associated with more severe disease, blindness, and increased mortality from respiratory and diarrheal causes, but vitamin A supplementation can reduce the severity of these complications. Patients with HIV infection and other immunocompromising conditions often have more severe cases with higher complication rates and case-fatality rates.

376

RUBELLA (GERMAN MEASLES)

SUSAN E. REEF

DEFINITION

Rubella, also known as German measles, is an acute viral illness that usually presents with a generalized maculopapular rash of 1 to 3 days' duration, low-grade or no fever, and associated clinical symptoms such as lymphadenopathy, arthropathy, and conjunctivitis. However, about 20 to 50% of persons infected with rubella may present without a rash or other symptoms.

The Pathogen

Rubella virus is a member of the Togaviridae family and the genus *Rubivirus*. Rubella virus is a single-stranded enveloped RNA with a single antigenic type. It measures 50 to 70 nm in diameter and has two envelope proteins (E1, E2) and a core protein (c). The core protein is surrounded by a single-layer lipoprotein envelope with spikelike projections that contain the two glycoproteins, E1 and E2. Humans are the only known reservoir.

EPIDEMIOLOGY

In the pre-vaccine era, rubella epidemics occurred approximately every 6 to 9 years in the United States. The last major American epidemic, which occurred in 1964-1965, resulted in an estimated 12.5 million cases and approximately 20,000 cases of congenital rubella syndrome. In 1969, live attenuated rubella vaccines were licensed in the United States and were introduced into the routine childhood immunization program. The initial rubella vaccination strategy was to target children from 12 months of age to puberty with a catch-up mass campaign. During the first 8 years of the vaccination program, the reported number of cases of rubella and congenital rubella syndrome decreased by 78% and 66%, respectively. When a rubella resurgence occurred mainly among adolescents and young adults in 1977-1978, however, the rubella vaccination program was modified to include susceptible postpubertal girls, persons in military service, college students, and persons in certain work settings (e.g., health care). In 1979, the RA 27/3 rubella virus vaccine replaced the other rubella virus vaccines (HPV-77 and Cendehill). Since 2003, 16 or fewer cases have been reported annually in the United States, and rubella is no longer endemic in the United States.

Although rubella and congenital rubella syndrome are no longer endemic in the United States, they continue to be of global public health importance. For most countries, the epidemiology of rubella mirrors the epidemiology seen in the United States during the pre-vaccine era, when rubella occurred mainly among children. The number of reported rubella cases globally has decreased from 875,000 in 1999 to about 120,000 in 2009, but the incidence is substantially underestimated because rubella cases in many countries are identified through case-based measles surveillance, which focuses only on the detection of suspected measles cases. The annual number of new cases of congenital rubella syndrome in developing countries is estimated to be 110,000 during nonepidemic years.

During the 1970s and 1980s, the use of rubella-containing vaccine (RCV) was mainly limited to industrialized countries. The number of World Health Organization member countries using RCV in national childhood immunization schedules increased from 83 (43%) in 1996 to 130 (67%) in 2008. As of 2009, rubella control and congenital rubella syndrome prevention or elimination goals have been established in three of six World Health Organization regions (Americas, European, and western Pacific). With the success of the vaccination strategy in the Americas, the number of reported rubella cases decreased from 135,947 in 1998 to a provisional total of 11 in 2009, and only Argentina had endemic rubella virus transmission. The other three World Health Organization regions (i.e., Southeast Asia, eastern Mediterranean, Africa) have not established regional rubella control or congenital rubella syndrome prevention goals.

PATHOBIOLOGY

Rubella

Rubella virus is transmitted through person-to-person spread by droplets shed from the respiratory secretions of infected persons. The first point of

entry is the nasopharynx, where replication occurs and then spreads to the lymph nodes. Subsequent viremia may seed multiple organs, including the placenta. Viremia occurs between 8 and 9 days after exposure and peaks at 10 to 17 days, just before the onset of the rash, which usually occurs 16 to 18 days after exposure. Although individuals with rubella are considered to be only moderately contagious, they may shed virus from 7 days before the onset of the rash to approximately 5 to 7 days or more after its disappearance. Persons with both clinical and subclinical infections are considered contagious.

Congenital Rubella

Rubella virus viremia can infect the placenta of pregnant women, and viral replication can infect all fetal organs. In tissue specimens, infections with rubella virus have diverse effects, ranging from small foci of infected cells in apparently normal tissue to hypoplasia, generalized vasculitis, and cell destruction. The hallmark of fetal infection is chronic infection that persists throughout fetal life, with shedding of virus up to 1 year of age.

Infants with congenital rubella syndrome may shed large quantities of virus from body secretions, particularly from the throat. Rubella virus can be found in the nasopharyngeal secretions of more than 80% of infants during the first month of life. Rubella virus is found in 11% of infected infants between 9 and 12 months of age and in only 3% in the second year of life. Viral shedding by infants with congenital rubella syndrome can result in nosocomial outbreaks, so only individuals immune to rubella virus should be in contact with infants with congenital rubella syndrome or with congenital infection even in the absence of clinical signs of congenital rubella syndrome.

CLINICAL MANIFESTATIONS

Postnatally Acquired Rubella

Acquired rubella, which occurs in 50 to 80% of persons infected with rubella virus, is characterized by a generalized maculopapular rash that usually persists for 1 to 3 days (Fig. 376-1). The rash usually starts on the face and neck and progresses downward. The rash is fainter than the rash of measles (Chapter 375) and does not coalesce. Because of the mildness of the rash, it may be difficult to detect in persons with darker skin. Children usually have few or no prodromal symptoms, so the rash is usually the first sign of illness. However, in older children and adults, a 1- to 5-day prodrome of low-grade fever, malaise, and upper respiratory symptoms often precedes the rash. The incubation period is 14 days, with a range of 12 to 23 days. Lymphadenopathy, particularly occipital and postauricular, may be noted during the second week after exposure.

FIGURE 376-1. Rash of rubella on the skin of a child's back. The distribution is similar to that of measles, but the lesions are less intensely red. (From the Centers for Disease Control and Prevention Public Health Image Library, ID #: 712.)

Rubella disease is usually mild and results in few complications. Arthralgia and arthritis are commonly observed in infected adults, particularly in postpubertal girls. Other less common complications are thrombocytopenia (1 in 3000 rubella cases) and encephalitis (1 in 6000 rubella cases).

Congenital Rubella Syndrome

The most serious consequences of rubella virus infection occur when a woman becomes infected during pregnancy, particularly during the first trimester. Complications can include miscarriage, fetal death, or a live birth with a constellation of congenital defects known as congenital rubella syndrome. The most common defects of congenital rubella syndrome affect the eyes (e.g., cataracts, pigmentary retinopathy, microphthalmos, congenital glaucoma), the ears (e.g., hearing impairment), and the heart (e.g., patent ductus arteriosus, pulmonary arterial stenosis). Other clinical manifestations of congenital rubella syndrome may include microcephaly, developmental delay, and purpura, including dermal erythropoiesis (blueberry muffin syndrome).

Among pregnant women infected with rubella virus during the first 10 weeks of gestation, up to 90% of their live born infants may have congenital rubella syndrome. Among women infected during the first 20 weeks of pregnancy, the rate of congenital rubella syndrome in live born infants is 20%. Infants who are born with rubella virus infection but who do not have any apparent signs or symptoms of congenital rubella syndrome are referred to as infants with congenital rubella infection only.

DIAGNOSIS

Postnatally Acquired Rubella

Because many rash illnesses may mimic rubella virus infection and because 20 to 50% of rubella virus infections may be subclinical, laboratory testing is the only way to confirm the diagnosis. Some illnesses with clinical presentation similar to that of rubella include scarlet fever (Chapter 298), roseola (Chapter 447), fifth disease (Chapter 379), and measles (Chapter 375).

Serologic testing is the most common method of diagnosis of acquired rubella. IgM antibody is generally detectable for up to 6 weeks after the onset of the rash. Because IgM antibodies may not be detectable before day 5 of the rash, serologic testing should be repeated no sooner than then. Diagnosis also can be made on the basis of a significant rise in the IgG antibody titer in paired acute and convalescent specimens. The acute serum specimen should be collected within 7 to 10 days after the onset of the rash, and the convalescent serum specimen should be collected 14 to 21 days after the first specimen.

Rubella virus can be isolated from nasopharynx (i.e., nasal, throat), blood, urine, and cerebrospinal fluid specimens of persons with rubella and congenital rubella syndrome. The most frequently positive results are from throat swabs. Rubella virus can be isolated during the prodromal period and up to 2 weeks after onset of the rash. For viral cultures, specimens should be obtained during the time of maximum virus secretion—up to 4 days after the onset of rash. During the first 4 days after the onset of the rash, rubella RNA detection by reverse transcription–polymerase chain reaction (RT-PCR) is more sensitive than rubella IgM testing.

Diagnosis in Pregnant Women

In the United States, all pregnant women should be screened for rubella IgG antibodies as part of routine prenatal care. Pregnant women who have a positive serologic test result for IgG antibody to rubella virus are considered to be immune if they do not have a recent history of exposure to rubella virus. Susceptible pregnant women should be vaccinated postpartum. Pregnant women exposed to rubella virus should be evaluated for evidence of acute infection by testing for presence of IgM antibodies in sera or a significant rise of IgG antibodies in acute and convalescent sera. Pregnant women with evidence of acute infection should be monitored clinically and evaluated for gestational age at infection to assess the risk of fetal infection.

Congenital Rubella

Diagnosis of congenital rubella syndrome in infants can be confirmed by either serologic or virologic methods. Serum IgM antibodies may be present in an infant with congenital rubella syndrome for up to a year after birth; however, IgM antibody may not be detectable during the first month of life. Thus, infants younger than 1 month and with symptoms consistent with congenital rubella syndrome should be retested at 1 month of age. Congenital rubella syndrome also can be confirmed by documentation of a persistent rubella serum IgG titer beyond the time expected from passive transfer of

maternal IgG antibody (i.e., a rubella titer that does not decline at the expected rate of a two-fold dilution per month).

Rubella virus from congenitally infected infants can be isolated most commonly from throat swabs and less commonly from urine and cerebrospinal fluid specimens. Infants with congenital rubella may excrete virus for up to 1 year, but specimens for virus isolation are most likely to be positive if they are obtained within the first 6 months after birth. Rubella virus in infants with congenital rubella syndrome also can be detected by RT-PCR with use of the same specimens as for viral isolation.

TREATMENT

Rx

There is no specific treatment of rubella or congenital rubella syndrome. For persons with rubella, symptomatic treatment may be warranted for clinical manifestations such as arthralgias, myalgias, and fever. Infants with congenital rubella syndrome should be evaluated and treated by specialists for their specific clinical manifestations.

PREVENTION

Passive Immunization

Administration of immune globulin after exposure to rubella virus will not prevent infection or viremia but might modify or suppress symptoms. Therefore, immune globulin is not recommended for routine postexposure prophylaxis of rubella in any circumstance.

Active Immunization

One dose of live attenuated rubella vaccine (RA 27/3, RCV) induces rubella IgG antibody seroconversion in 95% or more of persons. Immunity is considered long term, probably lifelong. RCV is available as a monovalent formulation or in combination with measles-mumps (MMR) and measles-mumps-varicella (MMRV) vaccines (Chapter 17).

In the United States, the routine rubella vaccination policy is to immunize children with the first dose of MMR at 12 to 15 months of age and to provide a second dose at 4 to 6 years of age. The MMRV vaccine also can be given to children up to age 12 years. Persons who were born in 1957 or later (except women of childbearing age who are or could become pregnant) and who do not have a medical contraindication (e.g., pregnancy) should receive at least one dose of MMR unless they have documentation of one dose of live rubella virus vaccine or laboratory evidence of immunity or laboratory confirmation of disease. High-risk groups who should be targeted for vaccination include health care personnel, persons attending post–high school educational facilities, the military, international travelers, and nonpregnant women of childbearing age.

In follow-up studies of more than 2700 susceptible women who were unknowingly pregnant and who received a live attenuated rubella vaccine, none of their infants was born with congenital rubella syndrome. Nevertheless, because of the theoretical risk of congenital rubella syndrome in infants born to pregnant women vaccinated with RCV, the vaccine should not be given to pregnant women, and pregnancy should be avoided for at least 28 days after receipt of vaccine. Receipt of RCV during pregnancy is not generally considered to be an indication for termination of pregnancy.

PROGNOSIS

Because rubella is usually a mild disease, the prognosis is excellent, with complete recovery in almost all persons. Deaths are seen in 0 to 50% of patients who develop rubella encephalitis. The prognosis for infants with congenital rubella syndrome is dependent on their clinical manifestations and access to quality medical care.

MUMPS

JOHN W. GNANN, Jr.

DEFINITION

Mumps is an acute systemic viral infection that occurs most commonly in children, is usually self-limited, and is clinically characterized by nonsuppurative parotitis.

The Pathogen

Mumps virus is a member of the Paramyxoviridae family. Mumps virions are pleomorphic, roughly spherical enveloped particles with an average diameter of 200 nm. Glycoprotein spikes project from the surface of the envelope, which encloses a helical nucleocapsid composed of nucleoproteins and linear, nonsegmented, single-stranded, negative-sense RNA. Humans are the only natural hosts for mumps virus, although infection can be induced experimentally in a variety of mammalian species. In vitro, mumps virus can be cultured in many mammalian cell lines and in embryonated hens' eggs.

EPIDEMIOLOGY

In unvaccinated urban populations, mumps is a disease of school-aged children (5 to 9 years), and more than 90% of individuals have mumps antibodies by 15 years of age. Before the mumps vaccine was released in the United States in 1967, mumps was an endemic disease with a seasonal peak of activity between January and May. The largest number of cases reported in the United States occurred in 1941, when the incidence of mumps was 250 cases per 100,000 population. In 1968, when the mumps vaccine was first entering clinical use, the incidence of mumps was 76 cases per 100,000 population. In 1985, only 2982 cases of mumps were reported, an incidence of 1.1 per 100,000 population, which represents a 98% decline from the number of cases reported in 1967. Epidemiologic studies of mumps epidemics in high schools, colleges, and military units during the 1980s demonstrated that outbreaks were principally due to failure to vaccinate. In 1989, the Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices issued a recommendation that all children receive a second dose of the measles-mumps-rubella (MMR) vaccine, which reduced the problem of primary vaccine failure. In 2003, the CDC reported only 231 cases of mumps in the United States, the lowest annual total ever recorded. However, a series of outbreaks in the United States and Canada in 2005-2006 reemphasized the potential for mumps virus to cause epidemics even in highly vaccinated populations. In 2006, a total of 6584 cases of mumps were reported, with a national incidence of 2.2 cases per 100,000 population. In a 2006 Midwest outbreak, the highest risk group was persons aged 18 to 24 years (median age, 22 years), many of whom were college students; 7% of cases were unvaccinated, 14% had received only one dose of MMR, 49% had received two doses, and 30% had an unknown vaccination status. In 2009, another mumps outbreak resulted in more than 1500 cases in New York and New Jersey, with the highest rate among boys who were 7 to 18 years old and who attended tradition-observant Jewish schools. Among patients with known vaccination status, 88% had received at least one dose and 75% had received a second dose. Although some cases in recent U.S. outbreaks can be attributed to failure to vaccinate, most represented primary (insufficient initial immune response) or secondary (waning immune response) vaccine failure, thereby suggesting the need either for a mumps vaccine with a longer duration of protection or for a vaccination policy focusing on young adults.

PATHOBIOLOGY

Mumps is highly contagious and can be transmitted experimentally by inoculation of virus onto the nasal or buccal mucosa, thus suggesting that most natural infections result from droplet spread of upper respiratory secretions. The mean incubation period for mumps is 18 days. Primary viral replication takes place in epithelial cells of the upper respiratory tract, followed by spread of virus to regional lymph nodes and subsequent viremia. Because virus can be isolated from saliva for 5 to 7 days before and up to 9 days after the onset of clinical symptoms, an infected individual is potentially able to transmit mumps for a period of about 2 weeks. An estimated 30% of mumps infections

FIGURE 377-1. Mumps. Child with submandibular swelling due to mumps parotitis. (From the Centers for Disease Control and Prevention Public Health Image Library, ID #: 4491.)

in children are subclinical or associated only with nonspecific upper respiratory infection symptoms. Transient IgM antibody responses are detected early in the course of mumps infection, followed by the appearance of IgG antibody and cytotoxic T lymphocytes. Mumps-specific IgG can be detected during the first week of acute infection, peaks at 3 to 4 weeks, and persists for decades. Lifelong immunity follows natural infection. Patients who report more than one episode of mumps probably had parotitis of another cause.

CLINICAL MANIFESTATIONS

Parotitis

Mumps usually begins with a short prodromal phase of low-grade fever, malaise, headache, and anorexia. Young children may complain of ear pain initially. The characteristic parotid tenderness and enlargement, in which the earlobe is lifted forward and obscures the angle of the mandible, then develops (Fig. 377-1). The parotid glands are involved most commonly, although other salivary glands may occasionally be enlarged. Parotitis may initially be unilateral, with swelling of the contralateral parotid gland occurring 2 to 3 days later; bilateral parotitis with symptomatic salivary gland involvement eventually develops in 70% of patients. Painful parotid gland enlargement progresses for a period of about 3 days, followed by defervescence and resolution of the parotid pain and swelling within about 7 days. Long-term sequelae of mumps parotitis are uncommon.

Aseptic Meningitis

Symptomatic meningitis occurs in 15% of cases and is the second most common manifestation of mumps. About 50% of patients with mumps parotitis have cerebrospinal fluid (CSF) pleocytosis, but many have no clinical evidence of meningitis. Signs and symptoms of meningeal inflammation (headache, neck stiffness, vomiting, and lethargy) plus high fever usually develop 4 to 5 days after the onset of parotitis, although the meningitis may occasionally precede the parotitis. Indeed, 40 to 50% of all cases of documented mumps meningitis occur in patients who never exhibit clinical parotitis. For unexplained reasons, symptomatic central nervous system (CNS) involvement with mumps is two to three times more common in boys than in girls. Examination of CSF usually reveals normal opening pressure and a mononuclear cell pleocytosis with an average cell count of 450/mm^3. Polymorphonuclear leukocyte predominance in CSF may be seen in some patients early during the course of mumps meningitis. CSF protein is generally normal or mildly elevated (<100 mg/dL). Hypoglycorrhachia, which is not usually seen in viral meningitis, may be present in 10 to 30% of patients with mumps meningitis. Mumps virus can be recovered from CSF. Whereas the symptoms of mumps meningitis typically resolve within 7 to 10 days, the CSF abnormalities may persist for up to 5 weeks. Mumps meningitis is generally benign, and significant neurologic complications are rare.

Encephalitis

The spectrum of mumps-induced CNS disease ranges from mild "aseptic" meningitis (which is common) to severe encephalitis (which is rare). Some cases of encephalitis develop concurrently with the parotitis and are thought to result from direct extension of viral infection from the choroid plexus ependyma into parenchymal neurons. Other cases of mumps encephalitis occur 1 to 2 weeks after the onset of parotitis and may represent a demyelinating postinfectious encephalitis. Clinical findings in mumps encephalitis include obtundation (and less commonly delirium), generalized seizures, and high fever. Other neurologic findings can include focal seizures, aphasia, paresis, and involuntary movements. Recovery from mumps encephalitis is generally complete, although complications such as aqueductal stenosis with hydrocephalus, seizure disorders, and psychomotor retardation have been reported. The overall mortality from mumps encephalitis is 0.5 to 2.3%.

Orchitis

Epididymo-orchitis is rare in young boys with mumps but occurs in 15 to 35% of postpubertal boys with mumps. Orchitis is most often unilateral (bilateral involvement occurs in 17 to 38% of cases) and results from replication of mumps virus in the seminiferous tubules, with resulting lymphocytic infiltration and edema. Orchitis typically develops within 1 week of the onset of parotitis, although orchitis, like mumps meningitis, can develop before or even in the absence of parotitis. Mumps orchitis is characterized by marked testicular swelling and severe pain accompanied by fever, nausea, and headache. The pain and swelling resolve within 5 to 7 days, but residual testicular tenderness can persist for weeks. Testicular atrophy may follow orchitis in 35 to 50% of cases; however, sterility is an uncommon complication, even in men with bilateral orchitis.

Other Manifestations

Mumps can cause inflammation of other glandular tissues, including pancreatitis and thyroiditis. Oophoritis and mastitis have been reported in postpubertal women with mumps. Transient renal function abnormalities are common in mumps, and virus can be isolated readily from urine; significant renal damage is rare, however. Other infrequent manifestations of mumps include sensorineural deafness (either transient or permanent), arthritis, myocarditis, and thrombocytopenia. Maternal mumps infection during the first trimester of pregnancy results in an increased frequency of spontaneous abortions, but no clear association between congenital malformations and maternal mumps has been demonstrated.

DIAGNOSIS

The diagnosis of mumps is usually based on clinical findings in a child with fever and parotitis, particularly if the individual is known to be susceptible and has been exposed to mumps during the preceding 2 to 3 weeks. An atypical clinical presentation (e.g., meningitis or orchitis without parotitis) requires laboratory confirmation. Culturing for mumps virus is definitive but not universally available. Testing of acute and convalescent sera should demonstrate a diagnostic four-fold rise in mumps IgG antibody titer. Alternatively, finding mumps IgM antibody provides good evidence of recent infection. About 30% of patients have an elevated serum amylase level that may be due to parotitis or pancreatitis.

The differential diagnosis of a mumps-like syndrome includes infections caused by other viruses, such as Epstein-Barr virus (Chapter 385), adenovirus (Chapter 373), influenza A virus (Chapter 372), parainfluenza virus (Chapter 371), coxsackievirus (Chapter 387), or lymphocytic choriomeningitis virus. Parotid gland enlargement can also occur in patients with AIDS, particularly children. Bacteria such as *Staphylococcus aureus* can cause suppurative parotitis. Parotid gland enlargement can also be associated with Sjögren's syndrome (Chapter 276), sarcoidosis (Chapter 95), amyloidosis (Chapter 194), thiazide ingestion, iodine sensitivity, tumor, or salivary duct obstruction. Careful examination should distinguish parotitis from lymphadenopathy.

TREATMENT Rx

Management of a patient with mumps consists of conservative measures to provide symptomatic relief, adequate hydration, and nutrition. Treatment of orchitis includes bedrest, scrotal support, analgesics, and ice packs. Patients with significant CNS involvement require hospitalization for observation and supportive care. There is currently no established role for antiviral drugs, corticosteroids, or passive immunotherapy in the treatment of mumps.

PREVENTION

The cornerstone of mumps prevention is active immunization with the live attenuated mumps vaccine. In the United States, mumps vaccine is

administered in combination with the measles and rubella vaccines (MMR) to children at 12 to 15 months of age, with a second dose at 4 to 6 years of age. Efficacy of the mumps vaccine is estimated to be 79 to 95% after two doses. The mumps vaccine is also indicated for susceptible adults.

The Jeryl-Lynn strain of attenuated mumps virus used in the United States since 1967 is a very well tolerated vaccine, although rare instances of fever, parotitis, and possibly aseptic meningitis have been reported after immunization. In recent years, an increased frequency of cases of vaccine-related mumps meningitis has been recognized in other countries. These cases occurred after the administration of an MMR vaccine that contained the Urabe AM9 or Leningrad 3 strains of mumps virus. This problem has not been recognized in the United States, where the Jeryl-Lynn mumps vaccine continues to be used.

Questions about prevention often arise when an individual with no history of mumps (typically an adult man) is exposed to a patient with active mumps. The immune status of the exposed individual can be determined by enzyme-linked immunosorbent assays. The mumps skin test is not a reliable indicator of immune status. Most adults born in the United States before 1957 were naturally infected and are therefore immune. Mumps vaccine can be safely administered to an individual of unknown immune status, although vaccine given to a susceptible individual after exposure to mumps may not provide protection.

For infection control purposes, patients with mumps require both standard precautions and droplet precautions. In the outpatient setting, a patient with suspected mumps should wear a mask and be isolated from other potentially susceptible persons. When a patient with mumps is hospitalized, a private room is required; caregivers should wear masks, and the patient should wear a mask while being transported.

mentation and variable motor features, including hyperreflexia, ataxia, and weakness. CMV ventriculitis is characteristically present, and progressive ventricular enlargement may be observed. Other features may suggest brain stem encephalitis, including internuclear ophthalmoplegia, nystagmus, cranial nerve palsies, gaze paresis, ataxia, and quadriparesis. Rarely, CMV infection may be manifested as a cerebral mass lesion. Other findings in these patients include cerebral infarction resulting from CMV vasculitis, acute subarachnoid hemorrhage, and intracerebral hemorrhage. Virtually all patients with CMV encephalitis have systemic CMV infection. CMV myelitis, polyradiculitis, and multifocal neuritis may also occur with CMV encephalitis. Distinctive retinal lesions can often be seen ophthalmoscopically (Chapter 384).

Cerebral imaging studies are of limited sensitivity and low specificity in patients with CMV encephalitis. Ependymal or meningeal enhancement as well as areas of focal infarction or necrosis may be visualized. Progressive ventricular enlargement should suggest CMV ventriculitis. Cerebrospinal fluid (CSF) findings are variable. Most patients have elevated protein levels and a CSF pleocytosis, but leukocytes may be absent and glucose levels may be normal or decreased. A marked pleocytosis with a polymorphonuclear leukocyte preponderance may occur in patients with CMV ventriculoencephalitis. CMV can rarely be cultured from CSF. CSF polymerase chain reaction (PCR) is the most specific diagnostic method, but the diagnosis is often difficult and relies on a high index of clinical suspicion.

Myelitis

CMV transverse myelitis, which may be seen in both immunocompetent and immunosuppressed patients, is indistinguishable neurologically from other forms of transverse myelitis (Chapters 407 and 419). A severe necrotizing CMV myelitis may occur in the immunosuppressed host, particularly with human immunodeficiency virus (HIV) infection, and is commonly associated with polyradiculitis. Some cases of necrotizing myelitis in the absence of a typical polyradiculitis syndrome have been described, with patients displaying acute or progressive paraplegia and disturbances in urinary and rectal sphincter function. Reflexes are preserved or enhanced in the legs unless concurrent neuropathy is present. A sensory level may be demonstrable. The combination of radicular complaints and a CSF polymorphonuclear pleocytosis may serve as clues to the diagnosis. Serology for CMV may be useful in immunocompetent individuals.

Polyradiculomyelitis

Approximately 25% of patients dying of AIDS have neuromuscular disease from CMV, predominantly localized to the perineurial and epineurial regions. CMV polyradiculomyelitis in HIV-infected patients is manifested subacutely during a period of days to weeks. Initial symptoms of paresthesias or dysesthetic pain localized to the perineum and lower extremities are followed by rapidly progressive paraparesis with hypotonia and diminished or absent lower extremity reflexes. Urinary retention is characteristic, and rectal sphincter incontinence is common. Variable sensory findings are typically overshadowed by weakness. Babinski signs and diminished sensation below a discrete level across the trunk are evidence of an associated myelitis. With time, symptoms progress by ascending to involve the upper limbs and sometimes the cranial nerves. CSF examination generally shows polymorphonuclear pleocytosis, prominent elevation of protein levels, and a low glucose level. Spinal magnetic resonance imaging (MRI) may be normal or show enhancement of the conus medullaris, cauda equina, meninges, and nerve roots. Electrophysiologic studies reveal axonal neuropathy with evidence of acute denervation. Variable slowing of nerve conduction may occur.

The appearance of acute cauda equina syndrome in a patient with AIDS or in a solid organ or bone marrow transplant recipient is suggestive of CMV infection when a polymorphonuclear pleocytosis is present in CSF; however, the syndrome is not pathognomonic. Other conditions that may produce a cauda equina syndrome in AIDS patients include lymphomatous meningitis, syphilis, toxoplasmosis, other herpesvirus infections, and cryptococcal or bacterial meningitis. Progressive multifocal motor and sensory neuropathy that evolves during a period of weeks to months has also been seen in patients with CMV infection. Paresthesia and dysesthesia are quickly followed by prominent motor weakness involving both the upper and lower limbs asymmetrically. Neurogenic atrophy may be prominent. Nerve biopsy reveals necrotizing neuritis with mononuclear and polymorphonuclear infiltrates and cytomegalocytes localized around endoneurial capillaries in the nerve trunks and roots. Some patients may have necrotizing arteritis. PCR for CMV in CSF may be useful in establishing the diagnosis.

378

CYTOMEGALOVIRUS, EPSTEIN-BARR VIRUS, AND SLOW VIRUS INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

JOSEPH R. BERGER AND AVINDRA NATH

CYTOMEGALOVIRUS INFECTION

Human cytomegalovirus (CMV) is a ubiquitous herpesvirus that is acquired throughout life (Chapter 384). In children, CMV is an important and relatively common cause of congenital neurologic deficits. In the United States, seroprevalence rates are 40% in adolescents and 60 to 90% in adults. Primary infection is usually asymptomatic in young, healthy adults but may be associated with a transient mononucleosis-like syndrome. CMV results in major neurologic disability in the setting of immunosuppression, particularly in transplant recipients and in persons with acquired immunodeficiency syndrome (AIDS) and hematologic malignant neoplasms. In addition to the retina, CMV may involve the meninges, brain, spinal cord, peripheral nerves, and muscle.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Cytomegalovirus Encephalitis

CMV encephalitis has several manifestations in patients with AIDS. The most typical is a subacute, diffuse encephalopathy evolving during a period of weeks and characterized by headache, impaired cognition and sensorium, apathy, and social withdrawal. Neurologic examination reveals abnormal

TREATMENT

Rx

CMV neurologic complications should be treated with ganciclovir (5 mg/kg intravenously every 12 hours) plus foscarnet (60 mg/kg intravenously every 8 hours or 90 mg/kg intravenously every 12 hours until symptomatic improvement), followed by maintenance therapy with oral valganciclovir (900 mg daily) and intravenous foscarnet (90 to 120 mg/kg intravenously during 2 hours, every 24 hours); however, evidence of efficacy in these conditions is limited chiefly to case reports and small series. Cidofovir is a second-line agent (5 mg/kg by intravenous infusion during 1 hour once a week for 2 consecutive weeks, with saline hydration and probenecid, 2 g orally 3 hours before the dose and 1 g orally at 2 hours and 8 hours after the dose). CMV strains resistant to these agents have emerged, and CMV encephalitis has developed in the presence of maintenance ganciclovir therapy for CMV retinitis. Combination therapy (foscarnet and ganciclovir) or different drugs should be considered in patients already undergoing suppressive monotherapy or in those with persistent CSF pleocytosis. Maintenance therapy, which is the same regimen given every other week, is required unless the patient experiences immune reconstitution, such as after highly active antiretroviral therapy (HAART) in an AIDS patient or discontinuation of immunosuppressive regimens in a transplant or cancer patient.

PROGNOSIS

The prognosis for long-term survival, especially with AIDS, is very poor.

EPSTEIN-BARR VIRUS INFECTION

Epstein-Barr virus (EBV), the cause of infectious mononucleosis (Chapter 385), is distributed worldwide. Individuals in areas of high population density and lower social strata acquire the virus in early childhood. However, seroepidemiologic studies indicate that virtually all persons are infected by EBV by 30 years of age.

Neurologic manifestations occur in 1 to 5% of patients with primary EBV infection and may be the predominant clinical finding. The most common neurologic disorder associated with infectious mononucleosis is meningoencephalitis, which is rare in early childhood and is most often observed in persons between the ages of 15 and 25 years. Its onset may be gradual during a span of several days or be explosive. Fever, headache, mild stiff neck, confusion, lethargy, seizures, and hyperreflexia are the most typical features. On occasion, focal neurologic features, including hemiparesis, focal seizures, and cerebellar and brain stem findings, may be detected. Hyperintense signal abnormalities on T2-weighted and fluid attenuated inversion recovery (FLAIR) cranial MRI are frequently observed but are nondiagnostic. PCR for EBV in CSF may be useful.

Ganciclovir treatment (10 mg/kg/day intravenously for 3 weeks followed by 1000 mg/day orally for another 3 weeks or until the virus is cleared) has been used in some cases but is of unproven value. The prognosis for patients with EBV meningoencephalitis is excellent, with complete resolution anticipated in 1 to 2 weeks.

SLOW VIRUS INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

Human T-Lymphotropic Virus Type 1 and Human Immunodeficiency Virus

These viruses and their neurologic sequelae are considered in Chapters 386 and 401, respectively.

Subacute Sclerosing Panencephalitis

EPIDEMIOLOGY AND PATHOBIOLOGY

Subacute sclerosing panencephalitis (SSPE), which is caused by the measles virus (Chapter 375), usually affects children but can present in young adulthood. Patients generally have a history of measles within the first 2 years of life, and it is speculated that such early host exposure allows the emergence of persistent but defective virus replication because the SSPE virus genome, particularly the matrix gene, differs from wild-type measles. As a result of effective vaccination strategies against measles virus, the incidence of SSPE has decreased markedly.

Gray matter is most prominently involved. The pathologic features of SSPE include gliosis, loss of myelin, and perivascular infiltrates of lymphocytes and plasma cells in white and gray matter. Neuronal cell loss is seen in later stages of the illness. Intranuclear Cowdry type A inclusions containing viral nucleocapsids are identified in neurons and glia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

SSPE usually begins with cognitive and behavioral changes, and cortical blindness is often an early feature. Progression is associated with motor dysfunction, including prominent myoclonus, choreoathetosis, dystonia, and rigidity. Its course progresses during a period of 1 to 3 years to rigid quadriparesis and a vegetative state, frequently accompanied by autonomic features, such as hyperthermia, excessive sweating, and altered pulse and blood pressure. The condition is more common in rural settings and affects boys more often than girls.

The electroencephalogram reveals periodic complexes with synchronous bursts of two or three high-amplitude slow waves per second, with recurrence at regular intervals of 5 to 8 seconds and a 1 : 1 relationship with myoclonic jerks. Computed tomography (CT) of the brain shows generalized atrophy. CSF protein, glucose, and cell levels are usually normal; CSF is characterized by a high immunoglobulin concentration, oligoclonal bands, and intrathecal synthesis of antibody to measles virus antigens. Serum measles antibody titers are also high. These findings are usually sufficiently characteristic for diagnosis, but measles RNA can be detected in the brain by PCR. Rarely, brain biopsy is needed for definitive diagnosis in atypical cases. Measles virus may also cause subacute encephalitis in an immunocompromised host. The prominence of cognitive and motor dysfunction in these patients resembles that of SSPE, but in the clinical setting, its subacute onset and more rapid evolution and the presence of generalized seizures rather than myoclonus are distinctive. Brain abnormalities include abundant intranuclear inclusions, but inflammation is minimal, and neither serum nor CSF antibody titers against measles virus are high. For this reason, brain biopsy is generally needed for diagnosis.

TREATMENT AND PROGNOSIS

Rx

There is no established, unequivocally effective treatment of SSPE, but arrest of the disease has been reported in some patients with SSPE after long-term treatment with intrathecal interferon alfa or with intrathecal ribavirin. The usual prognosis is progression to coma, brain stem involvement, and death in 2 to 5 years.

Progressive Rubella Panencephalitis

Progressive rubella panencephalitis is a rare disorder resembling SSPE but caused by rubella virus (Chapter 376). It occurs as a complication of congenital rubella syndrome or, more typically, after childhood rubella. With the advent of widespread rubella immunization, this disorder has been nearly eliminated in the United States.

A hiatus of years separates early infection from the onset of neurologic deterioration, which is characterized by behavioral changes, cognitive impairment, cerebellar ataxia, spasticity, and sometimes seizures. Myoclonus is a less prominent feature than it is in SSPE. Serology or isolation of the virus from brain or peripheral blood lymphocytes confirms the cause. There is no effective treatment, and the prognosis is similar to that for SSPE.

Progressive Multifocal Leukoencephalopathy

DEFINITION

This demyelinating disease is associated with infection of oligodendrocytes by JC virus, a papovavirus widely distributed in humans. JC virus exhibits a neurotropism exclusive to glial cells. Progressive multifocal leukoencephalopathy (PML) was the first demyelinating disease to be unequivocally associated with a viral infection.

EPIDEMIOLOGY

Serologic studies indicate that approximately 10% of children have antibody to JC virus by 5 years of age, 40 to 60% have antibody by the age of 10 years, and 80% have antibody by the age of 20 years. Despite the wide dissemination of JC virus infection, PML is rarely observed in the absence of underlying cellular immunosuppression. It is also rarely observed in childhood. Until the AIDS epidemic, PML was most commonly observed in patients with lymphoproliferative disorders (62% of cases) and less commonly with myeloproliferative diseases (7%), carcinomatous diseases (2%), acquired immunodeficiency states (11%), and no underlying disease (6%). Since the

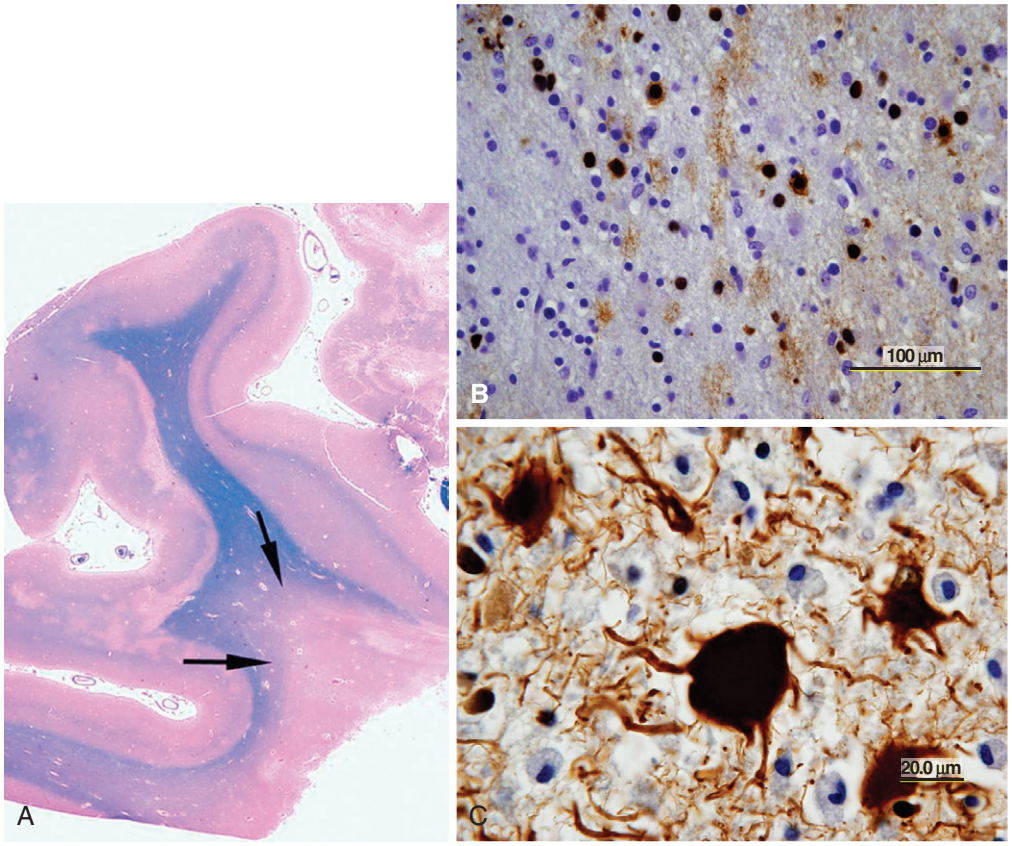

FIGURE 378-1. Pathology of progressive multifocal leukoencephalopathy. A, An area of demyelination is seen in the white matter that fails to stain with Luxol fast blue dye. **B**, Immunohistochemical staining with antibody to papovavirus shows brown-staining nuclei in oligodendrocytes, indicative of JC virus infection. **C**, Immunohistochemical staining for glial fibrillary acidic protein shows large bizarre astrocytes. (Courtesy of Dr. Carlos Pardo, Johns Hopkins University, Baltimore.)

inception of the AIDS epidemic, AIDS has been the most common underlying disorder associated with PML. PML develops in up to 4% of AIDS patients. PML also occurs in association with the administration of monoclonal antibodies for diseases that had not previously been associated with it, including natalizumab, an α4β1 and α4β7 integrin inhibitor used in the treatment of multiple sclerosis (Chapter 419) and Crohn's disease (Chapter 143); efalizumab, an anti-CD11a antibody that is effective in the treatment of psoriasis (Chapter 446); rituximab, an anti-CD20 antibody; and mycophenolate mofetil.

PATHOBIOLOGY

The cardinal feature of PML is demyelination, which is typically multifocal but occasionally unifocal (Fig. 378-1). These lesions may occur in any location in the white matter but have a predilection for the parieto-occipital regions. The lesions range in size from 1 mm to several centimeters; larger lesions may reflect the coalescence of multiple smaller lesions. The other histopathologic hallmark of PML is the presence of hyperchromatic, enlarged oligodendroglial nuclei and enlarged bizarre astrocytes with lobulated hyperchromatic nuclei. Electron microscopic examination reveals the JC virions, which are 28 to 45 nm in diameter and appear singly or in dense crystalline arrays in oligodendroglial cells and, less frequently, in reactive astrocytes. Inflammatory infiltrates are typically absent, except in patients who have reconstitution of their immune system, such as HIV-infected patients being treated with HAART, in whom macrophages and lymphocytes may be found.

CLINICAL MANIFESTATIONS

The clinical hallmark of PML is the presence of focal neurologic symptoms and signs associated with radiographic evidence of white matter disease in the absence of a mass effect. The most common initial symptoms include weakness, speech abnormalities, and cognitive disturbances, each seen in approximately 40% of patients. Although it is rare in non-AIDS patients, headache may occur in as many as one third of patients with AIDS. Gait disturbances, sensory loss, and visual impairment all occur in approximately 20 to 30%. Seizures and brain stem symptoms are less common. Signs noted on physical examination parallel the reported symptoms, with weakness, typically a hemiparesis, detected in more than half of patients at initial evaluation. Gait abnormalities, cognitive problems, and language disorders (i.e., dysarthria and dysphasia) are observed in about 25% of patients at initial contact. Limb and trunk ataxia, which reflects cerebellar involvement, is detected in as many as 10% of patients but may occasionally result from severe impairment in position sense (i.e., sensory ataxia). Neuro-ophthalmic symptoms occur in 50% of patients with PML and are the initial manifestation in 30 to 45%. The most common visual deficit is homonymous hemianopia or quadrantanopia secondary to lesions of the optic radiations. Cortical blindness is present in as many as 5 to 8% of patients at the time of diagnosis. Other neuro-ophthalmic manifestations include optic agnosia, alexia without agraphia, and ocular motor abnormalities. Sensory disturbances occur with PML but are distinctly less common than impairment of strength or visual function.

DIAGNOSIS

The diagnosis of PML may be strongly suggested by the clinical manifestations and the radiographic imaging. When the clinical manifestations are coupled with a positive JC virus PCR finding in CSF, the diagnosis of PML is virtually certain. Brain biopsy with demonstration of the characteristic histopathologic triad of PML coupled with immunohistochemical or electron microscopic evidence of JC virus remains the "gold standard" for diagnosis.

CT of the brain reveals hypodense lesions of the affected white matter that generally have a "scalloped" appearance because of involvement of the subcortical arcuate fibers lying directly beneath the cortex. Cranial MRI shows a hyperintense lesion on T2-weighted or FLAIR images in the affected regions (Fig. 378-2) and usually shows a hypointense lesion on T1-weighted images. Faint contrast enhancement at the periphery of lesions is seen in approximately 5 to 10% of pathologically confirmed cases of PML with either brain imaging technique, but intense intralesional nodular enhancement may be seen in patients with immune reconstitution. In patients without AIDS, the lesions of PML have a predilection for the parieto-occipital lobes, but the lesions are more often found in the frontal lobes in AIDS patients. Involvement of the basal ganglia, external capsule, and posterior fossa structures (i.e., cerebellum and brain stem) is also seen.

The results of routine analysis of CSF are not diagnostic, but CSF protein may be elevated. CSF PCR for JC virus is of great value in diagnosis; although not always positive, it is highly specific.

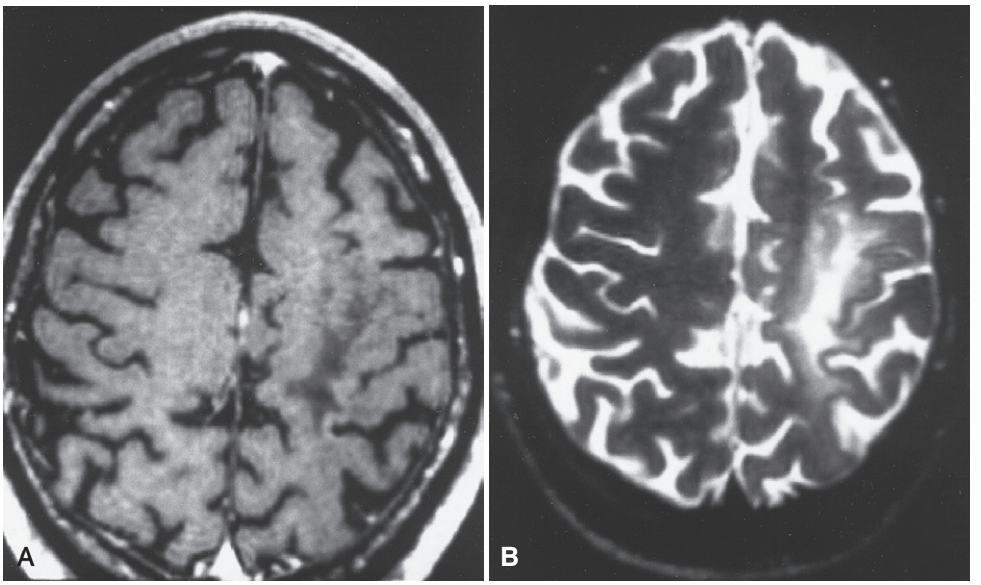

FIGURE 378-2. Cranial magnetic resonance images of progressive multifocal leukoencephalopathy. A, A T1-weighted image shows a hypointense signal abnormality of the left frontal lobe white matter. **B**, On T2-weighted imaging, the lesion is hyperintense.

TREATMENT

Rx

There is no effective therapy for PML. Although cytosine arabinoside prevents JC virus replication in vitro, a randomized, double-blind trial in which it was administered intrathecally or intravenously in patients with AIDS-associated PML demonstrated no benefit. This lack of efficacy may have been a reflection of inadequate concentrations of the drug at the sites of infection. The antimalarial agent mefloquine has demonstrated efficacy in suppressing viral replication in vitro and is under investigation as a therapy. Spontaneous recovery in untreated patients, especially in patients who have immunologic recovery with HAART or after the removal of an offending immunosuppressive agent, makes it difficult to assess the results of experimental treatments in small or uncontrolled treatment trials.

PROGNOSIS

Previously, PML was regarded as a fatal illness, with survival averaging 3 to 4 months in the typical patient. After the introduction of HAART, approximately 50% of patients with AIDS-associated PML survive for more than 12 months, often with partial or nearly complete clinical and radiographic recovery. Factors associated with a more benign course include the presence of PML as the heralding manifestation of AIDS, high or climbing $CD4^+$ T-lymphocyte counts, contrast enhancement of the lesions on radiographic studies, and any clinical or radiographic evidence of recovery. JC virus–specific T lymphocytes appear to be critical for control of the infection.

PARVOVIRUS

NEAL S. YOUNG

DEFINITION

B19 parvovirus, which was discovered in the mid-1970s by electron microscopic observation of an anomalous precipitin reaction of a normal blood donor's serum (occupying position 19 in plate B), was first linked to human disease by the observation of virus-specific IgM antibody or the virus itself in the sera of sickle cell disease patients suffering transient aplastic crisis (Chapter 166). The common illness caused by the virus was identified later during outbreaks of fifth disease, a highly contagious rash illness of childhood long suspected of having a viral etiology. The ability of parvovirus to persist and to be manifested as an isolated hematologic syndrome was demonstrated by the presence of the virus in fetal liver at autopsy of hydropic newborns and in immunosuppressed patients with chronic pure red cell aplasia (Chapter 168).

The Pathogen

The parvoviruses form small icosahedral capsids of about 25 nm. They have a limited genome of single-stranded DNA. The approximately 5600 nucleotides of B19 parvovirus show remarkably little sequence variation among isolates; two variants, V9 and A6, are of uncertain clinical significance.

The Parvoviridae family contains many pathogenic animal viruses: feline panleukopenia virus, the cause of a fatal agranulocytosis in cats; canine parvovirus, which probably arose from the cat virus as a host range variant in the 1970s to produce a global pandemic and can cause fatal myocarditis in puppies; Aleutian mink virus infection, a model of immune complex disease; and porcine parvovirus, responsible for fetal wastage in pig litters. B19 is the only parvovirus known to be pathogenic in humans.

EPIDEMIOLOGY

B19 infection is global; infectivity rates, inferred from the presence of antiparvovirus IgG antibody in sera, are similar in the United States, Europe, and Asia, and only isolated populations, Amazonian tribesman and residents of remote islands off the coast of Africa, have escaped exposure. B19 parvovirus infection is common in childhood, and half of 15-year-old adolescents have specific antiparvovirus B19 antibodies. Infection continues throughout adult life, and the great majority of the elderly are seropositive. In temperate climates, most infections occur in the spring, with small epidemics every few years being typical. Transmission is respiratory by droplet spread, and secondary infection rates among household contacts are high. Nosocomial infection can occur, and B19 parvovirus has been transmitted in blood products, especially pooled components such as factor VIII and IX concentrates. Producers of plasma derivatives now voluntarily screen by quantitative measurement of B19 DNA to reduce the risk for iatrogenic transmission. The lack of a lipid envelope and the stable DNA genome make parvoviruses notoriously resistant to heat inactivation and solvent detergents.

PATHOBIOLOGY

The biology of the Parvoviridae makes them especially dependent on helper function from host cells or other viruses. The autonomous parvoviruses propagate in actively dividing cells; the family Parvoviridae includes disease-causing animal parvoviruses. Adeno-associated viruses grow in tissue cultures infected with adenoviruses and herpesviruses and are popular vectors for gene transduction and therapy. B19 is the type member of the

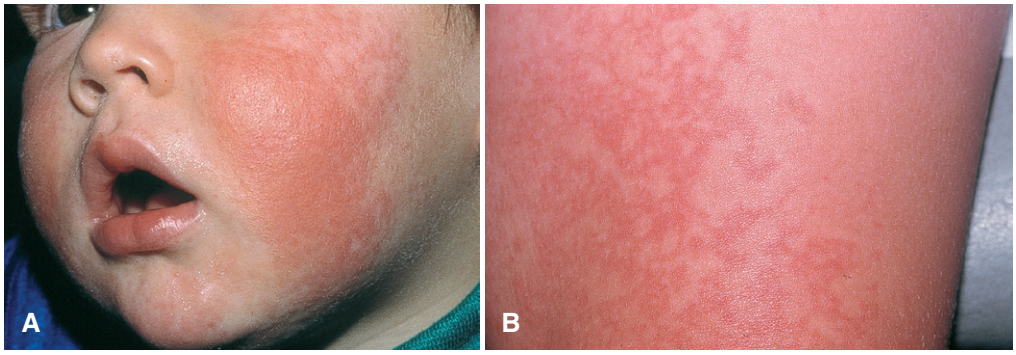

FIGURE 379-1. Erythema infectiosum. In this infection by parvovirus B19, a child will develop prominent erythema of the cheeks, "slapped cheeks" **(A)**, followed by a lacelike erythema on the extremities **(B)** and buttocks. It is also known as fifth disease.

Erythrovirus genus, which includes very similar simian viruses, all of which are best propagated in the erythroid progenitor cells that are responsible for red blood cell production in the bone marrow. Active replication of virus can be detected by the presence of double-stranded intermediate forms by simple DNA hybridization methods. The transcription map of the erythroviruses differs markedly from that of other Parvoviridae. Only three genes produce proteins of known function. Many antigenic determinants recognized by the host immune system are located in helical loops that form the surface of each capsomere. Most of the capsid is composed of a major structural protein, called VP2, but about 5% of the capsid is a minor structural protein, VP1, which differs from VP2 only by an additional 226 amino acids at the amino terminus; this VP1 unique region is located external to the capsid surface and contains linear epitopes recognized by neutralizing antibodies.

The only known natural host cell of B19 parvovirus is the human erythroid progenitor. The tropism of the virus for an erythroid cell host results from its cellular receptor, globoside, a neutral glycolipid also known as erythrocyte P antigen. Rare individuals with the p phenotype, who congenitally lack globoside on their erythrocytes, are genetically insusceptible to B19 parvovirus infection; they show no serologic evidence of previous infection, and their marrow erythroid progenitors proliferate normally in the presence of high concentrations of virus. Parvovirus kills erythroid progenitors by expression of its nonstructural protein, and it is possible that some cells, such as megakaryocytes, may be lysed by restricted expression of viral proteins in the absence of viral propagation. B19 can be efficiently propagated in tissue culture of primary human hematopoietic cells in which erythropoietic differentiation is stimulated by erythropoietin.

The humoral immune response is dominant in B19 parvovirus infection. Natural antibody production correlates with disappearance of the virus from blood, and the presence of IgG appears to confer lasting protection against a second infection. Parvovirus infection can persist if immunoglobulin production is defective such that antibody fails to neutralize the virus; reactivity of antibodies to the unique amino-terminal region of VP1 is especially important.

CLINICAL MANIFESTATIONS

Fifth Disease

Most B19 parvovirus infections are asymptomatic. The most common manifestation of infection is erythema infectiosum, or fifth disease, a rash illness of childhood characterized by a "slapped cheek" appearance (Fig. 379-1). In volunteers inoculated intranasally with B19, nonspecific influenza-like complaints occurred early along with viremia; the cutaneous eruption a week later corresponded to the appearance of antiviral antibodies. These more specific symptoms of B19 parvovirus infection are secondary to immune complex formation and deposition. Serologic testing generally shows seroconversion, IgM antibody, or the appearance of IgG antibody to parvovirus. The rash of fifth disease may be evanescent, and recurrences can be provoked by sunlight, heat, emotion, or exercise. Fifth disease can be confused with rubella. In adults, the rash is less characteristic and may be difficult to visualize in dark-skinned individuals.

B19 Arthropathy

In contrast to the mild course in children with fifth disease, acute parvovirus infection in adults, particularly middle-aged women, may cause significant arthropathy. Not only arthralgia but also a true inflammatory arthritis occurs in about 50% of older patients, and approximately 15% of new arthritis cases may be the sequelae of B19 parvovirus infection. Symmetrical joint involvement of the hands, ankles, knees, and wrists can resemble rheumatoid arthritis (Chapter 272), and the test result for rheumatoid factor may be positive. B19 arthropathy usually resolves within a few weeks; joint destruction does not occur. Parvovirus is not the cause of rheumatoid arthritis, but case reports suggest that B19 infection may mimic, precipitate, or worsen a variety of rheumatologic diseases, including juvenile rheumatoid arthritis, systemic lupus erythematosus, and fibromyalgia.

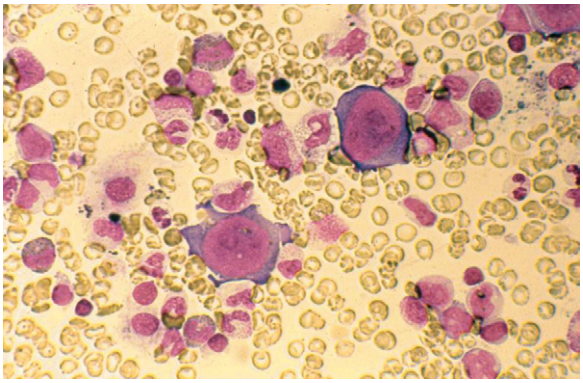

FIGURE 379-2. Bone marrow aspirate of a patient with chronic pure red cell aplasia secondary to persistent B19 parvovirus infection. Mature erythroid precursors are absent, and giant pronormoblasts are typical of B19 infection.

Transient Aplastic Crisis

In persons with underlying hemolysis or a high demand for production of circulating erythrocytes, acute B19 parvovirus infection causes transient aplastic crisis, an abrupt cessation of red blood cell production that exacerbates or, in previously compensated states, provokes severe anemia. Erythropoiesis is temporarily suppressed in all B19 parvovirus infections, but hemoglobin levels ordinarily remain stable because of the long lifespan of erythrocytes. The anemic crises associated with low or absent reticulocytes in hereditary spherocytosis and sickle cell disease are virtually always secondary to B19 parvovirus infection. Parvoviremia is present in patients with transient aplastic crisis, and red cell production resumes once antibodies to the virus are produced and the infection is cleared. Transient aplastic crisis is generally a unique event in the patient's life, thus suggesting induction of long-lasting protective immunity. Although it is self-limited, aplastic crisis often requires transfusion and can lead to severe, occasionally fatal anemia that precipitates congestive heart failure and cerebrovascular accidents. Transient aplastic crisis is associated with a pathognomonic bone marrow appearance, absence of maturing erythroid precursors, and the presence of "giant pronormoblasts" (Fig. 379-2) that represent the cytopathic effect of parvovirus infection.

White blood cell and platelet counts may fall modestly during transient aplastic crisis, especially in patients with functioning spleens. Occasional cases of agranulocytosis may be due to B19; thrombocytopenia and pancytopenia have been reported, and B19 can precipitate a benign virus-associated hemophagocytic syndrome.

Persistent Infection

B19 parvovirus persists in the absence of an appropriate host antibody response. Absent specific immunity, there are none of the clinical features of fifth disease but instead a purely hematologic syndrome of pure red cell aplasia. The anemia is severe and requires transfusion; reticulocytes are

absent from blood, as are erythroid precursors from marrow. Observation of giant pronormoblasts in the marrow may lead to the diagnosis. There is no antibody to parvovirus in the blood, but the virus can be detected in the circulation, often at extremely high levels (>10^{12} genome copies per milliliter). Failure to produce neutralizing antibodies to B19 parvovirus occurs in patients with congenital immunodeficiency (Nezelof's syndrome), in those with iatrogenic immunodeficiency (chemotherapy or immunosuppressive drugs), or as a result of acquired immunodeficiency secondary to HIV-1. Pure red cell aplasia secondary to parvovirus may be the first manifestation of acquired immunodeficiency syndrome (AIDS).

Hydrops Fetalis

B19 parvovirus infection of the pregnant mother followed by transplacental transmission to the fetus can lead to an adverse outcome, either miscarriage or hydrops fetalis. Parvovirus infects the fetal liver, the site of erythrocyte production during early development. Hydrops is the result of severe anemia as well as perhaps myocarditis, contributing to congestive heart failure. Prospective studies have led to an estimated 30% risk of transplacental infection and 9% risk of fetal loss in women who are exposed to B19 during pregnancy. Infection during the second trimester poses the greatest risk for birth of a hydropic infant; B19 parvovirus probably accounts for 10 to 20% of all cases of nonimmune hydrops fetalis. The risk of spontaneous abortion resulting from first trimester infections has been more difficult to quantitate. The likelihood of an infection increases in epidemic years and correlates with the level of contact of the pregnant woman with children. Although most B19 infections during pregnancy probably do not lead to either loss of the fetus or congenital anomalies, B19 infection is a relatively frequent cause of fetal death. Congenital malformations have not been consistently associated with intrauterine parvovirus infection. However, severe anemia at birth with a bone marrow histology consistent with either constitutional pure red cell aplasia (Diamond-Blackfan anemia) or congenital dyserythropoietic anemia has occurred in infants salvaged by in utero blood transfusions or exchange transfusion at birth.

Other Syndromes

Elevated levels of hepatic transaminases can accompany fifth disease, and parvovirus infection has been associated with severe but self-limited hepatitis in a few children. The presence of B19 genetic sequences in cardiac tissue has led to a diagnosis of parvovirus myocarditis. Serologic and DNA evidence of B19 infection implicated parvovirus in some patients with necrotizing vasculitis, Kawasaki disease, Henoch-Schönlein purpura, and giant cell arteritis. Glove-and-sock syndrome, an exanthem localized to the hands and feet and consisting of edema, erythema, paresthesia, and pruritus, has been linked to B19. Chronic fatigue syndrome may follow parvovirus infection. Meningitis, encephalitis, and a variety of neurologic complications may occur with fifth disease and parvovirus infection.

False-positive results arise when the diagnosis of infection rests on detection of amplified B19 genome by polymerase chain reaction, and furthermore, B19 parvovirus can persist at low levels in normal individuals for many months after infection.

DIAGNOSIS

Because of the difficulty in propagating B19 parvovirus in standard tissue culture, laboratory diagnosis relies on serologic and DNA tests (Table 379-1). Virus-specific antibodies are measured in standardized commercial solid-phase enzyme-labeled immunoassays, generally involving the use of capsid proteins generated in the baculovirus system. "Capture" formats are preferred to detect serum IgM, which is first bound to a solid phase coated with anti–μ-chain antibodies, followed by the addition of viral antigen and an antiviral monoclonal antibody. IgM antibodies are diagnostically positive in almost all cases of fifth disease at initial evaluation and appear within a few days of the onset of transient aplastic crisis, and IgM may persist for months after acute infection. IgG is usually assayed in conventional indirect assays. IgG circulates later than IgM, generally at the end of the first week of illness. Although titers of IgG are generally highest in the year after an acute infection, substantial interindividual variation and the presence of IgG in a large proportion of the population make measurement of IgG less helpful than other tests for diagnosis of parvovirus. DNA assays are required for persistent B19 infection, in which antibody production is absent or minimal. Parvovirus can also be found in the sera of patients with early transient aplastic crisis. Direct hybridization methods are reliable, and they detect clinically relevant viral titers of greater than 10^6 international units (orders of magnitude below levels present in both acute and persistent infection). Gene amplification methods are more sensitive but less reliable because of false-positive results. Virus can be detected in amniotic fluid, and both virus and IgM antibody to B19 are found in umbilical cord blood; the mother's serum will show seroconversion during pregnancy, but maternal IgM may be absent at the onset of hydrops fetalis.

TABLE 379-1 DIAGNOSIS OF PARVOVIRUS B19

DISEASE	IgM	IgG	B19 DOT BLOT*	B19 PCR
Fifth disease	+++	++	–	+
Polyarthropathy syndrome	++	+	–	+
Transient aplastic crisis	+/–	+/–	++	++
Persistent anemia	+/–	+/–	++	++
Hydrops/congenital infection	+/–	+	+/–	++
Previous infection	–	++	–	+/–

*Sensitivity about 10^6 genome copies per milliliter.
PCR = polymerase chain reaction.

PREVENTION

Effective vaccines exist for animal parvoviruses, and human B19 infection can also probably be prevented. A recombinant immunogen in development for the human virus lacks DNA and is therefore noninfectious; the empty capsids have been engineered to overexpress the highly immunogenic minor structural protein VP1, and a single 2.5-μg dose of empty capsids elicited excellent neutralizing antibody responses in normal volunteers. Vaccination could prevent transient aplastic crisis in patients with sickle cell disease and other hemolytic anemias, pure red cell aplasia in some immunodeficient individuals, and hydrops if seronegative mothers were inoculated early in pregnancy.

TREATMENT

Most parvovirus infections in normal children and adults do not require specific therapy. Isolation of infected individuals is impractical, with the exception of hospitalized cases. Pure red cell aplasia and the underlying persistent B19 parvovirus infection can be dramatically terminated by discontinuation of immunosuppressive therapy or institution of effective antiretroviral drugs in patients with AIDS. Commercial immunoglobulins are a good source of antibodies to parvovirus, and persistent B19 infection responds to a 5- or 10-day course of IgG at 0.4 g/kg with a prompt decline in serum viral DNA, as measured by hybridization methods, accompanied by reticulocytosis and increased hemoglobin levels. This regimen has been curative in congenital immunodeficiency, but in AIDS, parvovirus often persists at lower levels, and relapses of anemia may require repeated IgG administration. Immunoglobulin therapy can precipitate fifth disease rash and arthralgia. Hydrops fetalis may resolve spontaneously, but intrauterine blood transfusions have been used with apparent success. Chronic arthropathy has been treated symptomatically with anti-inflammatory drugs, and there is not a clear role for the administration of immunoglobulin. As important as recognizing parvovirus infection is avoiding misinterpretation of laboratory studies, such as positive IgG serology or borderline IgM and DNA test results, and misguided maneuvers that delay appropriate alternative treatments.

380 SMALLPOX, MONKEYPOX, AND OTHER POXVIRUS INFECTIONS

INGER K. DAMON

DEFINITION

Human illness caused by a poxvirus is characterized by a cutaneous manifestation; illness may be localized or systemic, depending on the particular poxvirus and the route of introduction. DNA-based assays, including DNA sequencing, are the most precise methods for identification and differentiation of poxvirus genera, species, strains, and variants. The guanosine plus cytosine content of orthopoxviruses, yatapoxviruses, molluscum contagiosum virus, and parapoxviruses is approximately 33%, 32%, 60%, and 63%, respectively.

The Pathogens

All poxviruses described in this chapter (Table 380-1) belong to the family Poxviridae, subfamily Chordopoxvirinae.

EPIDEMIOLOGY

Recognition of the epidemiologic characteristics of poxvirus diseases is valuable in assessing the potential etiologic agent of a particular suspected poxvirus lesion. Knowledge of zoonotic reservoirs, geographic localizations, and capacity for epidemic transmission is critical for clinical assessment and control measures. All human poxvirus infections are zoonotic in nature, with the exception of molluscum contagiosum and variola, which are solely human pathogens. Parapoxvirus and molluscipoxvirus infections are endemic worldwide; orthopoxvirus and yatapoxvirus infections are geographically restricted, probably by the distribution of competent reservoir hosts. With the exception of variola virus (the causative agent of smallpox, a disease declared eradicated in 1980), none of these diseases is required to be reported to public health systems; furthermore, diagnostics are not widely available, so it is difficult to estimate disease incidence and prevalence with any certainty. In addition to variola virus, both monkeypox and camelpox viruses are considered to be select agents by the U.S. government; they must be reported and appropriately handled if discovered and if samples are maintained in the United States.

Orthopoxvirus

The epidemiology of smallpox, caused by the orthopoxvirus variola, is understood through detailed studies conducted during the end of the eradication campaign. Interhuman transmission of variola virus generally occurred through the inhalation of large airborne respiratory droplets of infectious variola virus. Transmission usually required prolonged face-to-face or other close contact, although airborne transmission over longer distances had been reported. Transmission by fomites or contact with infectious material from the rash also occurred. Aggregate data, collected during the smallpox eradication campaign, suggest a secondary attack rate of 58.4% in unvaccinated close or household contacts and a secondary attack rate of 3.8% in previously vaccinated close or household contacts. Case-fatality rates for variola major varied with the type of disease manifested, but aggregate rates of 10 to 30% in various outbreaks have been recorded. Severity of disease correlated with rash burden and was also more severe in children and pregnant women. Variola alastrim minor, a variant of variola with a case-fatality rate of less than 1%, has similar human-to-human disease transmission characteristics.

TABLE 380-1 TAXONOMY OF POXVIRUSES KNOWN TO INFECT HUMANS

GENUS	SPECIES
Orthopoxvirus	Variola virus, vaccinia virus, cowpox virus, monkeypox virus
Parapoxvirus	Orf virus, milker's node virus, bovine papular stomatitis virus, sealpox virus
Yatapoxvirus	Tanapox virus (Yaba-like disease virus), Yaba monkey tumor virus
Molluscipoxvirus	Molluscum contagiosum virus

Monkeypox has a more complex epidemiology. The virus is zoonotic, and two genetically discrete virus clades have been described, each with apparent distinct clinical and epidemiologic parameters. Human infections in western and central Africa were first identified in 1970. Investigations in the Congo basin country Zaire, now the Democratic Republic of Congo, demonstrated that human-to-human transmission of monkeypox was less prevalent than that of smallpox. The secondary attack rate in unvaccinated contacts of monkeypox cases was calculated to be 9.3% versus 37 to 88% for smallpox. Previous smallpox vaccination (3 to 19 years previously) appeared to be 85% protective in preventing disease acquisition in contacts and also ameliorated the severity of disease. Overall, the majority of identified cases acquired disease from presumed animal exposure; only 28% of cases were ascribed to person-to-person transmission. A case-fatality rate of approximately 10% was observed in unvaccinated persons, and the majority of fatalities and the most severe disease manifestations were observed in children younger than 5 years. Serosurveys suggested that subclinical infection may have occurred in up to 28% of close contacts of monkeypox patients in some communities; this relatively low rate may contribute to the rarity of sustained generations of human-to-human transmission in household and other close contact situations.

Among primary cases, recent close contact—through hunting, skinning, killing, cooking, or playing with carcasses—was identified with *Cercopithicus, Colobus,* and *Cercocebus* (primate); *Cricetomys* (terrestrial rodent); and *Funisciurus* and *Heliosciurus* (squirrel species). Samples of animals collected in areas of western and central Africa surrounding human cases demonstrated orthopoxvirus and sometimes monkeypox-specific seroprevalence in various members of these species, except in *Cricetomys* species. The prevailing hypothesis was that squirrel species were the probable reservoir of disease.

The disease reemerged in 1996 in the Democratic Republic of Congo, this time with 88% of cases derived from secondary human-to-human contact because of the cessation of routine smallpox vaccination in 1980 after the eradication of smallpox. Mortality was only 1%. Ecologic serosurveys showed orthopoxvirus seroprevalence in terrestrial rodents *(Cricetomys emini)* and in one domestic pig *(Sus scrofa).*

Monkeypox virus was introduced to the United States in 2003 through a consignment of animals from the west African country of Ghana. The virus was identified as belonging to a distinct clade of monkeypox that included previous west African monkeypox isolates as well as isolates derived from earlier outbreaks in primate colonies. The U.S. cases had a less pronounced rash and a less severe illness, with no mortality or human-to-human transmission. These data suggest at least two populations of monkeypox virus.

Cowpox virus is found in Europe and Asia and is maintained in rodents; in Britain, the reservoirs are bank voles and wood mice. Human infection is a zoonosis. The domestic cat is the most common source of human infection, which probably explains the occurrence of cases in children; 26% of 54 cases occurred in children younger than 12 years. Most feline and human cases occur between July and October, with only occasional cases between January and June. No case of bovine cowpox has been detected since 1976. Cowpox virus also is prevalent in European zoos, where cheetahs, lions, anteaters, rhinoceros, elephants, and okapi have occasionally transmitted infection to animal handlers.

Vaccinia is the live virus contained in preparations of the smallpox vaccines used to eradicate smallpox. In the United States, the vaccine is recommended for laboratory workers who use replicative orthopoxviruses and for selected military personnel. Contacts of vaccinees occasionally develop vaccinia infections. The origin of vaccinia is unknown, and no natural host for the virus is known. Vaccinia "variants" have been described, including buffalopox from contact with infected animals in India and vaccinia viruses in cattle handlers in Brazil.

Parapoxvirus

Human infection is an occupational hazard of farm workers, abattoir workers, veterinary surgeons, and students. It is most common in the lambing and calving seasons and among sheep workers.

Factors responsible for ongoing transmission have been attributed both to the environmental stability of orf virus in scab material and to the manifestation of chronic infections in some animals. There is no known latent state for

this or any other poxvirus. Transmission of virus to humans and to animals is through direct contact with lesions or by fomites.

Molluscipoxvirus

Molluscum contagiosum virus occurs worldwide, and increasing reports of the disease have paralleled the number of reported cases of acquired immunodeficiency syndrome (AIDS). Traditional modes of transmission are associated with mild skin trauma such as abrasions, direct contact with a lesion, and fomites (e.g., shared towels) in some cases. However, the disease appears to be sexually transmitted, and genital lesions are more common than lesions elsewhere on the body. Children in daycare or school situations may transmit the disease to other children. Secondary spread of lesions may occur by autoinoculation (excoriation of primary lesions and spread to areas of normal skin) as well as by shaving. No known animal reservoir exists.

Yatapoxvirus

Tanapox virus is restricted to Africa, principally to Kenya and the Democratic Republic of Congo, and probably has a simian reservoir. Direct primate-to-human transmission through a break in skin has rarely been described in animal handlers, but an insect or arthropod intermediary may be involved in the transmission of tanapox virus to humans. No human-to-human transmission has been reported. Yaba monkey tumor virus causes localized infections after contact with infected primate lesions. Little is known about the epidemiology of this virus.

PATHOBIOLOGY

The majority of smallpox infections were initiated by inhalation of respiratory droplets and implantation of virus on the oropharyngeal and respiratory mucosa. No primary localized site of infection was evident if the route of exposure was by inhalation. Disease could also be introduced through suspensions of virus obtained from scabs of patients that were introduced percutaneously and constituted the practice of variolation. In these cases (when skillfully administered), illness was usually less virulent, a localized primary infectious lesion was present, and the asymptomatic incubation period was truncated.

After entry, virus moves to local lymph nodes and then disseminates to the reticuloendothelial system to replicate further. At this time, the individual is asymptomatic. In 10 to 14 days, secondary viremia occurs and heralds the prodrome of symptomatic illness. During this time, virus seeds the oropharynx and epidermis. The absence of a keratinized structure in the mucosa of the oropharynx leads to ulceration and release of virus in saliva; virus replicates in the epidermis to cause the characteristic macular, papular, and vesicular eruptions of smallpox.

In experiments in monkeys, high levels of type I interferons, interleukin-6, and interferon-γ are seen; D-dimers and thrombocytopenia suggest disseminated intravascular coagulation. Apoptosis with loss of T cells in lymphoid organs was also observed. Of note, tumor necrosis factor-α (TNF-α) levels were minimal in the infected animals, with a notable decrease in the expression of genes regulated by nuclear factor κB and TNF-α.

In humans, the viral lesion primarily develops in the epidermis, where the cells of the malpighian layer swell and vacuolate to undergo ballooning degeneration. The cytoplasm continues to enlarge, loss of nuclear material is noted, and coalescence of vacuoles through cell rupture creates reticulating degeneration of the middle and upper layers of the stratum spinosum. In the next stages, the vesicle is formed. High titers of virus are found within the lesions. In mucosal surfaces, the absence of a horny layer allows the necrosis caused by proliferation of virus within the epithelium to create ulcers and leads to liberation of large quantities of virus into the oropharynx. Evaluation of other organs in human smallpox has been done only in select autopsy cases. Mild pathologic changes are seen in the lungs.

CLINICAL MANIFESTATIONS

Orthopoxvirus

Smallpox

Naturally acquired variola virus infection is characterized by fever and a distinctive rash, with several different clinical presentations (Table 380-2). When the disease still existed, an asymptomatic incubation period of 10 to 14 days (range, 7 to 17) was followed by a fever that quickly rose to about 103° F (38° to 40° C), sometimes with dermal petechiae. Associated constitutional symptoms included backache, headache, vomiting, and prostration. Within a day or two after incubation, a systemic rash with a characteristic centrifugal distribution (i.e., lesions present in greater numbers on the oral mucosa, face, and extremities than on the trunk) appeared. The fever typically abated as the rash developed. Lesions commonly appeared on the palms and soles. The rash lesions were initially macular and then advanced to the papular stage, at which point they enlarged and progressed to a vesicle by day 4 to 5 and a pustule by day 7. When lesions became pustular, the fever typically returned. Lesions became encrusted and scabbed by day 14 and then sloughed off. Skin lesions in the vesicular and pustular stages were deep seated and in the same stage of development in any one area of the body (Fig. 380-1). The ordinary disease type was subgrouped into three categories based on the extent of rash on the face and the body: confluent, semiconfluent, and discrete. In *ordinary confluent disease,* no area of skin was visible between vesiculopustular rash lesions on the trunk or the face. In *ordinary semiconfluent* and *discrete disease,* patches of normal skin were visible between rash lesions on the trunk and face, respectively. Less severe manifestations (modified smallpox or variola sine eruptione) occurred in both unvaccinated and, more commonly, vaccinated individuals. The mortality rate correlated with the rash burden.

Four main clinical types of variola can be subgrouped according to the World Health Organization (WHO) classification schema: *ordinary smallpox* (≈90% of cases) produced viremia, fever, prostration, and rash, and mortality rates were generally proportional to the extent of rash and ranged as described earlier; *(vaccine) modified smallpox* (5% of cases) produced a mild prodrome with few skin lesions in previously vaccinated people and had a mortality rate

TABLE 380-2 WORLD HEALTH ORGANIZATION SMALLPOX TYPES

WHO SMALLPOX TYPE	CLINICAL DEFINITION
Variola sine eruptione	Fever, no rash
Modified	Like ordinary, with an accelerated course
Ordinary discrete	Fever, rash; areas of normal skin between pustules, even on the face
Ordinary semiconfluent	Fever, rash; pustules confluent on the face, discrete elsewhere
Ordinary confluent	Fever, rash; pustules confluent on the face and forearms
Flat	Fever, erythema, and edema of the skin; vesicles soft, flat, and bullous
Hemorrhagic, early	Fever (persistent), hemorrhages and petechiae, purpuric rash at illness onset
Hemorrhagic, late	Fever (persistent), rash, hemorrhage into the base of vesicles late in illness

FIGURE 380-1. Pustular lesions of smallpox and beginning of scarring on the face and upper part of the torso. (From the Centers for Disease Control and Prevention Public Health Image Library, ID #: 7055. Photograph by Stan Foster.)

well below 10%; *flat smallpox* (≈5% of hospitalized cases) produced slowly developing lesions that were difficult to ascertain because they appeared flush with the (edematous) skin at the vesicular stage, and it was almost always fatal; and *hemorrhagic smallpox* (<1% of cases) induced bleeding into the skin and the mucous membranes and was invariably fatal. A discrete type of the ordinary form, with a typical febrile prodrome and rash, resulted from alastrim variola minor infection. Individuals with this form of disease were not nearly as moribund or "toxemic" as individuals with variola major infection. Previous vaccination was not necessarily protective against the hemorrhagic forms of disease but seemed to be protective against flat forms of disease.

In flat smallpox, illness was heralded by the abrupt onset of fever to 38.3° to 38.9° C and the appearance of the rash after 3 to 4 days. The oral enanthem was often confluent, and sloughing of rectal mucosal membranes was also reported. At the papulovesicular stage of disease, lesions appeared as small indentations (day 6) with hemorrhages in the bases and were surrounded by an erythematous ring. By day 7 or 8, the lesions appeared flat. Bullous lesions that would slough were reported. Fever persisted throughout the disease course, and respiratory complications were often observed by day 7 or 8 of illness. Thrombocytopenia, neutropenia, and lymphocytosis were reported.

In hemorrhagic forms of smallpox, illness began with fever and typical prodromal symptoms; the fever never abated. Early after the onset of fever, petechiae and purpuric rashes became apparent; subconjunctival hemorrhages, hematuria, and vaginal bleeding were also seen. Patients usually died by day 6 of illness, well before any classic vesiculopustular rash was evident. In late hemorrhagic disease, after the onset of fever, typical maculopapular lesions developed, but the fever did not abate. The lesion evolved slowly, and areas of hemorrhage were evident at the base of the lesions. Bleeding occurred in the mucous membranes, thrombocytopenia was profound, and death occurred between days 8 and 10 of illness.

Monkeypox

After an incubation period of 7 to 17 days (mean, 12 days), a prodrome of fever, headache, backache, and fatigue begins. The cutaneous eruption evolves similar to that of smallpox. Lesions evolve in the same stage in any one part of the body from macules, papules, and vesicles to pustules, and then they crust and scar (Fig. 380-2). After resolution of the rash, hypopigmentation is followed by hyperpigmentation of the scarred lesions. Pronounced cervical, postauricular, submandibular, and inguinal lymphadenopathy clinically distinguishes monkeypox from smallpox.

Vaccinia

Multiple-puncture vaccinia virus infection by a bifurcated needle is the current smallpox vaccination regimen used for laboratory personnel working with orthopoxviruses, public health care personnel, and military in the United States. Most commonly, the infection progresses through a standard course of events from vesicle to pustule. However, of all vaccines used today, the smallpox vaccine, which is composed of live, replicative vaccinia virus, has one of the highest rates of adverse events. Major complications include progressive vaccinia, eczema vaccinatum, generalized vaccinia, postvaccinial encephalitis, accidental infection, and carditis.

Progressive vaccinia, which is a rare and often fatal vaccine complication in persons with severe deficiencies in cellular immunity, occurs in about 1 per million vaccines, with a case-fatality rate of about 35%. Progressive vaccinia is characterized by frequently painless growth and spread of the vaccine virus beyond the inoculation site, often leading to necrosis and sometimes metastases to other body sites. The possibility of progressive vaccinia should be considered if the vaccination site lesion continues to progress and expand without apparent healing more than 15 days after vaccination.

Eczema vaccinatum can occur in people with a history of atopic dermatitis (eczema), irrespective of its severity or activity, owing to local spread or dissemination from the primary vaccination site or contact with the unscabbed vaccination site of another person. A localized or generalized papular, vesicular, or pustular rash can develop anywhere on the body or be localized to previous eczematous lesions. Systemic illness with fever, malaise, and lymphadenopathy may occur. In the 1968 national U.S. surveillance of smallpox vaccination, there were 66 cases (no deaths) of eczema vaccinatum among 14.5 million vaccinees (4.6 cases/million) and 60 cases (1 death) among their several million contacts.

Generalized vaccinia describes the vesicular rash that develops after vaccination. Excluding dissemination associated with eczema vaccinatum and progressive vaccinia, it has been extremely rare to document virus in these lesions. True generalized vaccinia is believed to represent the end product of viremic spread of virus, and no predisposing factors have been identified. Generalized vaccinia is estimated to occur in about 242 of every million primary vaccinations.

Postvaccination encephalomyelitis is a rare but serious complication that usually occurs only in primary vaccinees. Patients have variably displayed clinical and diagnostic features suggestive of a postimmunization demyelinating encephalomyelitis or direct viral invasion of the nervous system. This postvaccination reaction typically occurs 11 to 15 days after vaccination. Symptoms include fever, headache, vomiting, confusion, delirium, disorientation, restlessness, drowsiness or lethargy, seizures, and coma. Cerebrospinal fluid can demonstrate elevated pressure but generally has a normal cell count and chemistry profile. The diagnosis is one of exclusion, and no specific tests are available to confirm it.

Accidental infection occurs when virus from the vaccination site is transferred to another site or to another person through intimate skin contact. This complication generally occurs with primary vaccinees rather than revaccinees. Accidental self-inoculation, which most commonly occurs on the face, mouth, lips, or genitalia, is not usually serious and requires no specific treatment. Inoculation of the eye or eyelid is more serious and can be sight threatening if it is not evaluated and treated appropriately (Fig. 380-3). Between 1963 and 1968, ocular vaccinia was observed in 348 persons, including 22 who had evidence of corneal involvement and 11 who experienced permanent defects.

With buffalopox viruses in India and the Cantagalo virus in Brazil, up to 10 lesions have been described on the hands or arms of human handlers; fever, lymphadenopathy, backache, and fatigue are also associated symptoms. Transmission is believed to occur by unprotected contact with active lesions

FIGURE 380-2. Rash of monkeypox of the head (A) and extremities (B) in a 7-year-old girl in central Zaire. (From Peters W, Pasvol G. *Tropical Medicine and Parasitology,* 5th ed. New York: Mosby; 2002:238.)

present on animal teats and udders. Interhuman transmission of buffalopox to family members has been reported to occur through contact.

Cowpox

Cowpox lesions are generally restricted to the hands and face; most patients (72%) have only one lesion. Multiple lesions may be caused by multiple primary inoculations, by autoinoculation, and very infrequently by lymphatic or viremic spread. The cowpox lesion passes through macular, papular, vesicular, and pustular stages before forming a hard black crust. The lesion is generally very painful, and erythema and edema are common at the late vesicular and pustular stages. Patients usually have lymphadenitis, fever, and general malaise. These features are generally severe in children, and absence from school or work is common. About 30% may be hospitalized. Most patients take 6 to 8 weeks to recover, but up to 12 weeks may be required. On occasion, a very severe infection and death may occur, typically in immunosuppressed individuals. Scarring is usually permanent.

Parapoxvirus

Lesions, such as from the orf virus, start as erythematous papules and progress in 1 to 2 weeks to target lesions with a red center surrounded by a white halo and an outer inflamed halo. Lesions then progress to a nodular and then a papillomatous stage, which often has a "weeping" surface. In some patients, lesions may enlarge and persist for weeks before resolving by a crusting stage, which also may persist for weeks. Very large granulomatous lesions may occasionally require surgical removal.

Most patients have only one lesion, but multiple primary lesions may develop. Systemic reaction is relatively uncommon, and the lesion is often not particularly painful. Lymphadenopathy is present in some patients, and lymphangitis is relatively uncommon. Erythema multiforme (Chapter 447) can develop in up to one third of patients.

Molluscum Contagiosum Virus

Molluscum infection occurs when molluscum contagiosum virus comes into contact with nonintact skin. The characteristic lesion begins as a small papule and, when mature, is a discrete, 2- to 5-mm-diameter, smooth, dome-shaped, pearly or flesh-colored nodule that is often umbilicated. A cheesy, off-white or yellowish material is easily expressed from lesions. Most patients have 1 to 20 lesions, but hundreds of lesions may occasionally be present. Because of multiple simultaneous infections or mechanical spread, the lesions may become confluent along the line of a scratch, and satellite lesions are sometimes seen.

In children, molluscum lesions occur mainly on the trunk and proximal ends of the extremities; in adults, lesions tend to occur on the trunk, pubic area, and thighs. In all cases, however, infection can be transmitted to other areas by autoinoculation. In men infected with human immunodeficiency virus (HIV), molluscum lesions can occur along the beard line and result in ocular involvement.

Individual lesions persist for about 2 months, but the disease usually persists for 6 to 9 months. Individuals with impaired cell-mediated immunity, including persons with HIV infection, tend to have more severe and prolonged infection.

Yatapoxvirus

Tanapox infection begins with a short febrile (38° to 39° C) illness that persists for 2 to 4 days and is sometimes accompanied by headache, backache, or prostration. The eruption of a lesion is frequently heralded by pruritus at the site of the outbreak. The lesion appears as a hyperpigmented macule, which often has central elevation and evolves to a papule with palpable induration. About 80% have a solitary nodule, but as many as 10 lesions can occur. Most lesions (72%) occur on the lower extremities, and the fewest occur on the face and areas normally covered by clothing.

Fever and systemic symptoms wane as the lesion erupts. The papule then becomes more "pocklike" but contains no fluid; umbilication or a pseudocrust may develop. Typically, the papule evolves into a firm, deep-seated, elevated nodule. At the end of the first week, the lesion is surrounded by erythema and indurated skin, and regional lymphangitis is common. Lesions then either ulcerate or become larger nodules (up to 2 cm in diameter) within about 2 weeks, after which the local inflammatory response wanes and the lesions began to granulate. Resolution of lesions occurs within 6 weeks. Infection appears to confer lifelong immunity.

DIAGNOSIS

Before its eradication, smallpox was relatively easy to recognize. Chickenpox (Chapter 383) produces a centripetally distributed rash and rarely appears on the palms and soles; in chickenpox, prodromal fever and systemic manifestations are mild, the lesions are superficial in nature, and lesions in different developmental stages may be present in the same area of the body. Other diseases and conditions that could be confused with vesicular-stage smallpox include monkeypox, generalized vaccinia, disseminated herpes zoster or herpes simplex virus infection (Chapters 382 and 383), drug reactions (eruptions), erythema multiforme (Chapter 447), enteroviral infections (Chapter 387), scabies (Chapter 367), insect bites, impetigo (Chapter 447), and molluscum contagiosum. Diseases confused with hemorrhagic smallpox included acute leukemia (Chapter 189), meningococcemia (Chapter 306), and idiopathic thrombocytopenic purpura (Chapter 175). The Centers for Disease Control and Prevention has developed a worksheet for evaluation of patients for potential smallpox (available at *http://www.bt.cdc.gov/agent/smallpox/diagnosis/evalposter.asp*) and an algorithm for assessment of the vesiculopustular stage of rash (available at *http://www.bt.cdc.gov/agent/smallpox/diagnosis/rashtestingprotocol.asp*).

Orthopoxvirus

Viral culture or electron microscopic evaluation of virion particles from clinical rash specimens has been the approach to diagnosis of orthopoxvirus infections. Serologic tests are largely genus specific, detect IgG, and usually cannot differentiate among species, although IgM levels can help differentiate recent orthopoxvirus infection from remote vaccination. Nucleic acid–based tests and polymerase chain reaction (PCR) assays are other options. If the diagnosis of smallpox is being considered, viral culture requires a biosafety level 4 (BSL-4) containment facility that is sanctioned by the WHO to use variola virus.

Parapoxvirus

The differential diagnosis of parapoxvirus lesions can include ecthyma gangrenosum as a result of a *Pseudomonas aeruginosa* infection (Chapter 314), vaccinia or cowpox infection, cutaneous anthrax (Chapter 302), erysipeloid (Chapter 303), tularemia (Chapter 319), and tumor. Farm workers recognize the infection and tend not to seek medical attention for routine cases, so about 45% of reported cases may have no known contact with infected animals, and the clinical diagnosis of such cases may be difficult. With negative-stain electron microscopy, virions with the characteristic morphology of parapoxviruses are usually seen easily in lesion extracts, thereby providing a rapid, certain diagnosis of the genus. The virus can be grown in cell culture, and PCR detection can be performed. Species-specific and species-generic protein-based diagnostics have also been developed for parapoxviruses.

Molluscum Contagiosum Virus

The clinical appearance of molluscum lesions usually is sufficiently characteristic to permit a clinical diagnosis. Brick-shaped virions typically can be seen in large numbers if the cheesy material expressed from the lesion is examined by electron microscopy. The virus has not been cultured in standard tissue culture systems. The characteristic histopathology of these lesions is diagnostic, but PCR methods can also identify molluscum contagiosum.

Yatapoxvirus

The limited geographic distribution of tanapox virus and the patient's travel history help with the diagnosis of tanapox infection. Unique clinical features that differentiate tanapox from other orthopoxvirus infections are the nodular nature of the rash lesion, the paucity of lesions, the benign disease course, and the protracted resolution of the rash. The solid nodular and ulcerated lesions are larger and develop more slowly than those of monkeypox, but they are smaller and develop more rapidly than those of tropical ulcers.

Tanapox virus can be detected by electron microscopy, but the appearance of the virions cannot exclude infection with other morphologically similar brick-shaped poxviruses. Nucleic acid testing or cell line culture can make the definitive diagnosis.

TREATMENT AND PREVENTION

Rx

Orthopoxvirus

Vaccination with smallpox vaccine is the mainstay for prevention of orthopoxvirus infection and was the primary method used to eradicate smallpox. Stockpiles of vaccine are available should smallpox recur. In the United States, however, smallpox vaccine is currently recommended only for laboratory personnel who work with infectious orthopoxvirus, certain public health personnel, and certain members of the military. Adverse events are rare with vaccination, but myocarditis or pericarditis was documented in 18 of 230,734 (8 per million) U.S. military primary vaccinees immunized in 2002 and 2003. In recent trials, both an attenuated tissue-cultured smallpox vaccine (LC16m8) and a replication-deficient smallpox vaccine (MVA) were about 95% effective both in newly vaccinated adults and as a booster.[1,2]

Currently, no antiviral drugs are licensed to treat orthopoxvirus or other poxvirus illnesses. Early administration of vaccinia immune globulin (VIG) may reduce the mortality of eczema vaccinatum from 30 to 40% to 7%, and VIG may also be useful for other complications (e.g., progressive vaccinia, severe generalized vaccinia or contact infection) of vaccinia (smallpox) vaccine administration and for other orthopoxvirus infections. However, VIG alone has no clear benefit for treatment of smallpox infection itself.

Antiviral compounds with in vitro and in vivo activity against poxviruses include specifically 5-iodo-2′-deoxyuridine, adenine arabinoside, and trifluorothymidine. Because of their systemic toxicity, these compounds have been used topically for the treatment of orthopoxvirus ocular infections. In vitro, cidofovir is active against cowpox, vaccinia, monkeypox, and variola; in vivo, it protects challenged animals when it is given prophylactically or early in the evolution of disease. Cidofovir has known renal toxicity and is administered with hydration and probenecid. CMX-001 has been effective in treatment of systemic rabbitpox infection in rabbits and was used as part of a multiple-drug regimen to treat a case of progressive vaccinia. The drug ST-246 is effective in animal models of systemic orthopoxvirus infection and has been used as part of a multiple-drug regimen to treat a human case of eczema vaccinatum and a case of progressive vaccinia.

Parapoxvirus

Most workers at risk for parapoxvirus become infected, and reinfection also occurs. The vaccine used to control orf in sheep is fully virulent and has caused human infection. Treatment options are limited; anecdotal reports have described the use of topical cidofovir, and other options may be topical formulations of interferon-modulating compounds such as imiquimod.

Molluscum Contagiosum Virus

Molluscum contagiosum infection is benign and recovery is usually spontaneous, but treatment may be sought for cosmetic reasons, particularly for facial or multiple lesions. Options include cryotherapy, mechanical curettage, and chemical treatments such as podophyllin or podofilox, cantharidin, iodine, and tretinoin. Irritation has been a side effect of many of the chemical treatments. Topical application of a 3% cidofovir antiviral cream or suspension has been reported to be beneficial, as has the use of potentially immune-modulating cimetidine or topical imiquimod therapy. However, no therapy is documented to be beneficial by well-controlled randomized trials.[3] Covering of lesions and the use of proper hand hygiene after contact with lesions should prevent transmission in most situations. For individuals with AIDS and molluscum, highly active antiretroviral therapy with a resulting improvement in the $CD4^+$ cell count appears to be efficacious.

PROGNOSIS

Monkeypox and smallpox both cause human illness, with mortality ranging from 10% to 40%; variola minor variants, however, have mortality rates of less than 1%. Yatapoxvirus infections are self-limited, and the illness resolves in the course of a few weeks. Parapoxvirus infections are manifested chiefly by localized symptoms, and the lesions resolve during a month or so in non-immunocompetent hosts. Molluscum contagiosum infection is benign, usually with a spontaneous recovery, but the infection can persist for months. Variola minor has a mortality rate of less than 1%.

PAPILLOMAVIRUS

JOHN M. DOUGLAS, Jr.

DEFINITION

Human papillomaviruses (HPVs) are a group of small DNA viruses that cause a variety of benign and malignant lesions of the skin and mucous membranes. The most commonly recognized HPV-associated diseases include warts (Chapter 448) at anogenital sites (condyloma acuminatum), other skin surfaces (common warts or verruca vulgaris), and the plantar surface of the foot (verruca plantaris).

In addition, HPV infection causes squamous intraepithelial lesions of the cervix, also known as cervical intraepithelial neoplasia (CIN), and of other anogenital sites. It is considered the etiologic agent of a variety of anogenital cancers, especially cervical cancer (Chapter 205).

The Pathogen

HPV is a member of the family Papillomaviridae. Like all papillomaviruses, HPV is nonenveloped, measures 55 nm in diameter, and has a double-stranded circular DNA genome of approximately 7900 base pairs enclosed by an icosahedral capsid. The HPV genome contains three functional regions: early genes (E), which are expressed soon after infection and control replication, transcription, and cellular proliferation; late genes (L), which are expressed in later stages of infection and encode the structural capsid proteins; and the long control region, which contains regulatory sequences that control the replication and transcription of early and late genes. Papillomaviruses complete their life cycle only in terminally differentiated epithelial cells and thus are difficult to grow in cell culture. Papillomavirus taxonomy is based on a genotyping system involving the use of DNA sequence relatedness of the gene encoding L1, the major capsid protein, with different types defined as having less than 90% homology.

Papillomaviruses are classified taxonomically by genus (Greek letters) and species (numbered), each containing one or more types. Most HPV types are included in two large genera: alpha (primarily mucosal or genital types) and beta (primarily cutaneous types). Currently, more than 100 types of HPV have been well characterized, approximately 40 of which infect genital skin and mucosa. Of the genital types, approximately 15 are considered high risk because they are associated with high-grade squamous intraepithelial lesions and cervical and other genital tract cancers, whereas others are considered low risk because they are largely associated with genital warts and low-grade squamous intraepithelial lesions.

EPIDEMIOLOGY

HPV infections are primarily transmitted by direct contact of skin or mucous membranes with an infected lesion. Genital HPV infection is typically

contracted through sexual intercourse, although nonpenetrative genital contact, oral-genital contact, and manual-genital contact are also possible routes of transmission. In addition, genital HPV infection can be transmitted to the mouth and upper respiratory tract perinatally from infected mothers to newborns. For nongenital HPV infection, personal skin-to-skin contact also plays a primary role, although for plantar warts, fomite transmission from moist surfaces is likely to be an important source of infection. Both genital and nongenital infection can be transmitted to new sites by autoinoculation.

Overall, in the United States, it is estimated that more than 6 million new infections of genital HPV occur annually in sexually active adolescents and adults and that the lifetime risk for infection is 50 to 80%, thus making genital HPV one of the most common sexually transmitted infections. Acquisition of infection begins shortly after sexual debut, with an estimated 40 to 60% incidence of at least one type within 2 years of initiation of sex. Risk factors for infection include variables related to probable exposure (e.g., younger age, increased number of recent and lifetime partners, and number of partners of the sex partners), susceptibility (e.g., lack of circumcision for men), and absence of prevention factors (e.g., lack of consistent condom use or immunization). Most infections are asymptomatic and clear without treatment; only 10% are estimated to persist longer than 2 years. Only such persistently detectable HPV infections are associated with the development of high-grade squamous intraepithelial lesions and cancer. The prevalence of genital HPV infection is estimated to range from 25 to 35% in U.S. women. The prevalence of anogenital warts is estimated to be approximately 1% in the sexually active adult population. Cervical cancer has declined in developed countries since the initiation of cytologic screening programs, although an estimated 11,000 cases and 4000 deaths still occur in the United States annually. However, the disease is a major problem in the developing world, where screening is limited, and it is the second most common cancer in women worldwide, with an estimated 490,000 cases annually.

Nongenital HPV infection is most typically recognized as common and plantar warts, especially in children and adolescents, in whom prevalence rates of 3 to 20% have been reported. All types and manifestations of HPV infection are more common in persons with impaired cell-mediated immunity, such as those infected with human immunodeficiency virus (HIV) or receiving immunosuppressive therapy.

PATHOBIOLOGY

HPV infections cause disease by producing aberrant cell growth. In the case of cutaneous and low-risk genital types, lesions such as warts result from HPV-induced benign proliferation of epidermal layers. For high-risk genital types, precancerous and cancerous lesions result from replacement of the epithelium by undifferentiated cells as a result of HPV-induced interference with normal cellular growth.

Infection begins in the lowest and least well differentiated layer of the epithelium, the basal cells, where exposure is thought to be facilitated by microtrauma. Transcription and protein expression are highly coordinated with the level of cellular differentiation. In the basal layer, the viral genome becomes established in the nucleus as an episome that replicates in tandem with cellular replication, thus maintaining a stable copy number of viral genomes. As basal cells migrate up and differentiate in the superficial layers of the epithelium, full vegetative viral DNA replication and expression of structural proteins occur, with assembly of infectious virions in the most superficial layer of the epithelium, where they are released with the sloughing of dead cells during normal cellular turnover.

On the basis of a variety of epidemiologic and laboratory studies, persistent infection with various high-risk types of genital HPV is firmly established as the cause of squamous cell carcinoma and adenocarcinoma of the cervix (Chapter 205), and HPV 16 plays a causal role in other anogenital and oropharyngeal squamous cell cancers (Chapters 147 and 196). There are also associations of HPV of the genus beta with squamous cell cancer of the skin (Chapter 210). HPV DNA can be detected in more than 99% of cases of cervical cancer, with 70% of cancers being associated with the two most common high-risk types, HPV 16 and 18. The pathogenesis of HPV-induced cancer involves viral integration into the host genome with resulting disruption of the E2 transcription regulatory gene and increased expression of E6 and E7 proteins. These proteins have oncogenic activity and affect cell growth by binding with tumor suppressor proteins, E6 with p53 and E7 with the retinoblastoma tumor suppressor protein, thereby disrupting apoptosis and cell cycle regulation. Although persistent infection with high-risk types is "necessary" for the development of cervical cancer, it is not considered "sufficient" because cancer does not develop in the majority of infected women. Data support a variety of possible cofactors, including cigarette smoking, prolonged hormonal contraceptive use, multiparity, micronutrient deficiency, and other infections, (i.e., *Chlamydia trachomatis* and herpes simplex virus type 2). In addition, a variety of specific HLA class II alleles have been associated with both increased (e.g., DQB1*0301) and decreased (DRB1*13) risk for cancer, whereas polymorphisms of the p53 gene and the tumor necrosis factor-α promoter region have been associated with increased susceptibility to cancer.

The immune response after initial infection is less robust than for most viral infections; measurable antibody develops in only an estimated 60% of infected individuals, often as long as 6 to 12 months after infection. The limited immune response is probably due to the superficial location of infection in the epithelium and the fact that the capsid proteins are not expressed except in the most well differentiated cells, which are the least accessible to antigen-presenting cells of the immune system. The dynamics of the immune response are quite different after the administration of L1-containing vaccines, with almost 100% seroconversion within several months and antibody levels approximately 10-fold higher than those after natural infection. The high efficacy of these vaccines, which are believed to produce primarily humoral immunity, supports the importance of the antibody response in protection from infection. In contrast, once infection occurs, cellular immunity appears to be critical for clearance of infection on the basis of the experience of persons with impaired cell-mediated immunity, in whom persistent HPV infection and high-grade squamous intraepithelial lesions are more common than in normal hosts.

The histopathologic changes of warts include epithelial papillomatosis and acanthosis, with hyperkeratosis, parakeratosis, and hyperplasia of the parabasal cells. A characteristic feature is the presence in the upper epidermis of koilocytes, or large atypical keratinocytes with irregular, hyperchromatic nuclei surrounded by a perinuclear halo. Squamous intraepithelial lesions are characterized by hyperkeratosis, parakeratosis, and epidermal hyperplasia, with increased mitotic figures in the upper half of the epidermis; koilocytosis is common and often detected cytologically but less prominently than in warts. Several classification systems have been used to classify these lesions and their probable risk for progression based on the proportion of the epithelium replaced by undifferentiated cells. The CIN system grades lesions as CIN 1 (with undifferentiated cells occupying the lower third), CIN 2 (with undifferentiated cells in the lower third to two thirds), and CIN 3/carcinoma in situ (CIS, with undifferentiated cells across the full thickness of the epithelium). A newer classification, the Bethesda system, was originally developed for use with cytology but has increasingly been used for histologic classification; it includes only two categories: low-grade squamous intraepithelial lesions (CIN 1) and high-grade squamous intraepithelial lesions (CIN 2 and CIN 3/CIS).

CLINICAL MANIFESTATIONS

The clinical manifestations of HPV infection vary by anatomic site and viral type. Common warts are exophytic, hyperkeratotic papules that typically occur on the hands but can appear on any skin surface, including the genital skin; they are most commonly caused by HPV types 1, 2, 4, 27, and 57. Plantar warts, which are caused by similar types of HPV, are hyperkeratotic, endophytic, and often very painful. In contrast, flat warts (verruca plana), which are small flat-topped papules that occur more commonly on the face, hands, and legs, are caused by a different group of nongenital HPV types (e.g., types 3, 10, 28, 38, 42, 49, 75, 76).

Epidermodysplasia verruciformis is an uncommon autosomal recessive disease that is usually manifested in childhood as diffuse warts that respond poorly to treatment and typically are caused by HPV types uniquely associated with it (e.g., types 5, 8, 9, 12, 14, 15, 17, 19-25). This syndrome, which is thought to be due to a selective defect in cell-mediated immunity because other opportunistic infections do not occur, is associated with two types of lesions: flat warts caused by the same HPV types as in normal hosts and scaly tinea versicolor–type lesions caused by a large number of unusual types. The latter are associated with the development of squamous cell cancer in sun-exposed areas. Similar skin lesions and, rarely, associated skin cancers can develop in other patients with acquired defects in cell-mediated immunity. Other uncommon lesions caused by unique HPV types include butchers' warts (type 7), which are verrucous lesions found on the hands of meat handlers, and focal epithelial hyperplasia, which consists of flat mucosal lesions of the oropharynx (types 13 and 32).

The majority of genital HPV infections do not produce recognized lesions and remain subclinical, detected only by HPV DNA testing. Anogenital warts are papillomatous growths that occur throughout the anogenital skin and mucosa, generally at sites of genital friction. Perianal warts, which are more common in persons with a history of anal intercourse, are often associated with intra-anal warts but can occur without such contact, presumably through autoinoculation. The warts can range from flat or papular lesions to the classic pedunculated, cauliflower-shaped condyloma acuminatum. They are typically caused by low-risk types (>90% are due to HPV 6 or 11), although warts caused by high-risk or multiple types can occur in immunocompromised patients. Warts are typically asymptomatic, noticed either by the patient as a "bump" or inadvertently during a genital examination, although they can cause itching, burning, pain, or, rarely, bleeding or mechanical obstruction of the birth canal in pregnant women. Warts caused by genital types can also rarely occur in the mouth and upper respiratory tract, producing a serious condition known as recurrent respiratory papillomatosis, which can cause hoarseness and even airway compromise.

Squamous intraepithelial lesions are most commonly found on the cervix as a result of screening for cervical cancer precursors by cytology (Pap test) or HPV DNA testing, with confirmation by colposcopy and biopsy. Like warts, they also occur at other anogenital sites, and like cervical lesions, they are categorized either as low-grade or high-grade squamous intraepithelial lesions or as various stages of intraepithelial neoplasia (e.g., vulva—VIN; vagina—VaIN; anus—AIN; penis—PIN). At all sites, low-grade squamous intraepithelial lesions can be caused by either low- or high-risk types, whereas high-grade squamous intraepithelial lesions are primarily due to high-risk types. Most squamous intraepithelial lesions are not visible on mucosal surfaces without the application of 3 to 5% acetic acid and magnification, although they can appear as flat hyperpigmented papules known as bowenoid papulosis on the external genitalia.

FIGURE 381-1. Plantar wart. A hyperkeratotic, verrucous papule or plaque beneath a pressure point on the sole of the foot is characteristic. HPV types 1 (myrmecia), 2 (mosaic), and 4 are most common. Because plantar warts are driven into the skin by the pressure of walking or standing, they are usually the most treatment resistant.

DIAGNOSIS

Both cutaneous (Fig. 381-1) and genital (Fig. 381-2) warts generally present an easily recognized clinical picture and can be diagnosed by history and physical examination without laboratory testing. The application of 3 to 5% acetic acid causes whitening of HPV lesions on genital mucosa ("acetowhitening") and may be useful with magnification in women; however, because its sensitivity and specificity have not been defined, it is not recommended for routine use.

The differential diagnosis of cutaneous warts includes seborrheic and solar keratoses, nevi, irritated acrochordons, clavi, and squamous cell carcinoma (Chapters 210 and 448); lichen planus (Chapter 446) can mimic flat warts and calluses of the foot or plantar warts. Genital warts must also be distinguished from the condyloma latum lesions of secondary syphilis (Chapter 327) and molluscum contagiosum (Chapters 380 and 448). Biopsy for histopathologic examination may be helpful for lesions that are atypical or not responsive to therapy, those suggestive of high-grade squamous intraepithelial lesions or cancer (e.g., pigmented, indurated, fixed, bleeding, or ulcerated), or lesions in immunocompromised patients.

The principal approach to the diagnosis of cervical squamous intraepithelial lesions is cytologic screening, with assessment of abnormal results by colposcopy and biopsy for histopathologic examination. In the United States, the Digene Hybrid Capture 2 High-Risk HPV test (QIAGEN, Valencia, Calif) detects any of 13 high-risk types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68), whereas the Cervista HPV HR (Hologic, Inc., Bedford, Mass) detects the same 13 types as well as type 66. Results of both tests are reported as positive for any type or negative. Type-specific results are not available with these tests, but another assay (Cervista 16/18) can specifically identify HPV 16 and 18. HPV DNA testing is approved as an adjunct to cytology, referred to as the DNA Pap or HPV co-test, to enhance the sensitivity of screening in women older than 30 years but is not recommended for younger women. HPV DNA tests are also recommended for triage of women whose Pap test results show atypical squamous cells of undetermined significance, which is an equivocal test result (Chapter 205).

PREVENTION

Primary Prevention

Primary prevention of HPV infection depends on avoidance of contact with infectious lesions and reduction of susceptibility through immunization. For example, the use of footwear in locker rooms may prevent plantar warts. For genital HPV infection, avoidance of sexual contact is the most reliable preventive measure, but correct and consistent condom use can reduce the risk for both HPV infection and the HPV-associated diseases of genital warts, cervical squamous intraepithelial lesions, and cervical cancer. Male circumcision reduces the prevalence of both high-risk and low-risk types of genital HPV infection.■

Of greatest importance for prevention are newly licensed vaccines, composed of virus-like particles assembled from the major capsid protein, L1. The quadrivalent vaccine (types 6, 11, 16, and 18) given in three doses during a period of 6 months is highly effective for the prevention of CIN 1

TABLE 381-1 U.S. ADVISORY COMMITTEE ON IMMUNIZATION PRACTICES RECOMMENDATIONS FOR QUADRIVALENT (HPV 6, 11, 16, 18) and BIVALENT (HPV 16, 18) HPV VACCINES

- Routine vaccination with quadrivalent or bivalent vaccine recommended in females aged 11-12 years, starting as young as 9 years
- Catch-up vaccination recommended in females aged 13-26 years who have not previously received full vaccine series
- Quadrivalent HPV vaccine may be given to males aged 9 to 26 years to reduce their likelihood of genital warts
- Recommended dosage and schedule: 0.5 mL IM at 0, 2, and 6 months
- Schedule modifications: if doses are missed, series does not need to be restarted, but second and third doses should be given as soon as possible
- Cervical cancer screening: no change in recommended interval
- Special situations: females with genital warts, abnormal Pap test results, or positive HPV test results are unlikely to be infected with all four vaccine types and should be immunized per other recommendations
- Pregnant and lactating women: not recommended for use in pregnancy based on lack of data; may be used in lactating women
- Immunocompromised persons: no safety concerns because vaccine is noninfectious, but immune response and effectiveness might be reduced
- Not recommended for females or males <9 and >26 years

and CIN 2/3 as well as genital warts and VaIN and VIN, caused by any of the four types.[3] A bioalent vaccine (types 16 and 18) provides a high level of protection against CIN but not genital warts.[3] Both vaccines are recommended for the routine immunization of 11- to 12-year-old girls as well as females 13 to 26 years of age; girls 9 to 10 years of age may also be vaccinated at the discretion of the provider (Table 381-1). The vaccines have no therapeutic benefit against existing infection or lesions, and they are most effective if given before initiation of sexual activity. Because they provide protection against only two of the high-risk types associated with cancer, immunized women will continue to need Pap test screening. The quadrivalent vaccine is also recommended in males aged 9 to 26 years, in whom it reduces the likelihood of genital warts. Although men experience fewer HPV-related cancers than women do, the vaccine is likely to be particularly beneficial in preventing AIN in men who have sex with men on the basis of their high incidence of anal cancer. The quadrivalent vaccine is also effective in preventing HPV infection and disease in males.[4]

Secondary Prevention

Screening plus treatment of high-grade cervical squamous intraepithelial lesions is one of the most successful of all cancer prevention strategies. Current guidelines in the United States vary slightly among recommending organizations, but all agree that screening should begin within 3 years of initiation of sexual activity or by the age of 21 years and continue at 1- to 3-year intervals. Women older than 30 years who have had three negative Pap test results can be screened less frequently (e.g., every 2 to 3 years). Because of the higher sensitivity of the DNA Pap test, some groups recommend that women who are negative by both tests be screened no more frequently than every 3 years. Among women older than 30 years, HPV DNA testing appears to be more sensitive than cytology for detection of high-grade lesions and cancer,[3,4] thereby suggesting a potential shift in screening approaches. Assessment by colposcopy and biopsy is recommended for most abnormal results, although women with atypical squamous cells of undetermined significance can be managed safely without colposcopy if an HPV DNA test result is negative.

The value of cytologic screening for anal intraepithelial lesions in HIV-positive men who have sex with men is controversial but not currently recommended because of limited data on the natural history of these precursor lesions, the reliability of screening methods, and the safety and effectiveness of treatment.

TABLE 381-2 RECOMMENDED TREATMENT OF GENITAL WARTS

- Patient applied
  - Podophyllotoxin (podofilox) 0.5% solution or gel; to be applied in up to 4 weekly cycles (bid for 3 days, followed by 4 days without treatment)
  - Imiquimod 5% cream; to be applied once daily at bedtime 3 times per week for 6-10 hours for up to 16 weeks
  - Sinecatechins 15% ointment; to be applied 3 times daily for up to 16 weeks
- Provider administered
  - Cryotherapy with liquid nitrogen or cryoprobe; to be applied once every 1-2 weeks*
  - Podophyllin resin 10-25% in compound tincture of benzoin; to be applied once weekly
  - Trichloroacetic or bichloroacetic acid 80-90% solution; to be applied once weekly*
  - Office surgery* (excision, electrocautery, curettage)

*Safe for use in pregnancy.
Modified from Workowski KA, Berman SM; Centers for Disease Control and Prevention. Sexually transmitted disease treatment guidelines, 2010. *MMWR Morb Mortal Wkly Rep.* 2010;59(RR-12):70-74.

TREATMENT

Rx

Management of HPV infection is directed toward diagnosis and treatment of the lesions themselves because there are no virus-specific therapies. Many lesions resolve spontaneously, so the goal of treatment is amelioration or prevention of symptoms or, in the case of high-grade squamous intraepithelial lesions, prevention of progression to cancer. Treatment generally involves destruction of lesions by physical techniques or topically applied or injected cytotoxic agents. Because treatment does not eradicate infection in surrounding tissues, recurrent lesions are common.

Treatment of warts depends on their location and size, the patient's preferences, and the provider's experience. Recommended first-line treatment of common, flat, and plantar warts includes the application of topical salicylic acid and cryotherapy; second-line treatment of recalcitrant lesions includes topical imiquimod (5% cream applied once daily at bedtime three times a week for up to 16 weeks), intralesional bleomycin, pulsed dye laser therapy, and surgical excision.[7] Recommended treatment of genital warts (Table 381-2) includes patient-applied podophyllotoxin (0.5 or 0.15% solution or gel applied twice a day for 3 days, repeated weekly for four cycles), imiquimod, or sinecatechins and provider-administered cryotherapy, podophyllin, trichloroacetic acid, or surgical excision; alternative treatments include intralesional interferon and laser surgery.

For cervical lesions, treatment depends on histologic staging after colposcopy and biopsy and on the clinical context. Because CIN 1 usually regresses spontaneously, conservative management with close follow-up is recommended with either HPV DNA testing every 12 months or cervical cytology every 6 to 12 months. Treatment is generally recommended for all CIN 2/3 lesions, except in adolescents and pregnant women, who have higher rates of spontaneous regression and a greater risk of reproductive tract complications after treatment. Treatment options include a variety of ablative and excisional techniques such as cryosurgery, loop electrosurgical excision procedure, and laser surgery.

PROGNOSIS

Although the natural history of HPV infection is not fully characterized, the large majority of infections and premalignant lesions are self-limited in most immunocompetent patients. Whether infections no longer detectable have been cleared by the immune system or remain latent in the basal layer of the epithelium with the potential for reactivation is not clear, but the higher prevalence of detectable infection in advanced than in early HIV infection supports the possibility of long-term infection. Many if not most clinical lesions resolve spontaneously, presumably as a result of the development of cell-mediated immunity. Spontaneous regression is estimated to occur in 25% of genital warts and more than 50% of common warts in children.

The natural history of CIN has been most intensively studied because of its relationship to cervical cancer, although many questions remain unanswered. Estimates of the likelihood of regression versus the risk of progression to invasive cancer are 60% and 1% for CIN 1, 40% and 5% for CIN 2, and 32% and 12% for CIN 3. Traditionally, the various stages of precursor lesions have been viewed as a biologic continuum, with CIN 1 progressing through higher grades to invasive cancer. However, emerging data indicate that low-grade squamous intraepithelial lesions and high-grade squamous intraepithelial lesions may be distinct processes, in which low-grade lesions

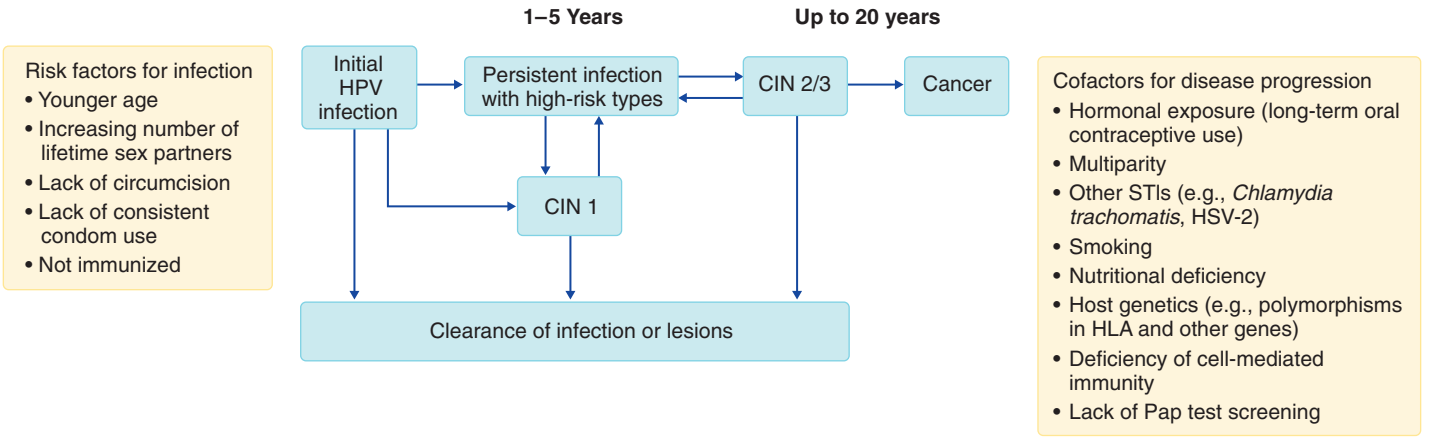

FIGURE 381-3. Natural history of genital human papillomavirus (HPV) infection and cervical cancer. CIN = cervical intraepithelial neoplasia; HSV = herpes simplex virus; STIs = sexually transmitted infections.

(CIN 1) represent a usually transient productive infection characterized by the production of capsid protein (and probably infectious virions) and only minor cellular abnormalities, whereas high-grade lesions (CIN 2/3) represent proliferation of immature cells as a result of the activity of oncogenic proteins of high-risk types. In this model (Fig. 381-3), initial infection frequently leads to a transient low-grade squamous intraepithelial lesion and less frequently to persistent infection. Persistent infection can, in turn, lead directly to high-grade squamous intraepithelial lesions within several years of initial infection and can progress to invasive cancer during a period of several decades. The natural history of squamous intraepithelial lesions at other anogenital sites is less well defined, but they may be associated with higher rates of regression.

Immunodeficient patients, such as those with HIV infection, have a lower rate of spontaneous regression of squamous intraepithelial lesions and may have a higher rate of progression to cancer. Whether antiretroviral therapy reduces the risk of progression of HPV-associated lesions in HIV-infected persons is unresolved, but current data indicate that it may reduce incidence of genital warts and progression of CIN but not the risk of high-grade AIN or VIN or of cervical or anal cancer.

382 HERPES SIMPLEX VIRUS INFECTIONS

RICHARD J. WHITLEY

DEFINITION

The Pathogen

Herpes simplex virus (HSV), a member of the family Herpesviridae, has been implicated in human infections since descriptions of cutaneous spreading lesions in ancient Greek times. Scholars of Greek civilization defined *herpes* to mean "to creep or crawl," in reference to the spreading nature of the observed skin lesions. More recently, infection has been defined by the spectrum of illnesses caused by HSV. In 1968, well-defined antigenic and biologic differences were demonstrated between HSV type 1 (HSV-1) and HSV type 2 (HSV-2). Of all the herpesviruses, HSV-1 and HSV-2 are most closely related, with approximately 60% genomic homology. Historically, HSV-1 was more frequently associated with nongenital infection and HSV-2 with genital disease, but these distinctions are much less relevant now. These two viruses can be distinguished most reliably by DNA restriction enzyme analysis, but differences in antigen expression and biologic properties also serve as methods for differentiation.

Inclusion in the family Herpesviridae is based on the structure of the virion (Fig. 382-1). HSV contains double-stranded DNA at its central core, has a molecular weight of approximately 100 million, and encodes at least 80 polypeptides. The DNA core is surrounded by a capsid that consists of 162 capsomers arranged in icosapentahedral symmetry. The capsid is 100 to 110 nm in diameter. Tightly adherent to the capsid is the tegument, which consists of amorphous material. Loosely surrounding the capsid and tegument is a lipid bilayer envelope derived from host cell membranes. The envelope consists of polyamines, lipids, and glycoproteins. These glycoproteins confer distinctive properties to the virus and provide unique antigens to which the host is capable of responding. Notably, glycoprotein G (gG) provides antigenic specificity to HSV and therefore results in an antibody response that allows distinction between HSV-1 (gG-1) and HSV-2 (gG-2).

EPIDEMIOLOGY

HSV infections occur worldwide and have been reported in both developed and underdeveloped countries. Animal vectors for human HSV infections have not been described, and there is no seasonal variation in the incidence of HSV infections. HSV is transmitted from infected to susceptible individuals during close personal contact, and the virus must come in contact with mucosal surfaces or abraded skin for infection to be initiated. Because approximately a third of the world's population has recurrent HSV infections and because infection is rarely fatal, a large reservoir of HSV exists in the community.

Seroprevalence studies have demonstrated that acquisition of HSV-1 infection is related to socioeconomic factors. Antibodies, which indicate past

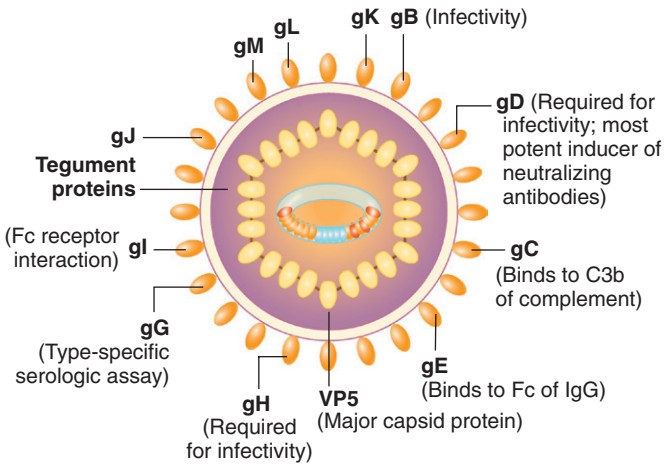

FIGURE 382-1. Schematic diagram of the herpes simplex virion.

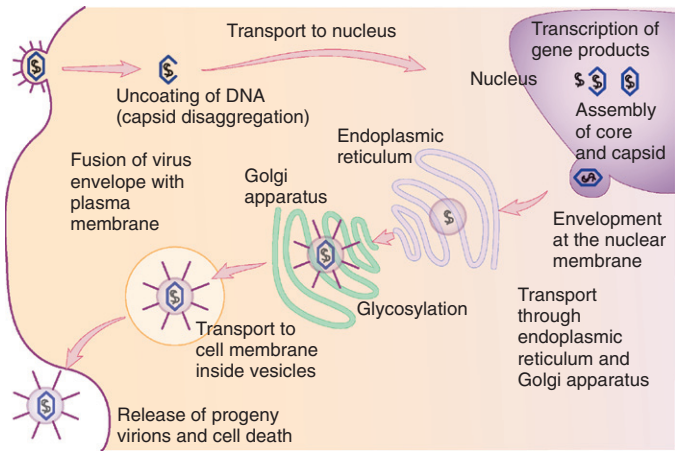

FIGURE 382-2. Schematic diagram of replication of herpes simplex virus.

infection, are found early in life among individuals of lower socioeconomic groups, presumably a consequence of crowded living conditions that provide a greater opportunity for direct contact with infected individuals. Antibodies develop in as many as 75 to 90% of individuals from lower socioeconomic populations by the end of the first decade of life. In contrast, only 30 to 40% of persons in the middle and upper socioeconomic groups are seropositive by the middle of the second decade of life.

Because infections with HSV-2 are usually acquired through sexual contact, antibodies to this virus are rarely found until the onset of sexual activity. There is a progressive increase in infection rates with HSV-2 in all populations beginning in adolescence. Overall, about one in five Americans has genital HSV-2 infection. As with HSV-1 infections, the rate of acquisition of HSV-2 infection appears to be related to socioeconomic factors. The number of sexual partners is also an important risk factor for the acquisition of HSV-2. Genital herpes infection has been found to be a risk factor for another sexually transmitted virus, human immunodeficiency virus (HIV; Chapter 394).

Localized, recurrent HSV-2 infection is the most common form of HSV infection during gestation. Transmission of infection to the fetus is most frequently related to shedding of the virus at the time of delivery. The incidence of cervical shedding in pregnant women with asymptomatic HSV infection is approximately 1%. Most infants in whom neonatal disease develops are born to women who are completely asymptomatic for genital HSV infection at the time of delivery and who have neither a past history of genital herpes nor a sexual partner reporting a genital vesicular rash. These women account for 60 to 80% of all women whose children acquire neonatal HSV infection.

PATHOBIOLOGY

Replication of HSV is a multistep process (Fig. 382-2). After the onset of infection, DNA is uncoated and transported to the nucleus of the host cell. This step is followed by transcription of immediate-early genes, which encode the regulatory proteins, and is followed by the expression of proteins encoded

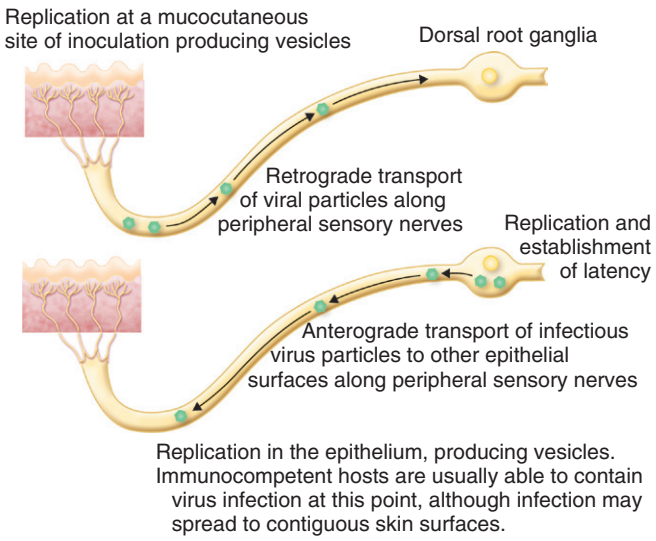

FIGURE 382-3. Schematic diagram of primary herpes simplex virus infection.

by early and then late genes. These proteins include enzymes necessary for viral replication and structural proteins.

Assembly of the viral core and capsid takes place within the nucleus. Envelopment at the nuclear membrane and transport out of the nucleus occur through the endoplasmic reticulum and the Golgi apparatus. Glycosylation of the viral membrane occurs in the Golgi apparatus. Mature virions are transported to the outer membrane of the host cell inside vesicles. Release of progeny virus is accompanied by cell death. Replication for all herpesviruses is considered inefficient, with a high ratio of noninfectious to infectious viral particles.

A critical factor for transmission of HSV, regardless of virus type, is intimate contact between a person who is shedding virus and a susceptible host. With inoculation onto skin or mucous membranes, HSV replicates in epithelial cells; the incubation period is 4 to 6 days (Fig. 382-3). As replication continues, cell lysis and local inflammation ensue and result in the characteristic vesicles on an erythematous base. Regional lymphatics and lymph nodes become involved as a result of draining of infected secretions from the area of viral replication. Viremia and visceral dissemination may develop, depending on the immunologic competence of the host. In all hosts, the virus generally ascends peripheral sensory nerves to reach the dorsal root ganglia. Replication of HSV within neural tissue is followed by spread of the virus to other mucosal and skin surfaces by means of peripheral sensory nerves. HSV replicates further in epithelial cells and reproduces the lesions of the initial infection until infection is contained through host immune responses.

The histopathologic changes induced by HSV replication are similar in both primary and recurrent infection. Changes induced by viral infection include ballooning of infected cells and the appearance of condensed chromatin within the nuclei of cells, followed by subsequent degeneration of cellular nuclei. Cells lose intact plasma membranes and form multinucleated giant cells. They may also demonstrate intranuclear inclusions known as Cowdry type A bodies, which are suggestive but not diagnostic of HSV infection. With cell lysis, clear vesicular fluid containing large quantities of virus accumulates between the epidermis and dermal layer. The dermis reveals an intense inflammatory response, more so with primary infection than with recurrent disease. As healing progresses, the clear vesicular fluid becomes pustular with the recruitment of inflammatory cells. The pustule then forms a scab; scarring is uncommon.

Vascular changes in the area of infection include perivascular cuffing and hemorrhagic necrosis. These changes are particularly prominent when organs other than skin are involved, as is the case with herpes simplex encephalitis or disseminated neonatal HSV infection. Local lymphatics can show evidence of infection with intrusion of inflammatory cells because of draining of infected secretions from the area of viral replication. As host defenses are mounted, an influx of mononuclear cells can be detected in infected tissue.

A unique characteristic of all herpesviruses is their ability to establish latent infection, to persist in an apparently inactive state for varying amounts of time, and then to be reactivated (Fig. 382-4). The latent viral genome may be either extrachromosomal or integrated into host cell DNA, depending on the virus.

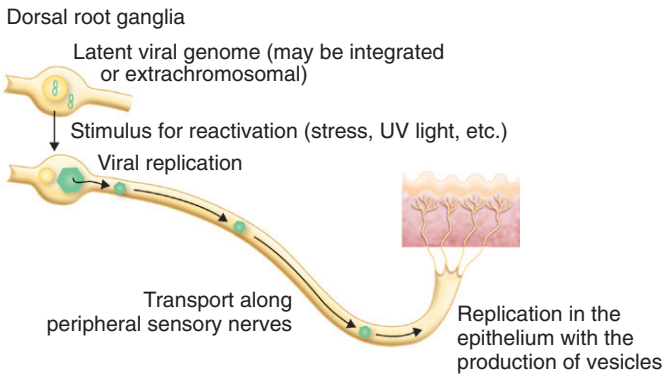

FIGURE 382-4. Schematic diagram of herpes simplex virus latency and reactivation. UV = ultraviolet.

FIGURE 382-5. Herpes labialis, classic grouped blisters.

Latency is established when HSV reaches the dorsal root ganglia after retrograde transmission through sensory nerve pathways. Latent virus may be reactivated and enter a replicative cycle at any point in time. Reactivation of latent virus is a well-recognized biologic phenomenon but not one that is understood from a molecular standpoint. Stimuli associated with the reactivation of latent HSV have included stress, menstruation, and exposure to ultraviolet light. Precisely how these factors interact at the level of the ganglia remains to be defined. Reactivation may be clinically asymptomatic, or it may produce life-threatening disease.

CLINICAL MANIFESTATIONS

Gingivostomatitis

Gingivostomatitis (usually caused by HSV-1) occurs most frequently in children younger than 5 years. Illness is characterized by fever, sore throat, pharyngeal edema, and erythema, followed by the development of vesicular or ulcerative lesions on the oral and pharyngeal mucosa. Recurrent HSV-1 infections of the oropharynx are most frequently manifested as herpes simplex labialis (cold sores) and usually appear on the vermilion border of the lip (Fig. 382-5). Recurrences are triggered by fever, stress, and exposure to ultraviolet light as well as by other factors. Intraoral lesions as a manifestation of recurrent disease are uncommon.

Genital Herpes

Genital herpes is most frequently caused by HSV-2. However, an increasing percentage is being caused by HSV-1. Indeed, among all new primary cases in young adults, approximately 50% are caused by HSV-1. Primary infection in women usually involves the vulva, vagina, and cervix. In men, initial infection is most often associated with lesions on the glans penis, prepuce, or penile shaft. In individuals of either gender, primary disease is associated with fever, malaise, anorexia, and bilateral inguinal adenopathy. Women frequently have dysuria and urinary retention as a result of urethral involvement. Aseptic meningitis develops in as many as 10% of individuals with primary infection. Sacral radiculomyelitis may occur in both men and women and results in neuralgias, urinary retention, or obstipation. Complete healing of primary infection may take several weeks. The first episode of genital infection is less severe in individuals who have previously had HSV-1 infections at other sites. Antibodies to HSV-1 appear to ameliorate the expression of HSV-2 clinical disease, although this effect is controversial.

Recurrent genital infections in either men or women can be particularly distressing. The frequency of recurrence varies significantly from one individual to another. Of note, viral DNA can be detected by polymerase chain reaction (PCR) in genital secretions three- to four-fold more frequently than symptomatic recurrences. Furthermore, recurrences detected by PCR can occur frequently during 24 hours and persist for brief periods. A third of infected individuals have virtually no or few clinical recurrences, a third have approximately three recurrences per year, and another third have more than three per year. Several seroepidemiologic studies have found that between 25 and 65% of individuals in the United States have antibodies to HSV-2 and that seroprevalence is correlated with the number of sexual partners.

Herpetic Keratitis

Herpes simplex keratitis is usually caused by HSV-1 and is accompanied by conjunctivitis in many cases. It is considered the most common infectious cause of blindness in the United States. The characteristic lesions of HSV keratoconjunctivitis are dendritic ulcers best detected by fluorescein staining. Deep stromal involvement has also been reported and may result in visual impairment.

Other Cutaneous Manifestations

HSV infections can occur at any skin site. Common among health care workers are lesions on abraded skin or the fingers, known as herpetic whitlow. Similarly, in wrestlers, disseminated cutaneous lesions known as herpes gladiatorum may develop as a result of physical contact.

HERPES SIMPLEX VIRUS INFECTIONS IN IMMUNOCOMPROMISED HOSTS

HSV infections in immunocompromised hosts, including patients with acquired immunodeficiency syndrome, are usually due to reactivation of latent infection and are clinically more severe, may be progressive, and require a longer time to heal. Manifestations of HSV infections in this population of patients include pneumonitis, esophagitis, hepatitis, colitis, and disseminated cutaneous disease. Individuals suffering from HIV infection may have extensive perineal or orofacial ulcerations. HSV infections are also noted to be of increased severity in individuals with extensive burns.

DIAGNOSIS

Definitive diagnosis of HSV infection requires isolation of virus. Swabs of clinical specimens or other body fluids can be inoculated into susceptible cell lines and observed for the development of characteristic cytopathic effects. This technique is useful for the diagnosis of HSV-1 and HSV-2 infection because of their short replicative cycles.

In the absence of diagnostic virology facilities, cytologic examination of cells scraped from a clinical lesion may be useful in making a presumptive diagnosis of HSV infection. Material obtained from scraping the base of a lesion should be smeared on a glass slide and promptly fixed in cold ethanol. The slide can be stained according to the methods of Papanicolaou, Giemsa, or Wright. The presence of intranuclear inclusions and multinucleated giant cells is indicative but not diagnostic of HSV infection. This method has a sensitivity of only 60 to 70% and should not be the sole diagnostic method used.

DNA amplification by PCR has gained greater acceptance for routine diagnostic purposes. DNA amplification has become the diagnostic method of choice in assessing cerebrospinal fluid (CSF) specimens for evidence of HSV infection of the central nervous system. Furthermore, PCR has significantly improved sensitivity for confirmation of HSV as the cause of lip and genital herpes infection.

In addition to new tests for viral DNA, type-specific serologic assays are commercially available. These tests are based on differences in HSV-1 and HSV-2 gG.

TREATMENT

Rx

For *immunocompromised* patients, such as patients with cancer or receiving immunosuppressive drugs, with mucocutaneous infections or for patients with herpes encephalitis, intravenous acyclovir (5 mg/kg every 8 hours for 5 to 7 days) is the treatment of choice. Caution must be exercised when acyclovir is used intravenously because it may crystallize in the renal tubules when it is given too rapidly or to dehydrated patients. Valacyclovir (500 to 1000 mg two or three times daily) and famciclovir (250 to 500 mg three times daily), depending on severity, are equally efficacious and have improved pharmacokinetics as demonstrated by improved biodistribution and less frequent dosing compared with oral acyclovir. Thus, they should preferentially be used for the treatment of non–life-threatening HSV infection. For life-threatening disease, only intravenous medications should be given. Immunocompromised

individuals with non–life-threatening mucocutaneous HSV infections may be given oral acyclovir (400 mg two or three times daily for 7 to 10 days), valacyclovir (500 to 1000 mg once or twice daily for 3 to 5 days), or famciclovir (250 to 500 mg three times daily for 7 days or 1000 mg twice daily for 1 day).

In *immunocompetent* hosts with mucocutaneous infections, oral acyclovir (200 mg five times daily for 5 days) reduces lesions and speeds recovery. Oral valacyclovir (1 g/day for 5 days or 500 mg twice daily for 3 days) and oral famciclovir (1 g twice daily for 1 day) are equally effective.[3-5] In general, recurrent episodes are not as responsive to treatment as first episodes are. Topical acyclovir is not as reliable as oral acyclovir and is not recommended.

HSV has been used for experimental gene therapy. By removal of the $\gamma_1 34.5$ gene, both neurovirulence and the propensity to establish latency are ablated. These engineered viruses are being experimentally tested in patients with glioblastoma multiforme and colorectal metastases to liver.

PREVENTION

Some patients with particularly disabling oral recurrences, genital recurrences, or aseptic meningitis triggered by genital recurrences are candidates for chronic suppressive therapy. Potential regimens include oral acyclovir 400 mg twice daily, oral valacyclovir 1 g/day, and oral famciclovir 250 mg twice daily. Such regimens are approved by the Food and Drug Administration for genital herpes but not for herpes labialis.

At present, experimental vaccines for HSV-1 and HSV-2 remain under investigation. Acyclovir, valacyclovir, and famciclovir are given to recipients of solid organ and bone marrow transplants in the immediate post-transplantation period in an effort to prevent reactivation of latent disease at the doses noted before. Valacyclovir (500 mg daily) decreases person-to-person transmission of HSV-2.

HERPES SIMPLEX ENCEPHALITIS

Herpes simplex encephalitis is characterized by hemorrhagic necrosis of the temporal lobe (Chapter 422). Disease begins unilaterally and spreads to the contralateral temporal lobe (Fig. 382-6). It is the most common cause of focal, sporadic encephalitis in the United States today and occurs in approximately 1 in 150,000 individuals. Most cases are caused by HSV-1. The actual pathogenesis of herpes simplex encephalitis requires further clarification, although it has been speculated that primary or recurrent virus can reach the temporal lobe by ascending neural pathways, such as the trigeminal tracts or the olfactory nerves.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical manifestations of herpes simplex encephalitis include headache, fever, altered consciousness, and abnormalities in speech and behavior, findings characteristic of temporal lobe involvement. Focal seizures also may occur. CSF findings in these patients are variable but usually consist of a pleocytosis with both polymorphonuclear leukocytes and monocytes present. The protein concentration is characteristically elevated, and the glucose level is usually normal. Magnetic resonance imaging can suggest the diagnosis by demonstrating edema of either temporal lobe. Diagnosis can be confirmed by PCR detection of HSV DNA in the CSF by experienced laboratories.

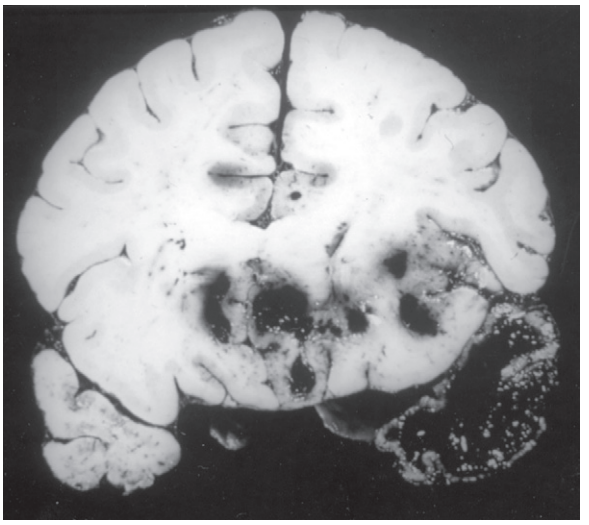

FIGURE 382-6. Hemorrhagic necrosis in herpes simplex encephalitis.

TREATMENT AND PROGNOSIS

Rx

Mortality and morbidity are high, even with appropriate acyclovir antiviral therapy. At present, the mortality rate is approximately 30% 1 year after treatment. In addition, approximately 50% of survivors have moderate or severe neurologic impairment.

NEONATAL HERPES SIMPLEX VIRUS INFECTION

Neonatal HSV infection is estimated to occur in approximately 1 in 3500 deliveries in the United States each year. Approximately 70% of cases are caused by HSV-2 and usually result from contact of the fetus with infected maternal genital secretions at the time of delivery. Manifestations of neonatal HSV infection can be divided into three categories: skin, eye, and mouth disease; encephalitis; and disseminated infection. As the name implies, skin, eye, and mouth disease consists of cutaneous lesions and does not involve other organ systems. Involvement of the central nervous system may occur with encephalitis or disseminated infection and generally results in diffuse encephalitis. CSF assay characteristically reveals elevated protein levels and mononuclear pleocytosis. Disseminated infection involves multiple organ systems and can cause disseminated intravascular coagulation, hemorrhagic pneumonitis, encephalitis, and cutaneous lesions. Diagnosis is difficult in the absence of skin lesions, which occurs in as many as 36% of cases. The mortality rate for each disease classification varies from zero for skin, eye, and mouth disease to 5% for encephalitis and 25% for neonates with disseminated infection, even with appropriate antiviral treatment. In addition to the high mortality associated with these infections, morbidity is significant in that children with encephalitis or disseminated disease develop normally in only 40% of cases, even with appropriate antiviral therapy (acyclovir, 10 mg/kg every 8 hours for 14 days for skin, eye, and mouth infections and 21 days for central nervous system or disseminated disease).

VARICELLA-ZOSTER VIRUS (CHICKENPOX, SHINGLES)

JEFFREY COHEN

DEFINITION

Primary infection with varicella-zoster virus (VZV) results in the rash of varicella (chickenpox). The virus establishes a latent infection in the nervous system and can reactivate later in life to cause zoster (shingles).

The Pathogen

VZV is a member of the alphaherpesvirus family and has a DNA core surrounded by a nucleocapsid, which is in turn surrounded by a viral envelope that is studded with glycoproteins. Antibody to viral glycoproteins is important for neutralizing the virus's infectivity and for protecting against primary infection. The virus encodes a thymidine kinase, which phosphorylates acyclovir, which in turn inhibits viral DNA replication by inhibiting the VZV DNA polymerase.

EPIDEMIOLOGY

Before the advent of an effective vaccine, more than 95% of children in temperate climates were infected with VZV. By comparison, infection is usually delayed until adulthood in tropical climates. Varicella usually occurs in children younger than 5 years. Zoster is less common in tropical areas, probably because of a delay in acquisition of varicella. Varicella is more common in the winter and spring, whereas zoster has no seasonal predilection.

Primary varicella infection can occur after exposure to either chickenpox or zoster. The virus is spread by droplets and aerosols from patients or by contact with vesicular lesions. Persons are infectious beginning about 2 days before the rash appears and continuing until all lesions have crusted. Although 60 to 90% of susceptible household contacts develop varicella, only 20 to 30% of susceptible persons exposed to zoster become infected. More than 95% of primary infections result in the symptoms of varicella, and second episodes of varicella are rare. Varicella is more severe in persons with impaired cellular immunity, including patients with acquired immunodeficiency syndrome (AIDS) and infants whose mothers present with varicella 5 days before to 2 days after delivery.

About 30% of persons who have had varicella will develop zoster. The risk of zoster rises with increasing age (especially 50 years of age and older) and with increasing impairment of cellular immunity. For example, men with AIDS have a 20-fold higher risk for development of zoster than that of age-matched controls. Less than 5% of persons have a second episode of zoster, but recurrent zoster is more common in persons with impaired cellular immunity.

PATHOBIOLOGY

Varicella is transmitted by the respiratory route. The virus is thought to infect epithelial cells and lymphocytes in the oropharynx and upper respiratory tract or in the conjunctiva, and then infected lymphocytes subsequently spread the virus throughout the body. The virus then enters the skin through endothelial cells in blood vessels and spreads to epithelial cells, where it causes the vesicular rash of varicella. Lesions initially are vesicular but become pustular after the infiltration of inflammatory cells. Later the lesions break open and dry to form crusts that usually heal without scarring. During primary infection, neurons in cranial nerve ganglia and dorsal root ganglia become latently infected with the virus.

If VZV-specific cellular immunity declines, the virus can reactivate from a ganglion, travel down the axon, and replicate in epithelial cells to cause dermatomal zoster. In highly immunocompromised persons, high-grade viremia during reactivation causes disseminated zoster.

Antibodies, which usually are present at the time varicella presents clinically, persist for life. Antibody is important for protection against varicella, as evidenced by the ability of varicella immune globulin to attenuate the disease. Cytotoxic T cells are present within 2 to 3 days after the onset of varicella and limit its severity. Varicella is more severe in persons with impaired cellular immunity but not in patients with hypogammaglobulinemia. Cellular immunity, not antibody, is required to prevent reactivation of virus and zoster.

CLINICAL MANIFESTATIONS

Varicella

Varicella begins with fever and malaise followed 1 to 2 days later by a disseminated, pruritic, vesicular rash (Fig. 383-1). The usual incubation period for varicella is 2 weeks (range, 10 to 21 days) after exposure to an infected person. The lesions begin as papules that become vesicles, followed by pustules and then crusts. Lesions appear on the head and then spread to the trunk and then to the extremities; the mucosa can also be involved. There are typically 200 to 500 lesions in different stages on the skin. New lesions occur for up to 5 days in normal hosts, and crusting is complete within 2 weeks.

The most common complication of varicella is bacterial superinfection of skin lesions. Group A streptococcus (Chapter 298) or *Staphylococcus aureus* (Chapter 296) infections can cause cellulitis, bacteremia, and necrotizing fasciitis. Other complications include cerebellar ataxia, viral pneumonitis, hepatitis, and thrombocytopenia. Less frequent complications include viral meningitis, encephalitis, vasculopathy (which presents as a stroke), disseminated intravascular coagulopathy (Chapter 178), and Reye's syndrome (more common in children receiving aspirin). Complications involving the lungs and liver are more common in children with impaired cellular immunity including those receiving systemic steroids, children with chronic pulmonary or skin disease, adults, and pregnant women during the third trimester. The fetal varicella syndrome, which occurs in fetuses infected during the first trimester, is characterized by atrophy of limbs with scarring of skin, chorioretinitis or cataracts, and central nervous system abnormalities. Patients with AIDS and moderately reduced CD4 cell counts may develop recurrent varicella lesions in the absence of new exposures, and patients with CD4 cell counts below 200/mm^3 may develop progressive varicella with new lesions occurring for at least 1 month or chronic verrucous lesions.

FIGURE 383-1. Child with varicella. (Courtesy of Centers for Disease Control and Prevention.)

FIGURE 383-2. Dermatomal zoster. (Courtesy of Centers for Disease Control and Prevention.)

Zoster

In healthy persons, zoster presents with localized pain and increased sensation for 1 to 3 days before the development of a dermatomal vesicular rash that does not cross the midline (Fig. 383-2). Zoster most frequently presents in the dermatomes innervated by trigeminal or thoracic ganglia. The rash is usually accompanied by itching, tingling, or pain. The lesions evolve from vesicles to pustules, and crusting is usually complete by 10 days. In normal hosts, a few lesions may develop outside of the dermatome owing to low-grade viremia. Some patients with zoster sine herpete never develop a rash. In persons with very impaired cellular immunity, reactivation is often associated with high-grade viremia with dissemination to large areas of the skin and involvement of multiple organs.

A dreaded complication of zoster is postherpetic neuralgia (Chapter 29) with pain persisting for at least 1 month after the rash has resolved. Patients may have allodynia (sensation of pain after nonpainful stimuli), paresthesias, dysesthesias, or severe neuropathic pain. Postherpetic neuralgia is more common in persons older than 50 years. Other complications of zoster include bacterial superinfection; ocular disease, involving any of the structures of the eye, due to reactivation in the ophthalmic branch of the trigeminal ganglia; facial palsy caused by reactivation in the VII cranial nerve; Ramsay Hunt syndrome, with pain and vesicles in the ear, numbness of the anterior tongue, and ipsilateral facial palsy due to reactivation in the geniculate ganglion of the VII cranial nerve; motor neuropathy; and meningitis. Zoster vasculopathy, occurring at the time of zoster or a few months later, can present with stroke due to inflammation of the cerebral arteries.

Progressive outer retinal necrosis, with few inflammatory ocular cells, occurs when VZV reactivates in the eye of severely immunocompromised persons, including patients with AIDS and low CD4 cell counts. In contrast, acute retinal necrosis with a marked inflammatory response occurs when the virus reactivates in otherwise healthy persons. Patients with AIDS or recipients of hematopoietic stem cell transplants can have pancreatitis, hepatitis, and pneumonitis in the absence of or preceding a rash.

DIAGNOSIS

Most cases of varicella and zoster are diagnosed on the basis of their clinical presentation. A disseminated vesicular rash with lesions in various stages of evolution is usually sufficient for a diagnosis of varicella. The differential diagnosis includes impetigo (Chapter 449), enterovirus infections (Chapter 387), herpes simplex (Chapter 382), Stevens-Johnson syndrome (Chapter 448), and guttate psoriasis (Chapter 446). A dermatomal vesicular rash that does not cross the midline in a patient with a prior history of pain in the area is usually diagnostic of zoster. Herpes simplex is the most common disease that resembles zoster.

When the diagnosis of varicella or zoster must be confirmed definitively, polymerase chain reaction (PCR) for VZV from vesicular fluid is the most sensitive and specific test. PCR for VZV in the blood can be useful for diagnosis of visceral zoster in highly immunocompromised persons before the onset of rash. PCR for VZV in the cerebrospinal fluid and intrathecal synthesis of VZV-specific antibody is useful for diagnosis of VZV neurologic diseases. Culture is less sensitive than PCR because the virus is very labile. Direct fluorescent antibody testing of vesicle fluid is rapid and sensitive. Detection of multinucleated giant cells (Tzanck smear) is less specific because lesions of herpes simplex virus have a similar appearance. Biopsy specimens show eosinophilic intranuclear inclusion bodies and multinucleate giant cells.

Serology for VZV is useful to determine the need for postexposure prophylaxis in persons who are at high risk for disease after exposure to varicella or zoster. Enzyme-linked immunosorbent assay tests are less sensitive than latex agglutination assays and may not detect antibodies in vaccinees.

TREATMENT

Rx

Varicella

Symptomatic treatment includes acetaminophen for fever and lotion or baths for pruritus. Although acyclovir is licensed for the treatment of varicella, the drug is not recommended for otherwise healthy children because it only modestly decreases symptoms by about 1 day.[1] Acyclovir reduces visceral dissemination in immunocompromised persons, in whom intravenous acyclovir (500 mg/m^2 every 8 hours for children, 10 mg/kg every 8 hours for adults) is recommended for 7 to 10 days or until all lesions have crusted. Oral acyclovir (20 mg/kg four times daily for children or 800 mg five times daily for adults) given within 24 hours after the onset of rash reduces the duration of symptoms and is recommended for treatment of adolescents, adults, newborns whose mothers developed varicella near the time of delivery, immunocompromised persons, children with chronic pulmonary or skin disease, and persons with complications of varicella. Acyclovir also should be considered for household contacts of persons with varicella or for pregnant women in the third trimester; these patients often have more severe disease. Although acyclovir is the only drug approved for treatment of varicella, more expensive medications (e.g., oral valacyclovir, 1 g three times daily, or famciclovir, 500 mg three times daily) result in higher antiviral drug levels than does oral acyclovir and can be used in nonpregnant adolescents and adults.

Zoster

Acyclovir, valacyclovir, and famciclovir (for 7 days at the same doses as for varicella) are licensed for the treatment of zoster. Oral valacyclovir and famciclovir result in higher levels of antiviral activity than oral acyclovir does. Although therapy should be started within 3 days of the rash, therapy may still be of benefit if new lesions continue to occur after this time. Because patients younger than 50 years usually have little pain associated with zoster, antiviral therapy is not used in these patients unless they have moderate to severe pain or disease involving the eye. Antiviral drugs (see earlier) reduce the duration of lesions and zoster-associated pain but not the incidence of postherpetic neuralgia.[2] In severely immunocompromised persons, intravenous acyclovir (7 to 10 days or until all lesions have crusted) reduces the risk of visceral dissemination. Oral valacyclovir or famciclovir may be used in persons who are less severely immunocompromised.

Corticosteroids (e.g., prednisone, 60 mg/day and tapered over 21 days) in combination with acyclovir reduce acute pain and improve the quality of life in persons older than 50 years but do not reduce the risk of postherpetic neuralgia.[3] Patients with moderate to severe pain often require narcotics.

Treatment of postherpetic neuralgia is challenging. In addition to long-acting narcotics (Chapter 29) for persons with severe pain, gabapentin (initiated at a dose of 300 mg at bedtime and titrated to a maximum dose of 1200 mg three times daily) or pregabalin (initiated at a dose of 75 mg at bedtime and titrated to a maximum dose of 300 mg twice daily) may reduce pain.

Treatment of VZV Complications and Acyclovir-Resistant VZV

Intravenous acyclovir is recommended for persons with acute retinal necrosis. Corticosteroids (e.g., prednisone, 1 mg/kg/day for 3 to 5 days) and intravenous acyclovir (10 to 15 mg/kg every 8 hours for 14 days) are recommended for nonimmunocompromised persons with VZV vasculopathy. Zoster involving the eye should be evaluated by an ophthalmologist to assess the potential value of topical or intraocular therapy, such as the need to reduce intraocular pressure to treat possible glaucoma or to use mydriatics to prevent synechiae.

Acyclovir-resistant VZV infections are rare and are limited almost exclusively to patients with AIDS or recipients of transplants. Foscarnet (40 mg/kg every 8 hours) for 2 weeks or until all lesions have crusted is the treatment of choice for acyclovir-resistant VZV.

PREVENTION

Varicella

Patients with varicella or zoster are considered infectious until all lesions have completely crusted. Airborne and contact precautions are recommended for varicella, whereas only contact precautions are necessary for immunocompetent persons with localized zoster.

The live attenuated varicella vaccine is recommended for children aged 1 to 12 years and for persons 13 years of age and older without immunity to the virus. The vaccine is 75 to 90% effective in protection against symptomatic varicella and more than 95% effective in protecting against severe disease.[4] Two doses of vaccine are given subcutaneously. The varicella vaccine is also given as part of a combined measles, mumps, rubella vaccine (MMRV) for children 1 to 12 years of age in the United States. The rate of disease due to varicella declined by 85% in the United States during the first 10 years after the vaccine was licensed.

The most common complications of varicella vaccination are pain at the injection site, fever, and a mild rash within 2 weeks after vaccination. The rash is usually localized to areas of vaccination and is often papular; in some healthy persons, the rash can be disseminated, although there are fewer lesions and symptoms are much less severe than with wild-type virus. In persons with severely impaired cellular immunity, rash is more common, can be extensive, and may be accompanied by organ dysfunction. The varicella vaccine establishes latency and can cause shingles, although this complication occurs less commonly with vaccine virus than with wild-type virus. The vaccine strain of varicella has been transmitted to third parties only by vaccinees who developed a rash. Varicella vaccine is contraindicated in pregnant women and persons receiving high-dose immunosuppressive therapy (e.g., ≥2 mg/kg of prednisone daily) or with hematologic malignant neoplasms. Vaccination should be considered for human immunodeficiency virus (HIV)–infected children with age-specific CD4$^+$ T cells of 15% or more and adolescents and adults with CD4$^+$ T cell counts of 200 cells/mm^3 or higher. Serologic testing to verify immunity is not recommended for health care workers who have received two doses of vaccine because the currently available commercial antibody assays are not sensitive enough to detect protective levels of antibody.

Zoster

Zoster vaccine is recommended for persons 60 years of age or older. This vaccine is similar to the varicella vaccine, except that the titer of virus is ~14-fold higher. The vaccine is about 50% protective in preventing zoster and 66% effective in preventing postherpetic neuralgia.■ Although the vaccine's efficacy to prevent zoster declines in persons older than 70 years, efficacy to prevent postherpetic neuralgia does not decline. Transient pain and erythema at the injection site are not uncommon, but serious complications attributable to the vaccine have not been reported. The vaccine is contraindicated in persons with hematologic malignant neoplasms, AIDS, or HIV infection with CD4 count of 200/mm^3 or lower and in persons receiving high-dose immunosuppressive therapy (e.g., ≥20 mg of prednisone daily) or anti–tumor necrosis factor-α therapy.

Postexposure Prophylaxis

In persons exposed to varicella, three options are available. Varicella vaccine is preferred if exposure occurred within the prior 3 days and the patient is not immunocompromised.■ Vaccine is estimated to be 70 to 90% effective in healthy persons. VariZIG (formerly available as varicella immune globulin) prevents or attenuates varicella in 90% of susceptible persons if it is given within 4 days of exposure. VariZIG (given intramuscularly at 125 units/10 kg body weight, up to a maximum of 625 units) is indicated for susceptible persons at risk of severe varicella (e.g., pregnant women, preterm infants, neonates whose mothers have varicella between 5 days before and 2 days after delivery, immunocompromised persons) and for persons in close contact with patients with varicella or zoster. VariZIG has no effect in the treatment of zoster.

Oral acyclovir (40 to 80 mg/kg for 1 week beginning 7 to 9 days after exposure) is estimated to be 80 to 85% effective as postexposure prophylaxis. It is often used when the exposure occurred too long ago for vaccination or VariZIG.

PROGNOSIS

Before vaccination, about 100 children died of varicella each year in the United States. Now, only eight varicella-related deaths were reported during an 18-month period from 2003 to 2004.

Additional agents including nortriptyline (initiated at a dose of 25 mg at bedtime and titrated to a maximum dose of 150 mg daily), carbamazepine, lidocaine patches, topical capsaicin (which itself causes pain that is not tolerated in up to one third of patients), regional nerve blocks, acupuncture, and transcutaneous nerve stimulation have been effective in some patients.

CYTOMEGALOVIRUS

W. LAWRENCE DREW

DEFINITION

Cytomegalovirus (CMV) is a member of the herpesvirus family and shares, with the other members, the ability to establish a long-lived latent infection. Most of the clinical disease caused by this virus results from reactivation of latent virus in immune-impaired patients, although primary infection in such patients and in antibody-negative fetuses can also be devastating.

The Pathogen

CMV has a linear, double-stranded DNA genome with about 250,000 base pairs that encode about 160 proteins. On microscopic examination, the hallmark of CMV infection is a large (cytomegalic), 25- to 35-μm cell containing a large central, basophilic intranuclear inclusion (Fig. 384-1), referred to as an owl's eye.

EPIDEMIOLOGY

Multiple mechanisms account for the spread of this virus, including vertical (in utero, during vaginal delivery, and by breast milk) and horizontal (saliva, genital, urine) contact. These routes of transmission lead, collectively, to a 15 to 20% seroprevalence by 15 years of age in developed countries, with a higher seroprevalence in lower socioeconomic settings. From that age on, there is a steady upward trend of 1 to 2% per year that is due in part to sexual transmission. As a result, approximately 50% of the general population of the United States is antibody positive by 35 years of age, and a 1% per year rate of increase occurs thereafter. In underdeveloped countries, up to 90% of persons may be seropositive by 2 years of age. Presumably, crowded living conditions permit spread of the virus through close contact with body fluids. Two additional mechanisms of transmission are blood transfusion and organ transplantation. A final important epidemiologic fact is that reinfection with a different strain of CMV may occur in a CMV-seropositive person, especially those who are immunocompromised, pregnant, or sexually promiscuous.

PATHOBIOLOGY

In fully immunocompetent individuals, CMV rarely causes clinically evident end-organ disease. When immune mechanisms are deficient, especially those mediated by $CD4^+$ and $CD8^+$ lymphocytes, latent virus replicates and causes both direct and indirect effects. Examples of direct virally mediated diseases are necrotizing CMV retinitis and esophagitis. In contrast, CMV pneumonitis is frequently manifested as subtle histologic alterations accompanied by limited viral replication, thus suggesting that immune-mediated injury may be the primary pathologic mechanism. Such injury may result from the upregulation and release of cytokines, including tumor necrosis factor-α, interferon-γ, and interleukin-2. Immune-mediated tissue injury may also be

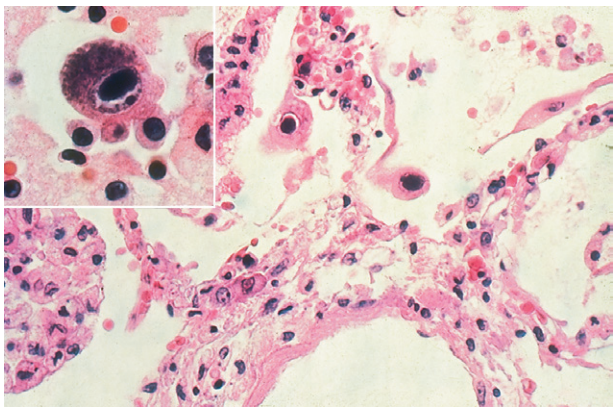

FIGURE 384-1. Cytomegalovirus (CMV) pneumonia. A lung biopsy specimen was stained with hematoxylin and eosin and magnified 250-fold. The inset shows a CMV "owl's eye" inclusion.

effected by $CD8^+$ cytotoxic T lymphocytes directed against CMV-infected target cells. The clinical manifestations of CMV infection, including meningoencephalitis, retinitis, enteritis, vasculitis, pneumonitis, myocarditis, lymphadenitis, hepatitis, adrenalitis, and pancreatitis, reflect the range of cell types that CMV is capable of infecting.

The immune response to CMV infection involves both the humoral and cell-mediated arms, but the $CD8^+$ cytotoxic T-cell response appears to be the most important. The CMV envelope glycoproteins that participate in viral entry are gB, gH/gL, and gCII. Humoral immunity directed at gB has been detected in convalescent phase sera and has been shown to block viral entry, cell to cell transmission, and syncytium formation in CMV-infected cells.

Fundamental to the pathogenesis of CMV is latency, or persistence of the viral genome in host cells without evidence of productive viral replication. It is thought that monocytes and bone marrow progenitor cells are sites of human CMV latency. Reactivation from the latent state has classically been associated with immunosuppression. Exposure to a rich milieu of cytokines and growth factors results in the activation of signal transduction pathways, generation of increased levels of intracellular transcription factors, and production of viable virus.

CLINICAL MANIFESTATIONS

Congenital and Neonatal Infection

In the United States each year, approximately 40,000 infants are born excreting CMV, and about 4000 of these newborns show clinical evidence of congenital disease, such as microcephaly, intracerebral calcification, hepatosplenomegaly, and rash. Ninety percent of these clinically infected newborns will survive, but most will have unilateral or bilateral hearing loss or mental retardation (or both). Mothers of most infants with these stigmata had a primary infection during pregnancy.

Infection in Immunocompetent Persons

Virtually all CMV infections occurring in immunocompetent persons are asymptomatic. In some patients, a clinical illness resembling infectious mononucleosis may develop (Chapter 385), but with minimal pharyngitis and lymphadenopathy. Atypical lymphocytosis develops in these patients, similar to Epstein-Barr virus infection, but they have a negative heterophil antibody test result. CMV reactivation is common (33%) in critically ill immunocompetent patients, in whom it is associated with prolonged hospitalization and mortality, but whether it causes these effects is unclear.

Infection in Transplant Recipients

When a CMV-seronegative recipient receives a solid organ from a CMV-seropositive donor, the resulting illnesses include the "CMV syndrome," characterized by fever, neutropenia, atypical lymphocytes, and often hepatosplenomegaly. CMV disease may also develop in the transplanted organ. For example, CMV hepatitis in liver transplant recipients is associated with fever, hyperbilirubinemia, and elevated liver enzymes; liver failure may ensue and necessitate retransplantation.

CMV pneumonia may occur after solid organ transplantation but is most common after stem cell transplantation. Fever, nonproductive cough, and dyspnea can progress rapidly. The diagnosis is suggested by interstitial to nodular infiltrates rather than by alveolar densities on chest radiographs. In contrast to solid organ transplantation, CMV disease after stem cell transplantation usually results from reactivation of latent CMV in a seropositive recipient rather than from a new, primary infection.

CMV may cause disease throughout the gastrointestinal tract. Colitis, which is a common syndrome in transplant recipients, is manifested as diarrhea, weight loss, and fever. It is characterized by diffuse submucosal hemorrhages and ulcerations.

Infection in Patients with Acquired Immunodeficiency Syndrome

In the era before highly active antiretroviral therapy, CMV retinitis occurred in approximately a third of patients with acquired immunodeficiency syndrome (AIDS), most often in those with CD4 counts below $50/mm^3$. It usually begins unilaterally with visual blurring, floaters, decreased acuity, and loss of visual fields and progresses to blindness if it is untreated. Retinal examination reveals apparent hemorrhages and exudates (Fig. 384-2). CMV colitis is similar to that seen in transplant recipients, but esophagitis is also common and characterized by distal ulceration, which may be single but extensive. CMV neurologic disease occurs in multiple forms, including encephalitis and a polyradiculopathy/myelitis syndrome.

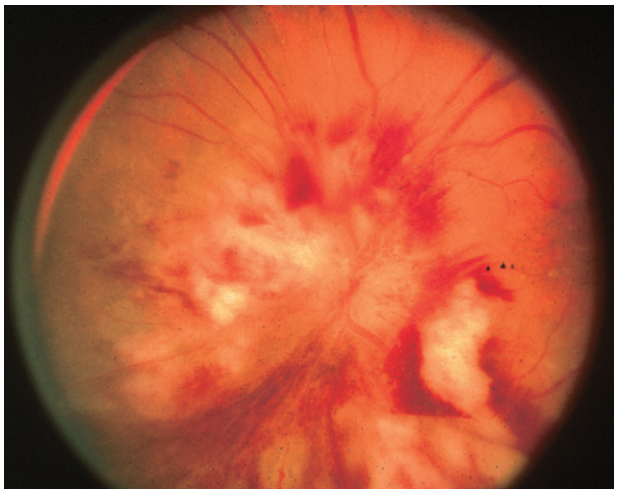

FIGURE 384-2. Cytomegalovirus retinitis as seen by direct ophthalmoscopic examination.

DIAGNOSIS

Culture

Historically, culture has been regarded as the "gold standard" for detection of CMV infection, but false-negative culture results do occur. Furthermore, CMV may require at least 4 to 6 weeks for detection. More rapid culture results may be achieved by centrifuging specimens in a shell vial seeded with diploid fibroblast cells and examining them after 1 to 2 days of incubation by immunofluorescence. Interpretation of cultures positive for CMV may be difficult, particularly in immunosuppressed patients. For example, CMV may be present in saliva or urine in up to 60 to 90% of transplant recipients or patients with AIDS. Recovery from these sites, however, does not prove that CMV is the cause of a patient's pneumonia or fever. Cytologic and histologic abnormalities are not sensitive measures of CMV infection, but they are specific and more indicative of CMV disease than is culture of virus from the tissue.

CMV Antigen or Nucleic Acid Detection

Identification of CMV in blood has greater diagnostic utility, but an assay for antigenemia or CMV DNA, not blood culture, should be used. Monoclonal antibodies can detect and count CMV antigens directly in peripheral blood leukocytes (antigenemia) (Fig. 384-3) with a high sensitivity. Assays of viral DNA by polymerase chain reaction or hybrid capture are also more sensitive than culture and at least comparable to antigenemia assays. These quantitative assays may be particularly useful for early detection of CMV disease and for monitoring of therapy.

Serology

Seroconversion is an excellent marker for primary CMV infection, but rises in IgG titers, even four-fold or greater, are not diagnostic of newly acquired infection. CMV-specific IgM antibody develops during primary infection but may reappear during reactivation of latent CMV. The presence of IgG antibody is a sensitive marker of past infection and is used to screen transplant recipients and donors as well as certain blood product recipients and donors.

PREVENTION

A nonviable CMV vaccine, containing the gB antigen, decreases primary infection in young women by 50%,■ but a strategy for use of this or any vaccine has yet to be developed.

Because CMV is transmitted by exchange of secretions or excretions, infection can be diminished by reducing exposure to body fluids. For example, both vaginal and anal intercourse, which are bidirectional risks for transmission, can be diminished by "safe sex." Similarly, limiting the contact of seronegative pregnant women with the secretions and excretions of preschool children can decrease primary infection and, in turn, congenital disease.

The risk of acquiring CMV disease can be reduced in seronegative, immunosuppressed patients through the use of blood products or organ grafts from CMV-seronegative donors. Valganciclovir and ganciclovir provide effective prophylaxis in solid organ transplantation.■ Prophylaxis is uncommon for stem cell transplant recipients; instead, these patients are monitored weekly

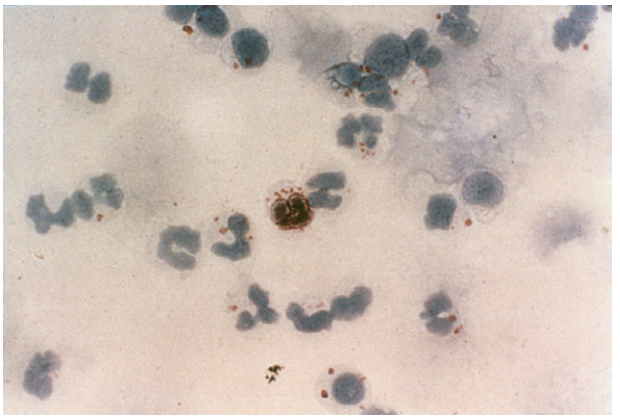

FIGURE 384-3. Peripheral blood leukocytes stained with monoclonal antibody to cytomegalovirus pp65 antigen by the immunoperoxidase technique (magnification ×500).

(from day 10 to day 100 after transplantation) for CMV DNA or antigenemia, and antiviral therapy is introduced preemptively if seroconversion occurs. Thus, active infection is not prevented, but end-organ disease is avoided.

TREATMENT

Rx

Oral valganciclovir, IV ganciclovir, IV ganciclovir followed by oral valganciclovir, IV foscarnet, IV cidofovir, and the ganciclovir intraocular implant coupled with valganciclovir are all effective treatments of CMV retinitis.[3,4]

Ganciclovir (dihydroxypropoxymethylguanosine [DHPG], Cytovene) is given intravenously, 5 mg/kg two times daily during initial induction (2 to 3 weeks); maintenance therapy consists of 5 mg/kg once daily (Chapter 368). The oral form of ganciclovir is given at a dose of 3 g/day for maintenance treatment, but it has been largely replaced by valganciclovir, which achieves levels comparable to intravenous ganciclovir at 5 mg/kg when it is given orally in a 900-mg dose. Initial response in retinitis (improvement or stabilization of vision or ophthalmoscopic appearance) occurs in approximately 75% of patients treated with ganciclovir alone. CMV retinitis can also be treated locally by implantation of a sustained-release device, but this approach should be accompanied by an oral drug to treat and to prevent extraocular end-organ disease. Ganciclovir together with CMV hyperimmune globulin may reduce the mortality of CMV pneumonia after stem cell transplantation from approximately 85% to 40%. CMV gastrointestinal disease should be treated with ganciclovir therapy. Ganciclovir resistance may occur as a result of mutations in the phosphorylating gene (*UL97*) or in the DNA polymerase gene (*UL54*). Granulocyte colony-stimulating factor may be needed to offset neutropenia.

Foscarnet, or phosphonoformic acid, blocks the pyrophosphate-binding site of viral DNA polymerase, thereby preventing cleavage of pyrophosphate from deoxyadenosine triphosphate. The recommended initial therapy with foscarnet is 60 mg/kg intravenously every 8 hours or 90 mg/kg every 12 hours. The maintenance dose ranges from 90 to 120 mg/kg daily. Adverse effects include renal impairment, anemia, hypocalcemia (especially ionized calcium), hypomagnesemia, and hypophosphatemia. Resistance to foscarnet can develop because of mutations in DNA polymerase. Toxicity and the absence of an oral formulation usually make foscarnet a second choice for treatment of CMV, but it is used in combination with ganciclovir for infections such as central nervous system disease or for treatment of ganciclovir-resistant virus.

Cidofovir, or 3-hydroxy-2-phosphonomethoxypropyl cytosine (HPMPC), appears to the cell as a nucleotide and does not require phosphorylation by virus-encoded enzyme. It is therefore active against ganciclovir-resistant CMV strains that have resistance mutations only in *UL97,* the phosphorylating gene. When polymerase, *UL54,* mutations occur in ganciclovir-treated patients, cross-resistance to cidofovir is frequent. These resistance mutations also occur in patients treated with cidofovir de novo. The drug has an extremely long half-life that permits intravenous administration as infrequently as every 2 weeks during maintenance treatment.

Cidofovir is nephrotoxic, especially to the proximal renal tubule, but this side effect can be diminished by prehydration and concomitant probenecid therapy. Cidofovir toxicities make it a second- or third-line agent for CMV.

PROGNOSIS

In immunocompetent patients, the mononucleosis-like CMV syndrome resolves spontaneously. Infections in immunocompromised patients are much more serious and may result in failure of a transplanted solid organ. For CMV pneumonia, death occurs even with antiviral therapy, especially after stem cell transplantation. In AIDS patients, CMV infection generally resolves when CD4 counts exceed 100/mm^3, but it is a grave prognostic sign if counts do not recover to those levels.

385 EPSTEIN-BARR VIRUS INFECTION

ROBERT T. SCHOOLEY

DEFINITION

Epstein-Barr virus (EBV), a member of the gamma human herpesvirus family, is the etiologic agent of infectious mononucleosis. In addition, the etiologic role of EBV in the pathogenesis of a number of neoplastic syndromes is increasingly becoming apparent.

EPIDEMIOLOGY

Ubiquitous in the human population, EBV is found in 90 to 95% of adults throughout the world. As in the case of other herpesviruses, infection with EBV is lifelong. The virus resides in B lymphocytes and is intermittently shed asymptomatically in oropharyngeal secretions, which accounts for the bulk of its transmission in the human population. The virus is not highly contagious; it is usually acquired during early childhood through sharing of saliva-bearing fomites or during adolescence through kissing, although it can be acquired in any decade of life. Thus, for example, EBV-seronegative platonic roommates of patients with acute infectious mononucleosis in college dormitory settings are not at higher risk than others in the college population for acquiring the virus. In addition to oropharyngeal spread, the virus can be transmitted by blood transfusion or through organ donation.

Most childhood EBV infections are clinically silent, but infection of adolescents and adults results in the clinical syndrome of infectious mononucleosis between 25 and 70% of the time, depending on the setting. The incidence of infectious mononucleosis is highest in the 15- to 24-year-old age group. Incidence rates in men and women are equal, but the peak incidence occurs 2 years earlier in women than in men. Incidence rates are lower in lower socioeconomic populations, in whom the likelihood of acquisition is greater in childhood than in adolescence.

PATHOBIOLOGY

EBV enters B lymphocytes through the CD21 molecule (also known as the C3d receptor) on the surface of B cells or nasopharyngeal epithelial cells.

Major histocompatibility complex class II molecules serve as secondary receptors on B cells. Once inside the cell, the virus expresses a series of nuclear proteins (called Epstein-Barr nuclear antigens [EBNAs]), which in turn activate EBV-encoded latent membrane proteins and other gene products responsible for the regulation of B-cell growth. This sequence of events leads to transformation or immortalization of B cells, which is the phenotypic hallmark of B-cell infection. EBV-transformed B cells proliferate vigorously both in vivo and in vitro and maintain EBV DNA within progeny cell nuclei in an episomal state. During acute EBV infection, up to 20% of peripheral blood B cells express EBNA.

The host response to acute EBV infection consists of a vigorous and coordinated cellular and humoral immune response. The humoral immune response includes IgM and IgG antibodies directed at the viral capsid antigen (VCA) and to EBNA, as well as antibodies to antigens on the surface of sheep red blood cells. Sheep red blood cell–directed antibodies, termed *heterophile antibodies*, are useful diagnostically and are present in up to 90% of patients, although they are not always demonstrable at initial evaluation. These antibodies are probably an epiphenomenon in host defense and are not cross-reactive with any known viral antigens.

The cellular immune response includes both natural killer (NK) and EBV-specific $CD4^+$ and $CD8^+$ T lymphocytes. Expansion of the $CD8^+$ subset of T lymphocytes during acute EBV infection includes a subset of large, activated cells that appear on standard peripheral blood smears as "atypical" lymphocytes. This vigorous cellular immune response is associated with an outpouring of cytokines, including tumor necrosis factor, interleukin-1, and interleukin-6, which are probably responsible for many of the symptoms and signs of infectious mononucleosis. Over a period of 4 to 6 weeks after initial evaluation in most patients, immune response mechanisms gain control of the EBV-driven B-cell proliferation and the virus enters into a lifelong period of symbiosis with the host. The virus is shed asymptomatically approximately 15% of the time in the oropharyngeal fluids of healthy human immunodeficiency virus type 1 (HIV-1)-seronegative adolescents and adults. The shedding rate increases significantly in patients with defects in cellular immunity, such as those that occur with HIV-1 infection or immunosuppression associated with organ allografts.

CLINICAL MANIFESTATIONS

Most cases of acute EBV infection are clinically silent. The syndrome of infectious mononucleosis consists of the clinical triad of fever, sore throat, and lymphadenopathy, in association with an atypical lymphocytosis and the transient appearance of heterophile antibodies. Epidemiologic studies indicate that the incubation period between exposure and the onset of symptoms is generally 30 to 50 days. The onset of symptoms may be abrupt, or it may be heralded by a several-day nonspecific prodrome of malaise and low-grade fever. Although the classic syndrome includes fever, sore throat, and adenopathy, the findings may be dominated by only one or any combination of these symptoms. Other common clinical manifestations include headache, malaise, and anorexia. On physical examination, patients are usually febrile. Pharyngeal erythema, tonsillar enlargement, and cervical adenopathy are generally present. Mild periorbital edema may also be observed. Abdominal findings may include splenomegaly, hepatomegaly, or both. Although most patients will have mild splenomegaly at some point in their illness, splenic enlargement is usually maximal in the second or third week of illness and might not be detectable at initial evaluation. Adenopathy may be observed in noncervical regions, but it is usually much less prominent than in the cervical regions. Approximately 5% of patients will exhibit a rash that may be macular, scarlatiniform, or urticarial. If patients with acute EBV infection are given ampicillin or its derivatives, a pruritic maculopapular eruption will develop in 90 to 100% of them. Patients with an ampicillin-induced rash during acute EBV infection generally tolerate the drug and other penicillin products when administered later in life.

DIAGNOSIS

Because the clinical manifestations of acute EBV infection vary from patient to patient and other organisms may cause similar clinical syndromes, laboratory tools are required to confirm an etiologic diagnosis. Heterophile antibodies to sheep red blood cells are classically used to diagnosis EBV-induced infectious mononucleosis. Though ultimately demonstrable in approximately 90% of symptomatic acute EBV infections, these antibodies are present in only about two thirds of patients at initial encounter. If antibodies are negative at the outset and clinical suspicion is high, repeated testing in the second or third week of the illness is warranted. Although EBV-specific antibodies remain the "gold standard" for the diagnosis of acute EBV infection, if heterophile antibodies are demonstrated in a straightforward case of infectious mononucleosis, it is not generally necessary to order EBV-specific serologic studies. IgM antibodies to the EBV capsid antigen (VCA) are the most useful serologic study for the diagnosis of acute EBV infection. Relatively high titers of IgG antibodies to VCA persist for life after initial infection and are not useful in making the diagnosis of acute EBV infection. Antibodies to EBNA are slower to arise than those to capsid antigens, and acute infection may be diagnosed by demonstration of seroconversion to this antigen. If the diagnosis is based on the emergence of antibodies to EBNA, both tests should be performed in the same laboratory.

Among pathogens causing clinical syndromes that can be mistaken for acute EBV infection, cytomegalovirus (Chapter 384) is the most frequent. Patients with cytomegalovirus infection are less likely to have an acute onset of illness, and pharyngitis is less frequently a prominent manifestation of the illness. *Toxoplasma gondii* (Chapter 357) infection can also cause a nonspecific febrile illness that can be confused with infectious mononucleosis. Streptococcal pharyngitis (Chapter 298) and primary herpes stomatitis (Chapter 382) may occasionally cause symptoms that are mistaken for acute EBV infection. None of these syndromes are associated with heterophile antibodies or with other serologic evidence of acute EBV infection. The differential diagnosis is generally made by serologic studies directed at these organisms or by culture. Nonetheless, physicians should be cognizant that organisms such as group A β-hemolytic streptococci and herpes simplex virus are also common in the human population and may be demonstrated in people whose symptoms are nonetheless due to acute EBV infection.

PREVENTION AND TREATMENT

Rx

Because the virus is usually transmitted by asymptomatic oral shedders and is so common in the human population, epidemiologic interventions to prevent spread are not practical. No vaccine has yet been developed. The clinical course is generally self-limited and does not usually require specific therapeutic intervention beyond the use of aspirin or acetaminophen for antipyresis and mild pain relief, except in the presence of specific complications, such as when lymphadenopathy threatens the airway or in certain cases of autoimmune hemolytic anemia (Chapter 163) or thrombocytopenia (Chapter 175). Short courses of corticosteroids, which have been used to hasten symptomatic recovery in patients in whom the symptoms are severe or refractory, should not be used routinely and should consist of no more than a 10- to 14-day tapering course that begins at a dose equivalent of 0.5 mg/kg of prednisone. Although EBV replication can be inhibited in vitro or in vivo by acyclovir and related antiviral agents, the symptoms of infectious mononucleosis are primarily driven by the immune response to the virus and follow the time of maximal viral replication. Antiviral agents have not been demonstrated to accelerate the resolution of symptoms significantly or to prevent complications of the disease.

PROGNOSIS

Most patients recover uneventfully from the acute symptoms and signs of infectious mononucleosis over a 2- to 3-week period, although many patients may have a variable period of malaise and fatigue that can last for another 3 to 4 weeks. Some patients, however, experience fatigue and difficulty concentrating for up to 6 months after diagnosis. Symptoms often wax and wane and can be extremely troublesome. Reassurance is usually the best approach to these patients. There is less evidence that corticosteroids are of benefit in this setting. Recovery may be less straightforward in patients with certain specific complications of acute EBV infection (outlined in the next section). Death from infectious mononucleosis is rare. When it does occur, it is most frequently associated with neurologic complications of the illness, splenic rupture, or X-linked lymphoproliferative syndrome (discussed later).

Complications

Although most patients recover spontaneously from acute EBV infection, a number of complications may arise. In some patients, these complications dominate the clinical findings, and seroconversion to EBV may be the only evidence of acute EBV infection. Mild hepatomegaly can occur in acute infectious mononucleosis, and biochemical evidence of hepatitis is to be expected in virtually every acute infection. More severe hepatic complications are uncommon.

The most serious complication of acute EBV infection arises in individuals with X-linked lymphoproliferative syndrome, which occurs in males with mutations in the signaling lymphocyte activation molecule (SLAM)-associated protein (SAP) that regulates T and NK cells. These otherwise healthy individuals have severe clinical symptoms, a large lymphocytosis consisting of T and B cells, and severe hepatitis. If patients survive the acute infection, the syndrome may evolve into progressive agammaglobulinemia or lymphoma in the following months.

Patients with acute EBV infection should be specifically warned about splenic rupture, a complication attributable to splenomegaly (Chapter 171) and associated stretching of the splenic capsule that occurs most frequently in the second or third week of the illness, when other symptoms of the disease are abating. Rupture is generally accompanied by trauma but can occasionally occur without an obvious antecedent event. Patients should be counseled against activities that might result in abdominal trauma for 6 to 8 weeks after the onset of symptoms. Left upper quadrant pain, especially pain radiating to the subscapular region, should raise this diagnostic consideration. As with other complications of acute EBV infection, splenic rupture may occur occasionally in patients without other prominent clinical manifestations of acute EBV infection.

Other hematologic complications of acute EBV infection include autoimmune hemolytic anemia (Chapter 163), thrombocytopenia (Chapter 175), and neutropenia (Chapter 170). These complications usually arise from a combination of self-reactive antibodies and hypersplenism and are generally self-limited and resolve with resolution of the illness. Corticosteroids may be of benefit in more severe cases of autoimmune hemolytic anemia or thrombocytopenia.

Neurologic complications during acute EBV infection can rarely cause clinical manifestations that are similar to those seen with herpes simplex encephalitis (Chapter 422). Although these patients have a much better prognosis than do patients with herpes simplex encephalitis, they should receive parenteral acyclovir (10 mg/kg every 8 hours). Other neurologic complications include aseptic meningitis (Chapter 420), cerebellitis, mononeuritis multiplex (Chapter 428), Bell's palsy (Chapter 428), Guillain-Barré syndrome (Chapter 428), and transverse myelitis (Chapter 407). These complications may be clinically dramatic but are usually self-limited and associated with full recovery in 85% of patients without specific antiviral therapy. Renal, cardiac, pulmonary, and skeletal muscle complications are rare.

OTHER CLINICAL MANIFESTATIONS

In addition to infectious mononucleosis, EBV is also associated with neoplasia and lymphoproliferative disorders, which are seen most frequently in patients with defects in cellular immunity but are not restricted to such patients.

Post-transplantation Lymphoproliferative Disease

EBV-driven B-cell proliferation that is insufficiently regulated in the presence of prolonged periods of severe T-cell immunodeficiency may result in a B-cell polyclonal proliferation that is initially similar to that seen in acute infectious mononucleosis. Though most frequently occurring in the setting of organ transplantation, especially when patients are immunosuppressed with agents directed specifically at T lymphocytes, such as anti-CD3 antibodies or cyclosporine, this syndrome can be seen in other conditions with similar levels and durations of immunodeficiency, such as HIV-1 infection. Patients with this disorder, termed *post-transplantation lymphoproliferative disease* (PTLD), often initially have fever, adenopathy, and splenomegaly. Intestinal B-cell proliferation is also common. If the immunodeficiency persists, these disorders often proceed from a polyclonal stage, which can be reversed with restoration of immunity, to a monoclonal or oligoclonal stage that is progressive despite restoration of cellular immunodeficiency. Elevated plasma levels of EBV DNA are associated with an increased risk for PTLD, but their predictive value is less well established after solid organ transplantation than after bone marrow transplantation. These tumors are becoming less common as allograft-associated immunosuppression is better targeted and less intense.

The diagnosis is not generally difficult to make in the appropriate clinical setting and can be made histopathologically. Successful management depends on the extent to which the immunosuppressive condition can be reversed before the evolution of restricted clonality. Therapy for PTLD with rituximab (375 mg/m^2 weekly for 4 weeks) is used in some centers. PTLD may be less frequent in patients who have received acyclovir or ganciclovir after transplantation, but these agents are less useful once the syndrome develops. Surgery or radiation therapy, or both, are also used.

Burkitt's Lymphoma

EBV is the cause of African Burkitt's lymphoma (Chapter 191), which is composed of small, noncleaved B cells and, unless aggressively treated, is rapidly fatal. This aggressive B-cell lymphoma with a predilection for the head and neck is endemic in equatorial Africa and is geographically linked to *Plasmodium falciparum* malaria. EBV DNA is readily demonstrable in tumor biopsy specimens, and high titers of antibodies to EBV structural antigens are found in plasma. Sporadic cases of abdominal B-cell lymphomas with a histologic appearance compatible with Burkitt's lymphoma are also observed but are associated with EBV only about 25% of the time. The tumor is likewise seen in patients with HIV-1 infection, but it is not as clearly associated with advanced immunodeficiency as are other complications of HIV-1 infection. The tumor is often quite responsive to combination chemotherapy with or without radiation therapy (Chapter 191).

Hodgkin's Lymphoma

EBV is associated with a subset of Hodgkin's lymphomas (Chapter 192), especially the lymphocyte-depleted and mixed-cellularity histologic subtypes. EBV DNA and proteins are detected in the Reed-Sternberg cells that are characteristic of Hodgkin's lymphoma. Therapy for EBV-associated Hodgkin's lymphoma is directed at the tumor (Chapter 192), not at EBV.

Central Nervous System Lymphoma

EBV is associated with central nervous system (CNS) lymphoma (Chapter 191). This tumor was most frequently observed in the post-transplantation setting before the HIV epidemic but is now the most frequent CNS neoplasm in HIV-1–infected individuals. The major differential diagnostic challenge is with *T. gondii* infection (Chapter 357). Although a tissue-based diagnosis is definitive, noninvasive neurodiagnostic approaches coupled with the demonstration of EBV DNA in cerebrospinal fluid by polymerase chain reaction can strongly support the diagnosis of lymphoma over that of *T. gondii* infection. Radiation therapy may be used but is generally only palliative.

Nasopharyngeal Carcinoma

EBV has been associated with certain cases of nasopharyngeal carcinoma (Chapter 196), a tumor that is rare in Western countries but is much more frequent in southern China and in the Inuit population of Alaska. EBV-associated cases are usually less histologically differentiated than the sporadic forms of nasopharyngeal carcinoma. EBV DNA is demonstrable in tumor tissue, and high titers of IgA and IgG antibodies to the EBV capsid antigens are found in plasma. The prognosis for this tumor is poor, although it is often treated with radiation therapy (Chapter 196).

Other Epstein-Barr Virus–Associated Neoplasms

EBV collaborates with another human gamma herpesvirus, human herpesvirus-8, to cause primary effusion lymphoma in the HIV-1–infected population. These aggressive tumors occur in body cavities such as the pleural, peritoneal, and pericardial spaces. EBV DNA may also be found in the moderate to slowly progressive destructive midline facial angiocentric tumors of T- and NK-cell phenotypes; this neoplasm is clinically manifested as a syndrome that was previously known as lethal midline granuloma (Chapter 191). EBV also plays a key role in the pathogenesis of an angiocentric EBV-associated B-cell tumor that is clinically manifested as lymphomatoid granulomatosis (Chapter 278).

Oral Hairy Leukoplakia

EBV infection can cause a corrugated or "hairy" plaquelike lesion that extends around the lateral aspects of the tongue. Oral hairy leukoplakia is most often observed in patients with chronic forms of cellular immunodeficiency, especially those with HIV-1 infection and CD4$^+$ cell counts lower than 200/mm^3. It is most often clinically confused with mucocutaneous candidiasis (Chapter 346) but can be differentiated because its distribution is restricted to the lateral surface of the tongue and, unlike thrush, does not involve the buccal mucosa, palate, or pharynx and is not readily removed by superficial scraping. Biopsy specimens demonstrate a characteristic histopathologic pattern, as well as the presence of EBV antigens and DNA within squamous epithelial cells. Although the lesions may be cosmetically troublesome, they are not generally painful. In HIV-1–associated oral hairy leukoplakia, the lesions resolve with successful antiretroviral chemotherapy. If the

immunosuppression cannot be reversed, oral hairy leukoplakia usually responds to weekly local treatment with podophyllin resin (25%), with or without topical acyclovir cream (5%),■ and to oral valacyclovir (1 g every 8 hours for 1 month).

Chronic Active Epstein-Barr Virus Infection

Infrequent patients with no apparent defect in cellular immunity may have chronic EBV infection associated with persistent or intermittent hepatitis, interstitial pulmonary disease, or both. These rare patients with bona fide organ system disease should not be confused with patients who have chronic fatigue syndrome. This nonspecific clinical syndrome, seen most frequently in young and middle-aged women, is characterized by malaise and difficulty concentrating but lacks objective physical findings. Although an etiologic or contributing role for EBV had been posited in the past, there is no convincing evidence that the virus plays a role in this condition.

RETROVIRUSES OTHER THAN HUMAN IMMUNODEFICIENCY VIRUS

WILLIAM A. BLATTNER

DEFINITION

There are now four members of the human T-lymphotropic virus (HTLV) family: HTLV-1, discovered in 1979; HTLV-2, discovered in 1982; and HTLV-3 and HTLV-4, discovered in 2005. HTLV-1 has been causally linked to adult T-cell leukemia/lymphoma (ATL) and to several chronic degenerative conditions, most notably HTLV-1–associated myelopathy/tropical spastic paraparesis (HAM/TSP), whereas disease associated with HTLV-2 is rare, and no disease associations have been established with HTLV-3 or HTLV-4.

The Pathogens

Within the taxa of RNA reverse transcribing viruses, the HTLV viruses, along with bovine leukemia virus, are classified in the subfamily Retroviridae within the genus Deltaretrovirus (formerly termed *oncovirus*). The oncogenic properties of these viruses and their molecular structure distinguish them from the human immunodeficiency retroviruses HIV-1 and HIV-2 (Chapter 394), which are members of the genus Lentivirus. Both deltaretroviruses and lentiviruses are capable of prolonged asymptomatic infection. In vitro, however, HIV-1 and HIV-2 have cytopathic effects on human T cells, whereas HTLV-1 and HTLV-2 are capable of transforming T cells into immortalized cell lines. The HTLVs are diploid single-stranded RNA viruses that replicate through cDNA, a proviral intermediate, by reverse transcriptase, a viral enzyme.

EPIDEMIOLOGY

HTLV-1 is widely disseminated worldwide and is estimated to infect 10 to 25 million persons, with the aggressive T-cell malignant neoplasm ATL developing in 2 to 6% and chronic inflammatory diseases, mainly HAM/TSP, developing in another 1 to 5% in their lifetime. Similar to HIV, molecular epidemiology suggests that the four major subtypes of HTLV identified in humans arose from separate interspecies transmission from simians to humans. The recent discovery of HTLV-3 and HTLV-4 was made in Cameroon, where closely related viruses in nonhuman primates led to discovery in humans with exposure as bush meat hunters. Related to such interspecies transmission, there are three major lineages of HTLV-1: Melanesian (Papua New Guinea, Melanesia, and Australian aborigines), central African, and cosmopolitan groups. Within the cosmopolitan group are four subtypes: A, transcontinental; B, Japanese; C, West African; and D, North African. The virus from Melanesia differs molecularly from the Japanese and African strains by 5 to 10%, the result of independent evolution of the virus in these populations separated for tens of thousands of years. The stability of HTLV-1 in comparison to HIV-1 reflects the observation that HTLV favors viral expansion through proliferation of proviral DNA-harboring cells rather than infection of new cells by cell-free virions. The HTLV subtypes differ phylogenetically by approximately 30 to 40% among each other.

HTLV-1 is not universally present in all human populations but rather clusters geographically: southern Japan; Melanesia; Australia, in aboriginal peoples; West Africa and, by the slave trade from Africa, the Caribbean and the United States in African Americans; southern India; and the Mashhad region of Iran. In the United States, HTLV-1 infection is often found in persons who migrate from these regions. HTLV-2 is found in Native American people throughout North, Central, and South America and in West Africa. Most HTLV-2 infections in the United States and Europe occur in injection drug users, in whom the virus is spread by needle sharing and other injection practices. Initial isolations of HTLV-3 and HTLV-4 are from Cameroon, but their extent in West Africa is not yet known.

Routes of Transmission

HTLV, like HIV-1, is transmitted sexually, perinatally, and by transfusion or injection drug use (Table 386-1).

Sexual Transmission

Sexual transmission of HTLV-1 from male to female and from female to male as well as from male to male has been documented. HTLV-1 transmission is cell associated and appears to be at least an order of magnitude less infectious than HIV-1. Coincidental infection with other sexually transmitted diseases,

TABLE 386-1 TRANSMISSION OF HTLV-1 AND HTLV-2

MODE OF TRANSMISSION	HTLV-1	HTLV-2
MOTHER TO INFANT		
Transplacental	Yes	Not known
Breast milk	Yes	Probable
SEXUAL		
Male to female	Yes	Yes
Female to male	Yes	Yes
Male to male	Yes	Not known
PARENTERAL		
Blood transfusion	Yes	Yes
Intravenous drug use	Yes	Yes
COFACTORS		
Ulcerative genital lesions	Yes	Not known
Cellular transfusion products	Yes	Yes
Sharing of "works"*	Yes	Yes
ELEVATED VIRUS LOAD		
Mother to infant	Yes	Not known
Heterosexual	Yes	Not known

*Intravenous paraphernalia, such as needles.

particularly those associated with ulcerative and inflammatory genital lesions, amplifies the risk of transmission. For HTLV-1, elevated viral load is linked to heightened transmission. In regions endemic for the virus, there is a characteristic age-dependent rise in HTLV-1 seroprevalence. This increase first becomes evident in the adolescent years; it is steeper in women than in men and continues in women after 40 years of age, whereas rates in men plateau around the age of 40 years. This pattern reflects more efficient male to female transmission. For HTLV-2, the rates for both genders are equal, thus suggesting that there may be differences in the kinetics of transmission between the two viruses.

Perinatal Transmission

For HTLV-1, transmission through breast-feeding is more efficient than in utero or perinatal transmission. On average, 20% of infants breast-fed by HTLV-1–positive mothers seroconvert to HTLV-1, whereas only 1 to 2% of bottle-fed infants of HTLV-1–positive mothers become infected. In contrast, in utero and perinatal transmission accounts for virtually all HIV-1 transmission in the West, and breast-feeding accounts for an additional 15 to 20% of infant HIV infection in Africa. This difference may reflect the fact that maternal antibody to HTLV-1 transmitted across the placenta appears to neutralize perinatal HTLV-1 but not the highly mutable HIV-1. HTLV-2 is detectable in breast milk and, similar to HTLV-1, accounts for many childhood infections.

Transfusion and Injection Drug Use

Parenteral transmission, through either transfusion or injection drug use, is a major source of HTLV infection. Among blood donors in the United States, more than half of HTLV infections are due to HTLV-2. Among injection drug users, most infections are due to HTLV-2, and HTLV-2 is more efficiently transmitted by this route than HTLV-1 is.

Both HTLV-1 and HTLV-2 are transmitted in association with cellular components through a "virologic synapse," unlike HIV-1, which is transmitted by cells, plasma, or plasma products. Approximately 50% of the recipients of HTLV-1/HTLV-2–positive blood seroconvert, compared with more than 95% for HIV-1.

The only documented illness linked to HTLV-1 or HTLV-2 transfusion-associated transmission is the HTLV-associated demyelinating neurologic syndrome HAM/TSP. Leukemia has not been associated with transfusion of HTLV-positive blood. Among U.S. blood donors who are confirmed to be HTLV positive (slightly less than half are HTLV-1 positive and the others are HTLV-2 positive), the major risk factors are intravenous drug use, birthplace in an area in the Caribbean or Japan endemic for the virus, and sexual contact with a person with this profile.

Coinfection with HTLV-1 and HIV-1 appears to increase the progression to acquired immunodeficiency syndrome (AIDS) through unexplained mechanisms, possibly related to the cell-proliferative effects of HTLV-1 on HIV-1–infected T cells. Such a relationship has not been shown for HTLV-2. Other modes of transmission involving "casual contact" are not a source of infection. Health care and laboratory workers who experience a needlestick or skin or mucous membrane exposure in the absence of protective barriers have little or no risk for infection but should be monitored.

PATHOBIOLOGY

Virology

The HTLV viruses, which are single-stranded RNA viruses that contain a diploid genome, replicate through a DNA intermediary that integrates into the genome of the target T cell as a provirus, thereby resulting in lifelong infection. HTLV-1 is approximately 100 nm in diameter and has a thin, electron-dense outer envelope and an electron-dense, roughly spherical core. The total provirus genome contains 9032 nucleotides with two identical sequences termed *long terminal repeats* (LTRs) at the 5′ and 3′ ends of the genome, which contain regulatory elements that control virus expression and virion production. The retroviral structural genes (*gag* and *pol*) code for large overlapping polyproteins that are later processed into functional peptide products by virally encoded protease and cellular proteases. The encoding genes of the virus are *gag* (group-specific antigen), *pol* (polymerase/integrase/protease), and *env* (envelope), and it has a series of regulatory genes, *tax* and *rex,* and several smaller gene products that regulate infection and virus expression. A newly discovered viral gene is the basic leucine zipper factor (*HBZ*) gene, encoded by the minus strand of the HTLV-1 provirus and transcribed from the 3′ LTR. Tax protein plays a central role in enhancing the transcription of viral and cellular gene products that promote viral replication and transformation of human T lymphocytes. Through binding to the LTR, Tax promotes transcriptional activation of the viral genome, and by binding to key regulatory proteins of the cell, it promotes cell activation and disease pathogenesis. Through binding to regulatory enhancers of the cell and through abrogation of key suppressor genes, Tax not only promotes cellular growth but also appears to have an impact on pathogenesis of the disease (see later). Rex stabilizes viral mRNA, essential for export of full-length Gag/Pol and single-spliced Env mRNA from the nucleus to the cytoplasm. HBZ inhibits the Tax-mediated activation of viral gene transcription through the 5′ LTR and promotes the proliferation of infected cells.

Viral Life Cycle

The life cycle of the HTLVs involves attachment, membrane fusion, and reverse transcription from an RNA template to a circular DNA provirus that is transported to the cell nucleus and integrated into the host genome. Both cell-free transmission and cell to cell transmission of HTLV-1 have been documented, with a cell to cell viral synapse involved in cell to cell transmission. Once the cell is infected, viral expansion is primarily achieved through proliferation of proviral DNA–harboring cells rather than through repeated cycles of cell to cell infection. Glut-1, the major vertebrate glucose transporter, is the cellular receptor for HTLV-1 attachment to the cell. Given the ubiquity of this receptor, the cellular trophism of HTLV-1 for $CD4^+$ cells and HTLV-2 for $CD8^+$ cells appears to involve postinfection transcriptional mechanisms; in contrast, HIV targets $CD4^+$ cells through direct binding with a cell-specific receptor. After uptake and uncoating, viral RNA is transcribed by reverse transcriptase, an RNA-dependent DNA polymerase complexed to the RNA in the core of the virus particle, into double-stranded DNA. This double-stranded viral DNA is integrated into the host cell nucleus by the virally encoded integrase, which results in lifelong cell infection. The viral LTR elements are essential for integration and regulation of viral genome expression with regulation from both Tax and HBZ.

Pathogenesis of Adult T-Cell Leukemia

HTLV-1 is integrally involved in the pathogenesis of ATL through a multistage process that includes clonal integration of virus (sometimes including partial viral sequences that always include *tax*) into active cellular gene sequences. Interestingly, HBZ is always present in ATL, and its quantification may be a useful marker for monitoring of the response to treatment. The clonal pattern of integration indicates that ATL is derived from a single transformed tumor cell that evolved from a virus infection *before* transformation rather than afterward as a passenger virus. Tax is an oncoprotein that interacts with numerous cellular proteins to reprogram cellular processes to alter transcription, cell cycle regulation, DNA repair, and apoptosis, thereby allowing cells with potential carcinogenic mutations to survive and to escape cell death.

In some healthy carriers, T-cell polyclonal and oligoclonal proliferations develop that can later progress to malignant transformation or may disappear spontaneously. Morphologically distinct "flower cells" (Fig. 386-1B), which represent T cells with deeply lobulated nuclei resembling ATL leukemic cells, are seen on peripheral blood smears of healthy carriers, and increased numbers are detected in persons with higher HTLV viral loads.

Pathogenesis of Myelopathy/Spastic Paraparesis

Viral overproduction, as measured by high viral loads, appears to result from defective host immune responses characterized by very high levels of cytotoxic T cells. Local pathologic changes in neuronal tissue may result from immune-mediated damage caused by misdirected responses to molecular mimics of viral proteins or by local damage due to cytokine-induced damage of neuronal tissue as HTLV-1 cells infiltrate the perivascular space and the neurons of the central nervous system (CNS), particularly the spinal cord.

ADULT T-CELL LEUKEMIA/LYMPHOMA

EPIDEMIOLOGY AND PATHOBIOLOGY

The cumulative lifetime incidence of adult T-cell leukemia/lymphoma (ATL) in persons infected with HTLV-1 is between 2 and 6%, so about 2500 to 5000 cases per year occur in the approximately 10 to 25 million infected persons worldwide. About 30 cases develop in the United States annually. Although rates of HTLV-1 infection in adults are much higher in women, the equal male to female rates of ATL suggest that early life exposure is associated with the greatest risk for subsequent disease. In areas endemic for HTLV-1, such as southern Japan and the Caribbean Islands, ATL accounts for half or more

TABLE 386-2 HTLV-ASSOCIATED DISEASES

DIAGNOSIS	NATURE OF SYNDROME	STRENGTH OF ASSOCIATION
HTLV-1–ASSOCIATED DISEASES		
Adult T-cell leukemia/lymphoma	Aggressive lymphoproliferative malignant disease of mature T lymphocytes	Strong
HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP)	Chronic progressive demyelinating syndrome of long motor tracts of spinal cord	Strong
Polymyositis	Degenerative inflammatory syndrome of skeletal muscles	Probable
Sporadic inclusion body myositis	Recently described HTLV-associated inflammatory muscle disease	Possible
Infective dermatitis	Chronic generalized eczema in adults and children; potential for pre-leukemia and immunodeficiency	Strong
Uveitis	Inflammatory infiltration of the uvea of the eye	Strong
Sjögren's syndrome/ keratoconjunctivitis sicca	Loss of tear production and dry eyes and dry mouth	Probable
Pulmonary lymphocyte alveolitis/ cryptogenic fibrosing alveolitis	Pulmonary infiltrate involving T lymphocytosis in lungs of patients with HAM/ TSP and HTLV uveitis	Possible
HTLV-associated arthritis	Large-joint polyarthropathy; rheumatoid factor positive, with HTLV-1–positive cells infiltrating the synovia	Probable
Immunodeficiency	Subclinical (e.g., decreased PPD response) or clinical (e.g., association with clinical tuberculosis and poor response to therapy for symptomatic strongyloidiasis)	Probable
Miscellaneous clinical conditions	Case reports of small cell lung cancer with monoclonal HTLV-1 integration and invasive cervical cancer	Uncertain
HTLV-2–ASSOCIATED DISEASES		
HTLV-associated myelopathy	Increased numbers of cases among blood donors	Definite but rare

PPD = purified protein derivative.

of adult lymphoid malignant neoplasms. In one series of pediatric cases of ATL, four of the eight patients shared a homozygous deletion in the p16 gene locus, and deletion of exons 7 and 8 of p53 was detected in another child, thereby suggesting that a genetic predisposition interacts with viral infection to accelerate disease progression.

CLINICAL MANIFESTATIONS

The most common disease caused by HTLV-1 is ATL, a type of T/natural killer–cell lymphoma in the new World Health Organization classification (Table 386-2). ATL is a high-grade lymphoma (Chapter 191), usually of large, medium, or pleiotropic morphology (or combined morphology) and advanced clinical stage, and it is associated with a poor prognosis.

The acute form of ATL, accounting for about 55% of cases, is characterized by an aggressive, mature T-cell lymphoma that presents with a high white blood cell count, hypercalcemia, and cutaneous involvement. Lymphoma type (about 20% of cases) shares all features of acute ATL except for peripheral blood involvement. Other cases resemble T-prolymphocytic leukemia and are termed *chronic ATL* (about 20% of cases). Smoldering ATL (about 5%) may clinically resemble mycosis fungoides/Sézary syndrome, with cutaneous involvement manifested as erythema or as infiltrative plaques or

tumors. A long prodrome of signs (e.g., cutaneous rashes) and symptoms (e.g., fevers) is sometimes noted in chronic and smoldering ATL before transformation to an acute or lymphoma-type ATL that is rapidly fatal.

DIAGNOSIS

The diagnosis should be considered in an adult with mature T-cell lymphoma and hypercalcemia or cutaneous involvement (or both) with characteristic flower cells (Fig. 386-1B), particularly if the individual is from a known risk group or endemic region. The diagnosis is established by testing of serum for HTLV-1 antibodies. HTLV-1 and HTLV-2 are routinely detected through blood bank screening assays and confirmed by Western blotting. Polymerase chain reaction (PCR) can detect infection and distinguish the type of virus. The cytologically distinct flower cell, a sine qua non of HTLV-1–associated leukemia (see Fig. 386-1), is also seen in apparently healthy carriers and may presage the risk for future ATL. Occasional cases with characteristic clinical features are antibody negative but provirus positive as detected by PCR in blood cells or in biopsy specimens.

TREATMENT Rx

Watchful waiting is an option for patients with smoldering or chronic ATL, but conventional chemotherapy (Chapter 191), including prednisone with or without cyclophosphamide, is sometimes used in the chronic form. More aggressive therapy is associated with altered immunity and high rates of opportunistic infection.

The acute and lymphoma types of ATL are aggressive high-grade lymphomas whose initial response rates to standard regimens (Chapter 191) are 66%, including a 32% complete response rate. However, responses are of short duration, with relapses occurring in weeks to months, often involving the CNS. Novel therapies with denileukin diftitox (interleukin-2–diphtheria toxin conjugate) that target the high-affinity interleukin-2 receptor on ATL cells are in clinical trials. Recent reports suggest a therapeutic role for allogeneic hematopoietic stem cell transplantation (Chapter 181), with a reported 3-year overall survival rate of 73% and progression-free survival of 67%, with disappearance of detectable virus in a majority of patients.

PROGNOSIS

Smoldering ATL has a relatively good prognosis, with a 5-year survival rate of 70%. The chronic subtype has a 5-year survival rate of 20%. For the aggressive forms of acute and lymphoma-type ATL, median disease-free survival is 0.6 years, with an overall survival of 0.8 years. Significant negative prognostic factors include poor performance status at diagnosis, older age, advanced stage, hypercalcemia, and elevated serum lactate dehydrogenase levels. Death usually results from rapid growth of tumor cells, hypercalcemia, bacterial sepsis, and opportunistic and other infectious complications.

HTLV-ASSOCIATED MYELOPATHY/TROPICAL SPASTIC PARAPARESIS

EPIDEMIOLOGY AND PATHOBIOLOGY

HTLV-1 causes an inflammatory neurologic syndrome known as HAM/TSP. The lifetime incidence is approximately half the rate for ATL, with approximately 1 to 2% of carriers affected. HAM/TSP is approximately two times more likely to develop in females. The majority of adult cases occur in the 30- to 50-year age group, but cases have occurred in children as young as 3 years. These patterns suggest that the latency period for HAM/TSP is shorter than that for ATL and that both early-life and adult exposure causes disease. More than a dozen HAM/TSP cases associated with HTLV-2 have been reported, but the occurrence is infrequent compared with HTLV-1 carriers.

The pathogenesis results from trafficking of infected T cells in the perivascular areas and parenchyma of the spinal cord, where they cause astrocytosis. Ongoing inflammation of spinal gray and white matter results in a progressive and preferential demyelination and degeneration of the lateral and posterior columns, followed over time by loss of myelin and axons in the anterior columns.

CLINICAL MANIFESTATIONS

Symptoms include stiff gait, spasticity, lower extremity weakness, back pain, urinary incontinence and impotence, and (rarely) ataxia. The presenting symptom is stiff gait that progresses (usually slowly) to increasing spasticity and weakness, with incontinence and impotence developing later. In contrast to classic multiple sclerosis (Chapter 419), HAM/TSP is characterized by a generally slow and progressive course, absence of waxing and waning symptoms, and demyelination of long motor neurons rather than the CNS. However, some cases are acutely progressive, especially those associated with transfusion of HTLV-1–positive blood. It is not uncommon for other manifestations of HTLV-1–associated "autoimmune" disease to present coincident with the neurologic syndrome (see later).

DIAGNOSIS

The diagnosis is suspected in patients with unexplained CNS disease and loss of pyramidal tract functions and is confirmed by testing of sera for HTLV-1 antibodies. Oligoclonal immunoglobulin bands in the cerebrospinal fluid (CSF) of patients with HAM/TSP react to HTLV-1 antigens, and the CSF to serum ratio of HTLV-1 antibodies is greater than 1. PCR detection of HTLV-1 antigen in the CSF is also diagnostic. Spinal cord lesions often appear hyperintense on T2-weighted magnetic resonance imaging.

TREATMENT Rx

Corticosteroids (intravenous methylprednisolone 1.5 g for 3 consecutive days in the first week, 2 consecutive days in the second week, 1 day in the third week, and then monthly for 6 months; an alternative is oral prednisone, 1 mg/kg/day in tapering doses for 2 to 4 months) reduce symptoms in approximately 40% of cases, especially in early disease or patients with rapid progression. Interferon alfa (3 MU three times per week) can improve neurologic symptoms. Pentoxifylline (400 to 1200 mg daily) decreases tumor necrosis factor-α and interferon-γ levels and has improved motor disability, especially spasticity, in uncontrolled trials. Cyclophosphamide also benefits some patients. Spasticity can be treated with tizanidine (2 to 12 mg daily) and botulinum toxin injection (100 to 400 IU every 4 to 6 months). Urinary incontinence is treated with oxybutynin (5 to 30 mg daily), imipramine (10 to 75 mg daily), or doxazosin mesylate (1 to 6 mg daily), and urinary retention is treated with bethanechol (10 to 50 mg daily). Treatment with danazol (100 to 400 mg daily in two divided doses) has resulted in improvement in urinary and fecal incontinence but not in the underlying neurologic deficit. Clinical trials are under way with Hu-Mik-(Beta)1, a genetically engineered antibody that blocks the action of interleukin-15 with the goal of blunting the autoimmune response that results in HAM/TSP.

PROGNOSIS

The prognosis of HAM/TSP is poor, with inexorable progression of neurologic deterioration.

OTHER HTLV-ASSOCIATED CONDITIONS

HAM/TSP is the prototype for a series of immune-mediated syndromes characterized by a high viral load, immune activation, and an indirect pathogenic mechanism produced by virally induced perturbations in immune function. Examples include skeletal muscle polymyositis, sporadic inclusion body myositis, uveitis (30 to 40% of cases in areas endemic for HTLV), large-joint arthropathy, pulmonary lymphocyte alveolitis/cryptogenic fibrosing alveolitis, Sjögren's syndrome/keratoconjunctivitis sicca, and infective dermatitis, which is a pediatric syndrome characterized by inability to clear saprophytic skin infections (see Table 386-2). Carriers of HTLV-1 also have elevated rates of invasive cervical cancer, tuberculosis, parasitic infestations (e.g., strongyloidiasis), scabies, and refractory generalized eczema associated with infective dermatitis. One prospective study of HTLV-2–positive drug users showed an excess of asthma-related deaths and an increased frequency of skin and soft tissue infections.

PREVENTION

Patients often seek medical attention when confronted with a positive HTLV test result based on blood bank screening. Confirmation with Western blot or PCR is needed. Confirmed positive patients must be told that complications related to HTLV-1 infection are rare and that HTLV-2 is hardly ever responsible for clinical disease. Second, it should be emphasized that these viruses are not easily transmitted. Third, the patient should be clearly counseled concerning the distinction between HTLV and HIV because the greatest fear that patients may experience is that they have the "AIDS virus." Other guidelines for prevention include the following:

- Blood for donation should be screened before transfusion, and positive donors should be deferred from donating.

- HTLV-1/HTLV-2–positive mothers should be discouraged from breast-feeding to prevent mother to infant transmission (except in particular settings, such as in the tropics, where diarrheal disease in non–breast-fed infants presents a high risk for morbidity and mortality).
- Condoms should be used by discordant couples, but given the relatively low frequency of sexual transmission per sexual encounter, couples who desire a pregnancy could time unprotected sexual intercourse to coincide with periods of maximal fertility. Such decisions, however, require careful discussion between the physician and the patient.

Postexposure prophylaxis with zidovudine is not recommended because the efficacy of such prophylaxis for HTLV infection has not been established. Vaccines containing whole virus and recombinant HTLV-1 envelope antigens have successfully prevented HTLV-1 infection in monkeys and in a rabbit model. However, a vaccine for humans is unlikely to be a high priority because of the relatively low incidence of clinical disease.

ENTEROVIRUSES

JOSÉ R. ROMERO

DEFINITION

The enteroviruses belong to the genus Enterovirus in the family Picornaviridae. The original taxonomic classification of the enteroviruses was initially based on disease manifestations in humans and animal models but was later based on patterns of replication in cell culture, as well as physicochemical characteristics. According to this scheme, the traditional classification recognized five species within the genus: polioviruses, group A coxsackieviruses, group B coxsackieviruses, enteroviruses, and numbered enteroviruses (Table 387-1). With the advent of molecular virology, the classification is now based on phylogenetic analysis of the nucleic acid sequence of VP1, the major enteroviral capsid protein. This molecular methodology expanded the number of recognized species from 64 to more than 100.

The Pathogens

Enteroviruses are small (30 nm in diameter), nonenveloped, icosahedral-shaped viruses. The viral capsid is composed of four viral proteins (VP1 to VP4). The enteroviruses possess an approximately 7.4-kilobase (kb) positive-sense single-stranded RNA genome. The 5′ end of the genome is covalently linked to a small protein, VPg. The genome is organized into a long (≈740 nucleotides) 5′ noncoding region that precedes a single continuous open reading frame measuring approximately 6630 nucleotides. The open reading frame, which is followed by a short 3′ noncoding region and a terminal polyadenylated tail, yields a single large polyprotein that is post-translationally modified to produce four capsid proteins and seven nonstructural proteins.

The 5′ and 3′ noncoding regions participate in replication of the viral genome. Determinants of neurovirulence have been identified within the 5′ noncoding region of polioviruses.

EPIDEMIOLOGY

Worldwide, an estimated 1 billion or more enteroviral infections occur annually. In the United States, about 30 to 50 million annual infections result in approximately 10 to 15 million symptomatic cases.

Humans are the only known reservoir for enteroviruses. Enteroviral infections are seasonal, and the majority of infections occur during the summer and early autumn in temperate regions. For example, more than 80% of infections occur in the United States from June through October. In tropical and subtropical regions, infections continue year-round, with an increased incidence during the rainy season.

Globally, the dominant circulating enterovirus serotypes may vary annually by geographic region. In the United States, 15 serotypes accounted for about 85% of all isolates reported (Table 387-2).

More than 80% of infections occur in individuals younger than 20 years, with the highest incidence in infants and children 4 years and younger. Nearly 45% of all infections occur in infants younger than 1 year. Among household members of infected children, clinical or serologic evidence of secondary

infection can be seen in more than 50% of susceptible individuals. A male preponderance is noted in persons younger than 20 years (male-to-female ratio of 1.4), but not in older individuals.

Community-wide as well as localized outbreaks have been reported in neonatal units, nurseries, daycare centers, schools, camps, and sports teams. The enteroviruses have also occasionally been associated with pandemics, as occurred with acute hemorrhagic conjunctivitis caused by enterovirus 70 and group A coxsackievirus 24.

The use of live attenuated poliovirus vaccines has led to the problem of vaccine-derived polioviruses (VDPVs) as a result of the excretion of neurorevertant vaccine (Sabin) strains from immunodeficient individuals or as a result of natural recombination between Sabin strains of poliovirus and members of the human enterovirus C species. VDPVs that can circulate in the environment with evidence of person-to-person transmission have been termed circulating vaccine-derived polioviruses (cVDPVs). A third group of VDPVs, designated ambiguous VDPVs, are clinical isolates from individuals without known immunodeficiency or sewage isolates whose ultimate source is unknown. Similar to wild-type poliovirus, cVDPVs can cause acute flaccid paralysis in unimmunized or incompletely immunized individuals. Outbreaks of cVDPV disease have been reported in Cambodia, China, the Dominican Republic, Egypt, Haiti, Indonesia, Madagascar, Myanmar, Nigeria, and the Philippines. As a result of effective antipolio immunization programs, wild-type polioviruses remain endemic only in India, Afghanistan, Pakistan, and Nigeria, where they are periodically introduced into neighboring countries.

PATHOBIOLOGY

The polioviruses and the majority of the nonpolio enteroviruses are transmitted via a fecal-oral route. Notable exceptions include group A coxsackievirus 21, which is spread via the respiratory route, and enterovirus 70, which may spread via contaminated fomites or ocular and respiratory secretions. Evidence also supports transplacental transmission.

Ingestion of the enteroviruses results in infection of cells of the pharynx and, because the virus is acid resistant, the lower gastrointestinal tract. Initial viral replication, which is thought to occur in the mucosal tissues of the nasopharynx and intestinal tract (i.e., tonsils and Peyer's patches), leads to seeding of the deep cervical and mesenteric lymph nodes. Further replication at these sites results in a minor viremia with seeding of multiple organs, including the liver, lungs, heart, and central nervous system (CNS). Viral replication at these sites causes many of the clinical manifestations of infection and is followed by a major viremia that may infect the CNS if it was spared during the initial viremia. The virus is cleared by type-specific neutralizing antibodies directed at the capsid proteins by day 7 to 10 after infection. IgA antibodies appear in the respiratory and gastrointestinal tracts 2 to 4 weeks after infection.

The host humoral immune response appears to be pivotal in the prevention and eradication of enteroviral infections. Congenital or acquired B-cell immunodeficiencies may result in prolonged or chronic infection, and the interferons, natural killer cells, and gamma or delta T cells may play roles in regulating the host T-cell response.

Histopathologic findings in patients who are dying of poliomyelitis (Chapter 423) reveal neuronal necrosis in association with mononuclear and polymorphonuclear infiltrates that are initially perivascular in distribution but are later found diffusely within the gray matter of the anterior horns of the spinal cord, the reticular formation of the hindbrain, the vestibular nuclei, and the roof nuclei of the cerebellum. In nonpolio enterovirus CNS infections in immunocompetent hosts, findings include edema of the meninges and cerebral parenchyma, with microscopic perivascular lymphocytic infiltration, increased numbers of oligodendrocytes, and focal areas of necrosis and hemorrhage. In cases of enteroviral myocarditis (Chapter 60), a mononuclear cell inflammation is associated with widespread myocardial necrosis followed by fibrosis, which may be focal but results in myocardial damage.

CLINICAL MANIFESTATIONS

The incubation period for enterovirus infections is generally 3 to 6 days. Depending on serotype and the age of the patient, as many 90% of infected individuals may have subclinical infections. The enteroviruses are responsible for a wide array of clinical syndromes affecting nearly every organ system, and no enterovirus serotype is uniquely associated with a single disease or clinical syndrome (Table 387-3).

TABLE 387-3 CLINICAL MANIFESTATIONS OF NONPOLIO ENTEROVIRUS INFECTIONS*

CLINICAL SYNDROME	GROUP A COXSACKIEVIRUSES†	GROUP B COXSACKIEVIRUSES	ECHOVIRUSES‡	ENTEROVIRUSES
Asymptomatic infection	All serotypes	All serotypes	All serotypes	All serotypes
Undifferentiated febrile illness ("summer grippe") with or without respiratory symptoms	All serotypes	All serotypes	All serotypes	68, 70, 71
Aseptic meningitis (often associated with an exanthem)	1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 14, 16, 17, 18, 22, 24	1, 2, 3, 4, 5, 6	1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11,12, 14, 16, 17, 18, 19, 20, 21, 25, 30, 31, 33	70, 71

Pleurodynia	1, 2, 4, 6, 9, 10, 16	1, 2, 3, 4, 5, 6	1, 2, 3, 6, 7, 8, 9, 11, 12, 14, 16, 19, 25, 30	
Herpangina	1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 16, 22	1, 2, 3, 4, 5	6, 9, 11, 16, 17, [22], 25	71
Hand-foot-and-mouth disease	4, 5, 7, 9, 10, 16	2, 5	7	71
Exanthems	2, 4, 5, 6, 7, 9, 10, 16	1, 2, 3, 4, 5	2, 4, 5, 6, 9, 11, 16, 18, 25	71
Common cold	2, 10, 21, 24	1, 2, 3, 4, 5	2, 4, 8, 9, 11, 20, 25	
Lower respiratory tract infections (bronchiolitis, pneumonia)	7, 9, 16	1, 2, 3, 4, 5	4, 8, 9, 11, 12, 14, 19, 20, 21, 25, 30	68, 71
Acute hemorrhagic conjunctivitis§	24			70
Generalized disease of the newborn	3, 9, 16	1, 2, 3, 4, 5	3, 4, 6, 7, 9, 11, 12, 14, 17, 18, 19, 20, 21, 30	

*A great many enterovirus serotypes have been implicated in most of these syndromes, at least in sporadic cases. The serotypes listed are those that have been clearly or frequently implicated. Serotypes with a strong association are underlined.
†Because isolation of many of the group A coxsackieviruses requires suckling mouse inoculation, they are likely to be underreported as causes of illness.
‡Conjunctivitis without hemorrhage is frequently seen in association with other manifestations in patients infected with many group A and group B coxsackieviruses and echoviruses, especially coxsackieviruses A9, A16, and B1 to B5 and echoviruses 2, 7, 9, 11, 16, and 30.
From Modlin JR. Enterovirus. *Cecil Textbook of Medicine*, 23rd ed. Philadelphia, PA: WB Saunders; 2008, with minor changes.

The most frequent enteroviral syndrome, seen in about 50 to 80% of cases, is febrile illness, which occurs most commonly in infants, toddlers, and young children. The onset of illness is abrupt, with fever, poor appetite, lethargy, irritability, emesis, diarrhea, and upper respiratory tract symptoms. Physical findings are minimal and consist of mild pharyngeal and conjunctival injection and lymphadenopathy. Exanthems may be present in about 25% of cases.

DIAGNOSIS

Nucleic acid amplification techniques (e.g., reverse transcription–polymerase chain reaction [RT-PCR] and nucleic acid–based sequence amplification) are the preferred methods for detecting and identifying all enteroviruses. Multiple studies have documented that nucleic acid amplification techniques are more sensitive than cell culture for the detection of enteroviruses in cerebrospinal fluid (CSF). RT-PCR can detect enteroviruses in CSF, blood, tissue, stool, and other body fluids within hours, and the results can shorten hospitalizations, decrease the use of antibiotics, and reduce health care costs.

Serologic testing is now of limited use, although a four-fold change in antibody titer to a specific serotype of enterovirus in paired acute and convalescent sera can establish the diagnosis. Viral cultures are not recommended because of their limited sensitivity, prolonged positivity even after the related clinical syndrome may have resolved, and the several days required for viral detection.

TREATMENT AND PROGNOSIS

Rx

Nonspecific febrile enteroviral infections generally resolve in less than 5 days without sequelae. Because of concern for possible occult bacterial infection, however, significant numbers of young infants and children are hospitalized for evaluation and empirical therapy. Following infection, virus may be shed into the nasopharynx for 2 to 6 weeks and in feces for several months.

SPECIFIC CLINICAL SYNDROMES

Central Nervous System Infections

ACUTE FLACCID PARALYSIS

CLINICAL MANIFESTATIONS AND DIAGNOSIS

During poliovirus epidemics, 90 to 95% of infections are subclinical. In another 4 to 8% of patients, infection results in fever, fatigue, headache, anorexia, myalgia, and sore throat, which resolve in 2 to 3 days. Paralytic polio (Chapter 423) develops in less than 1 to 2% of infected individuals.

Acute flaccid paralysis is also seen with other enteroviruses, including group A coxsackievirus 7, enterovirus 70, and enterovirus 71. With the exception of enterovirus 71, the paralysis associated with nonpolio enteroviruses tends to be milder, and fever is not present at the time of onset of the paralysis. The upper extremities and face are more commonly involved. Sensory pathways remain intact.

CSF may reveal a mild lymphocytic pleocytosis (<100 cells/mm^3) in association with mildly increased protein and a normal glucose concentration. Neuroimaging is not generally useful, but increased signal may be seen on T2-weighted magnetic resonance imaging (MRI) in the anterior horn regions in patients with acute flaccid paralysis caused by poliovirus and nonpolio enteroviruses.

TREATMENT AND PROGNOSIS

Rx

No specific therapy exists. Efforts should focus on monitoring for the development of respiratory failure or airway compromise, as well as control of pain associated with muscle spasms.

The mortality associated with spinal poliomyelitis is about 5%. Before modern methods of respiratory and cardiovascular support, mortality rates higher than 50% were common in patients with bulbar or medullary poliomyelitis. The ultimate outcome of the paralysis is highly variable and can range from complete resolution to lifelong persistence. The greatest gains in recovery of strength occur during the first 6 months. Paralytic limbs become atrophic, thereby leading to skeletal deformities. Patients with nonpolio enteroviruses usually have a more rapid recovery and less atrophy than do those with classic polio.

A syndrome of postpoliomyelitis muscular atrophy, which may be seen in up to 25% of individuals 2 to 3 decades after recovery from paralytic disease, is characterized by the gradual development of weakness, pain, and atrophy. Possible mechanisms include aging and neuronal dropout in compromised neuromuscular connections or reactivation/ongoing poliovirus infection.

MENINGITIS

The enteroviruses, especially echoviruses and group B coxsackieviruses, are the dominant cause of viral meningitis (Chapter 420) in all ages.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical picture varies with age. The predominant symptoms of meningitis in neonates are nonspecific fever, irritability, lethargy, and poor feeding, often with a full fontanelle and a generalized rash. In neonates with meningoencephalitis, clinical findings may consist of fever, lethargy, seizures, full fontanelle, and focal neurologic abnormalities. Hepatitis, myocarditis, or pneumonitis, singly or in combination, may be present in severe cases.

In older infants and children, an abrupt onset of fever is the most frequent initial symptom. The fever may persist for 1 to 5 days and may exhibit a biphasic pattern. Irritability or lethargy is common. Other nonspecific symptoms include poor feeding, vomiting, diarrhea, and rash. Headache is present in nearly all children old enough to report it. Rash, malaise, sore throat, abdominal pain, and myalgia are common, and photophobia may be reported. Seizures occur in less than 5% of cases. Examination may reveal a full fontanelle. Signs of meningeal irritation (i.e., nuchal rigidity, Brudzinski's and Kernig's signs) occur in less than 10% of infants younger than 3 months and increase with age.

In adolescents and adults, headache is nearly always present and severe enough to require narcotic analgesics for control. Some patients report temporary relief of headache following lumbar puncture. Fever is not universal, but photophobia, signs of meningeal irritation, nausea, emesis, and neck stiffness occur in more than two thirds of patients. Myalgia is reported in 20 to 90% of patients. Less frequent findings include rash and abdominal pain.

CSF analysis generally reveals a mild to moderate pleocytosis (<500 cells/mm^3). However, some patients have no cells and others may have several thousand. The protein concentration may be increased. Although the glucose concentration is generally normal, hypoglycorrhachia may occur, particularly in association with group B coxsackievirus meningitis. Neuroimaging in cases of meningitis is generally unrevealing. Nucleic acid amplification testing can detect enteroviruses in CSF. The serotypes most frequently identified from CSF specimens are, in descending order, enterovirus 9, enterovirus 11, enterovirus 30, group B coxsackievirus 5, enterovirus 6, group B coxsackievirus 2, group A coxsackievirus 9, enterovirus 4, group B coxsackievirus 4, enterovirus 7, enterovirus 18, enterovirus 5, and enterovirus 13.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive, with control of fever and pain. Hospitalization may not be necessary in adolescents and adults who appear well if a bacterial cause can be confidently excluded. In children or infants or when bacterial infection cannot be confidently excluded in adults, hospitalization and initial empirical antimicrobial therapy are advisable (Chapter 420) while awaiting the results of bacterial cultures of blood and CSF. Intravenous fluids may be required to prevent dehydration. Control of headache pain may require narcotic analgesics. Uncommon complications in all ages include coma, increased intracranial pressure, and inappropriate secretion of antidiuretic hormone.

The overwhelming majority of patients recover fully. The duration of illness in infants and children is generally less than 1 week. In adults, full recovery may take up to 3 weeks.

ENCEPHALITIS

The enteroviruses are responsible for up to 20% of identifiable causes of viral encephalitis (Chapter 422). In the single largest report of enterovirus-related encephalitis, 73% of confirmed cases occurred in individuals younger than 20 years, including about 40% of cases in patients younger than 10 years.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The onset of neurologic findings may be abrupt or be preceded by fever, headache, malaise, myalgia, upper respiratory symptoms, rash, nausea, emesis, or diarrhea. Somnolence, lethargy, and altered consciousness are common. Patients may exhibit irritability, changes in personality, or hallucinations. Generalized or focal seizures occur in up to 30% of patients, and a minority of patients may progress to coma. Neck stiffness and ataxia are frequent physical findings. Focal neurologic findings such as hemiplegia, hemichorea, and paresthesias are reported in nearly 30% of patients. The focal nature of the seizures and abnormal neurologic findings may be reminiscent of herpes simplex virus encephalitis (Chapter 382).

Among enteroviral encephalitides, enterovirus 71 is uniquely associated with severe brain stem encephalitis (rhombencephalitis), primarily in children. The initial manifestation may be a prodrome of either hand-foot-and-mouth disease or herpangina, which is followed by myoclonus that may be associated with ataxia, tremors, or cranial nerve abnormalities and a rapid onset of neurogenic pulmonary edema, shock, coma, and apnea.

Evaluation of CSF may reveal mild to moderate pleocytosis (<500 cells/mm^3), but the CSF white cell count may be normal. The protein concentration may be increased and may be the sole abnormality. The glucose concentration is generally normal. Enteroviruses may frequently be detectable by nucleic acid amplification testing of CSF.

TREATMENT AND PROGNOSIS

Rx

Management is supportive, with monitoring for the development of respiratory failure or airway compromise. Nearly 50% of patients require intensive care. In patients with focal neurologic findings, empirical acyclovir (10 to 15 mg/kg every 8 hours) is warranted until herpes simplex virus is excluded.

The median duration of hospitalization is less than 1 week, and mortality is below 10%. For severe enterovirus 71 rhombencephalitis, however, mortality may approach 70%. Long-term sequelae following rhombencephalitis include myoclonus, abducens nerve palsy, facial diplegia, ataxia, dysarthria, internuclear ophthalmoplegia, and central apnea.

Myopericarditis

The enteroviruses—predominantly group B coxsackieviruses—are responsible for approximately a third of cases of acute myocarditis (Chapter 60). The majority of cases occur in young adults.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

An upper respiratory tract infection may precede the onset of cardiac symptoms by 1 to 2 weeks. Fever may be present, and common initial symptoms include dyspnea, chest pain, and fatigue. Physical examination may reveal a gallop rhythm or a pericardial friction rub.

Cardiomegaly may be seen on the chest radiograph. Electrocardiographic findings vary and include low-voltage QRS complexes, ST segment depression, T wave inversion, pathologic Q waves, ventricular arrhythmias, and heart block. Echocardiographic findings include a decreased ejection fraction, ventricular dilation, or pericardial effusion. Blood troponin levels are frequently elevated. Cardiac MRI may help localize areas of myocarditis. Myocardial biopsy is recommended in selected patients who have refractory heart failure or suspected giant cell myocarditis (Chapter 60); enterovirus can be detected by nucleic acid amplification tests.

TREATMENT AND PROGNOSIS

Rx

Supportive treatment includes bedrest and management of heart failure (Chapter 59), arrhythmias (Chapters 64 and 65), and pericarditis with or without pericardial effusion (Chapter 77). Immunosuppressive therapy is not generally recommended (Chapter 60). In approximately a third of patients with acute myocarditis, chronic dilated cardiomyopathy develops. In patients with pericarditis, recurrent pericardial effusions or chronic constrictive pericarditis may develop in the future.

Exanthems and Enanthems

Enterovirus infections may result in a wide spectrum of febrile exanthems and enanthems, including macular, papular, maculopapular, morbilliform, rubelliform, vesicular, urticarial, papulopustular, and scarlatiniform types. Exanthems are more commonly observed in children 15 years or younger. Any serotype is capable of causing several different rashes. With the exception of group A coxsackievirus 16, no serotype is associated with a unique rash. Echovirus 9 and group A coxsackievirus 9 can cause petechial or purpuric rashes reminiscent of meningococcemia (Chapter 306).

Hand-Foot-and-Mouth Disease and Herpangina

Hand-foot-and-mouth disease is typically associated with group A coxsackievirus 16, but other group A coxsackieviruses and enterovirus 71 may also cause this syndrome. Herpangina is most commonly caused by the group A coxsackieviruses but has also been associated with group B coxsackieviruses, echoviruses, and numbered enteroviruses.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hand-foot-and-mouth disease begins with low-grade fever, malaise, anorexia, and oral soreness. In 1 to 2 days, oral macules appear and then rapidly vesiculate and ulcerate. Oral lesions are typically distributed on the buccal mucosa and tongue, but they may also occur on the palate, uvula, anterior pillars, and gums. In approximately two thirds of patients, the enanthem is accompanied by an exanthem, with tender 3- to 7-mm vesicles on the dorsum of the hands and feet, frequently involving the palms and soles. Lesions may appear on the buttocks but tend not to be vesicular.

Herpangina begins with high fever, particularly in young patients. Additional findings include sore throat, mild cervical lymphadenopathy, sialorrhea, anorexia, dysphagia, abdominal pain, and emesis. Examination of the mouth and throat reveals 1- to 2-mm papulovesicular, grayish white lesions with an areola of erythema, primarily located on the anterior pillars of the tonsillar fauces. The soft palate, uvula, and tonsils may also be involved. Rarely, the posterior buccal surfaces and dorsal tip of the tongue may be involved. Over a period of 2 to 3 days, the lesions increase to 3 to 4 mm in size. On average, five lesions are present.

TREATMENT AND PROGNOSIS

Rx

Hand-foot-and-mouth disease usually resolves in less than 1 week and herpangina generally resolves in 10 days, both typically uneventfully, without the need for hospitalization, and without sequelae. Infants and young children may require hospitalization for administration of parenteral fluids.

Acute Hemorrhagic Conjunctivitis

Acute hemorrhagic conjunctivitis is associated with enterovirus 70 and group A coxsackievirus 24. The illnesses caused by the two serotypes are indistinguishable from each other. However, acute hemorrhagic conjunctivitis caused by group A coxsackievirus 24 may be more commonly accompanied by upper respiratory and systemic symptoms and may be associated with less severe conjunctival hemorrhage. High secondary attack rates within households are common. Other enteroviruses can cause acute conjunctivitis or keratoconjunctivitis but generally without hemorrhagic manifestations.

CLINICAL MANIFESTATIONS

An incubation period of about 1 to 2 days precedes the rapid onset of palpebral swelling associated with lacrimation, photophobia, blurring of vision, and severe ocular pain. The hallmark subconjunctival hemorrhages vary in size from petechiae to large blotches. Although transient keratitis occurs frequently, it seldom results in subepithelial opacities. Preauricular adenopathy is common, but fever is not. An ocular mucopurulent discharge may occasionally be present.

TREATMENT AND PROGNOSIS

Rx

Management is supportive. The illness usually persists for 1 to 2 weeks, but complete recovery is generally the rule. A transient lumbar radiculomyelopathy and acute flaccid paralysis–like illness may develop in some patients.

Respiratory Tract Syndromes

The enteroviruses may cause upper and lower respiratory tract syndromes, alone or accompanying other syndromes. As determined by nucleic acid amplification testing, enteroviruses are responsible for up to 15% of upper respiratory tract syndromes. They also cause 18% of lower respiratory tract syndromes in hospitalized children and 25% of hospitalizations in patients with acute wheezing.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The enterovirus "summer cold" (Chapter 369) consists of nasal congestion, rhinorrhea, and sneezing. Malaise and cough may be present. Fever and sore throat are typically absent or minimal.

Pharyngitis, tonsillitis, or pharyngotonsillitis begins abruptly with fever and sore throat. The nasopharynx, tonsils, uvula, and soft palate demonstrate

erythema and inflammation. Petechiae may be present, and cervical lymphadenitis is common.

Enteroviral pneumonias begin gradually with coryza, anorexia, and low-grade fever. A nonproductive cough, tachypnea, retractions, nasal flaring, and wheezing may be present. In severe cases, cyanosis may develop. The chest radiograph may demonstrate perihilar infiltrates, patchy consolidation, air trapping, and atelectasis.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive and consists of control of fever and pain. In older children and adults, hospitalization is not usually required. Resolution occurs in 7 days or less.

Myositis

PLEURODYNIA

The group B coxsackieviruses are the usual cause of sporadic and epidemic pleurodynia, but the syndrome may also be caused by other enteroviruses.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The onset of illness is abrupt in approximately 75% of patients. In the remainder, the onset of pleuritic chest pain is preceded by a prodrome of headache, malaise, anorexia, and vague myalgia lasting up to 10 days. Pain may be referred to the lower ribs or the sternum, and it can radiate to the shoulders, neck, or scapula. Pain is exacerbated by deep breathing, coughing, sneezing, or movement. During paroxysms, patients tend to be tachypneic and to have shallow breathing. Additional findings can include abdominal pain, headache, cough, anorexia, nausea, vomiting, and diarrhea. Fever may be biphasic.

Physical examination does not generally reveal muscle tenderness, obvious myositis, or muscle swelling. A pleural friction rub may be present in 25% of patients. The chest radiograph is typically normal.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive, with an emphasis on nonsteroidal analgesics (e.g., ibuprofen, 200 to 400 mg per dose every 4 to 6 hours) or hydrocodone (5 to 10 mg four times per day) alone or in combination with acetaminophen to control pain. The symptoms may persist for 1 to 14 days (mean of 3.5 days) and resolve without sequelae, although recurrent symptoms may occur in 25% of patients.

INFLAMMATORY MYOSITIS

Multiple enteroviral serotypes are associated with focal or generalized myositis. In patients with B-cell immunodeficiencies, a dermatomyositis-like syndrome may develop.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Nonspecific findings include fever and chills. Involved muscles may be weak, tender, and edematous. Chemical evidence of myositis may be evidenced by elevated serum levels of creatine kinase, myoglobinemia, and myoglobinuria.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive. With the exception of patients with B-cell immunodeficiencies, recovery is complete and rapid.

Enterovirus Infections in Special Populations

PATIENTS WITH B-CELL IMMUNODEFICIENCIES

Nonpolio enteroviruses and polioviruses may result in chronic or prolonged infections in patients with congenital or acquired B-cell immunodeficiencies (Chapter 258), such as those with X-linked agammaglobulinemia, hyper-IgM syndrome, severe combined immunodeficiency syndrome, or common variable immunodeficiency, or in patients who are receiving chemotherapy or immunomodulatory therapies or undergoing bone marrow or solid organ transplantation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Meningoencephalitis, pulmonary infections, and severe gastroenteritis can occur. The initial symptoms may consist of only persistent headaches and lethargy. As the disease progresses, additional neurologic findings develop and may include ataxia, loss of cognitive skills and memory, dementia, emotional lability, paresthesias, weakness, dysarthria, and seizures. Non-CNS manifestations include dermatomyositis-like syndrome, edema, exanthems, and hepatitis. CSF demonstrates a persistently elevated protein concentration and pleocytosis. Enterovirus is detectable in CSF by viral culture or RT-PCR.

TREATMENT AND PROGNOSIS

Rx

Children with humoral immunodeficiency (Chapter 258) should receive lifelong immunoglobulin replacement therapy in an attempt to prevent chronic infection. However, chronic meningoencephalitis develops in some patients and is usually ultimately fatal.

PREVENTION

Handwashing is the primary method for the prevention of enteroviral infections. Only poliovirus infections (Chapter 423) are preventable through vaccination.

ROTAVIRUSES, NOROVIRUSES, AND OTHER GASTROINTESTINAL VIRUSES

MANUEL A. FRANCO AND HARRY B. GREENBERG

DEFINITION

Viruses are the agents of acute infectious gastroenteritis, a syndrome of vomiting, watery diarrhea, or both that begins abruptly in otherwise healthy persons. Two distinct viruses account for the majority of cases. Rotaviruses are the principal agent of sporadic, severe gastroenteritis in young children and are responsible for the death of approximately 1600 children daily worldwide, mainly in developing countries (Fig. 388-1). Noroviruses are the principal agent of epidemic infectious gastroenteritis in both infants and adults. For example, outbreaks of gastroenteritis in closed settings, such as cruise ships and nursing homes, are a typical manifestation of norovirus infections. However, noroviruses are also a common cause of sporadic, severe gastroenteritis in young children.

The Pathogens

Noroviruses

Noroviruses, which are one of the five genera of the Caliciviridae family, are nonenveloped, icosahedral viruses with a relatively small, positive-sense, single-stranded RNA genome. The norovirus genus is further classified into five genogroups (GI to GV), only three of which (GI, GII, and GIV) are known to infect humans. GIII and GV viruses infect bovines and mice, respectively, and to date these animal viruses have not been shown to infect humans. Viruses in each genogroup are further divided into genotypes (more

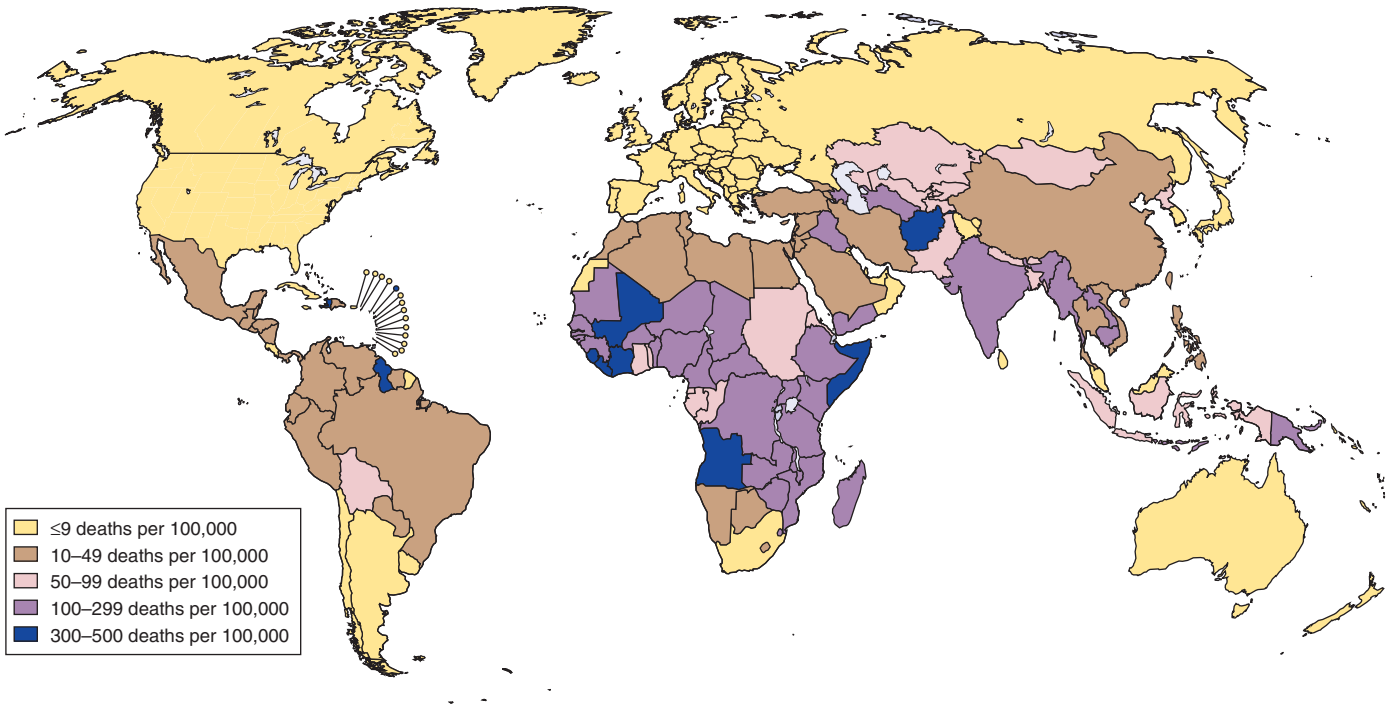

FIGURE 388-1. Mortality rate associated with rotavirus disease worldwide. (Based on World Health Organization data and modified with permission from Danchin MH, Bines JE. Defeating rotavirus? The global recommendation for rotavirus vaccination. *N Engl J Med.* 2009;361:1919-1921.)

TABLE 388-1 EPIDEMIOLOGIC AND CLINICAL FEATURES OF NOROVIRUS AND ROTAVIRUS

	NOROVIRUS	ROTAVIRUS	ASTROVIRUS
Epidemics	Occurs year-round; outbreaks tend to peak in cold weather	Year-round in equatorial countries; winter peak in others	Winter epidemics in children and endemic year-round
Key driver of epidemics	Antigenic drift strains promoted by population-based immunologic pressure	Size of the susceptible birth cohort	Unknown
Transmission	Fecal-oral, water, and food-borne outbreaks	Fecal-oral	Fecal-oral
Severity of diarrhea in children	Generally mild but can be severe	Most severe	Milder than rotavirus or noroviruses
Reservoir	Humans are the only known reservoir of noroviruses that infect humans	Mostly humans, but rotaviruses from farm animals and pets (especially in developing countries) infect humans	Humans are the only known reservoir of astroviruses that infect humans
Prevention	Viral protein 1-based vaccine in development	Several vaccines available	No vaccine in development
Age predisposition	All ages	Children <5 years; disease transmission in older family contacts is low (<25%)	Generally children, but adults may also get disease

VLP = Norwalk virus (NV) virus-like particles.

than 25 have been described) and subgroups. Norwalk virus is a prototype genogroup I genotype 1 (GI.1) virus. The norovirus genome is approximately 7.7 kilobases in size and consists of three open reading frames, the first of which encodes the nonstructural proteins that are essential for virus replication. The second open reading frame encodes the major capsid protein, viral protein 1 (VP1). When it is expressed as a recombinant protein, 180 molecules of VP1 autoassemble into virus-like particles that are critical to the study of noroviral epidemiology and immunity. Human noroviruses have not yet been adapted to cell culture, so diagnosis generally depends on amplification of virus genes by the polymerase chain reaction (PCR; see later).

Rotavirus

Rotaviruses, which belong to the family Reoviridae, are large, icosahedral, nonenveloped viruses with a segmented, double-stranded RNA genome and a triple-layered protein coat. Rotaviruses are classified into groups A through G on the basis of the presence of cross-reactive antigenic epitopes and their overall genetic relatedness. Group A rotaviruses are the principal enteric pathogen of humans and many other species. Group B viruses have been identified sporadically in outbreaks of adult diarrheal illness in China and more recently in studies of children with sporadic gastroenteritis, principally in India. Group C rotaviruses are relatively infrequently associated with diarrheal disease in humans and animals around the world. Groups D through G rotaviruses have been isolated only from animals, primarily avian species. Rotaviruses are 100-nm particles that have three concentric layers of proteins: the core is composed of VP1, VP2, and VP3 and the segmented, double-stranded RNA genome; the intermediate layer is formed by VP6, the most abundant and antigenic structural viral protein; and the external layer is composed of VP7 and VP4. The genome is composed of 11 segments of double-stranded RNA that together are approximately 18 kilobases and encode six structural and six nonstructural proteins. As is the case among virtually all other RNA viruses, the rotavirus RNA polymerase is error prone and, along with selective pressure such as the evolution of immunity, drives viral diversity. For rotaviruses, gene reassortment, which is the mixing of gene segments from different parental viruses in cells coinfected by two or more strains, and rearrangement of the viral genome also contribute to genetic diversity. Reassortment of gene segments between animal and human rotavirus strains also occurs in natural settings, especially in less developed countries.

Other Agents

Other viral agents that cause human acute infectious gastroenteritis that is difficult to distinguish from disease caused by rotaviruses and noroviruses include the sapovirus (like norovirus, a member of the Caliciviridae family), enteric adenoviruses (Chapter 373) belonging to types 40 and 41, and astroviruses (Table 388-1). The frequency of detection (by PCR assays) of these viruses in individuals with acute gastroenteritis depends on the setting, but

they are almost always detected less frequently than rotaviruses and noroviruses. Coronaviruses (Chapter 374), toroviruses, picobirnaviruses, picornavirus (Chapter 387), bocavirus, parechoviruses, and pestiviruses have also been isolated occasionally from persons with acute gastroenteritis, but their roles as causative agents of enteric disease remain uncertain. Among patients with acute gastroenteritis, no etiologic agent is found in approximately 25 to 50% of cases.

EPIDEMIOLOGY

Norovirus

Over time, noroviruses appear to undergo antigenic drift in response to the acquisition of immunity in the general population, much like influenza viruses. At present, gastroenteritis cases around the world are most frequently caused by the GII.4 norovirus strain, but new strains generally evolve every 2 to 4 years owing to antigenic drift. Outbreaks frequently take place in settings of close human contact, such as military establishments, cruise ships, nursing homes, and schools, especially in cold and dry weather (see Table 388-1). Viral spread is enhanced by the very high level of infectivity of noroviruses, as data suggest that 1 to 10 particles constitute an infectious dose.

Noroviruses also are responsible for about 12% of sporadic gastroenteritis in children younger than 5 years in both developed and developing countries. Overall, it is estimated that noroviruses annually cause 900,000 outpatient visits and 64,000 hospitalizations among children in developed countries as well as up to 200,000 deaths of children younger than 5 years in developing countries.

Rotavirus

The incidence of rotaviral disease is similar in children in both developed and developing countries, suggesting that measures such as access to clean water will not replace the need for an effective vaccine. Before the introduction of an effective vaccine, rotavirus was estimated to be responsible for about 600,000 annual deaths worldwide. In developed countries, rotavirus rarely is fatal; but before the introduction of vaccines in the United States, it resulted in hospitalization for rotavirus-mediated gastroenteritis in about 1 in 75 children by 5 years of age.

In the temperate zones of the world, rotaviral infection occurs primarily during epidemic peaks in the cooler months of the year (see Table 388-1). This pattern is not seen, however, in countries within 10 degrees of the equator, where infection occurs in an endemic fashion year-round. Before the introduction of rotavirus vaccination, a yearly wave of rotaviral illness spread across the United States and Europe following peculiar spatiotemporal patterns. In the United States, this pattern of spread has been correlated with variation in birth rates, thereby suggesting that the number of babies experiencing their first infection is one of the primary drivers of rotavirus epidemics. The high birth rates in developing countries may also influence the differential epidemiologic distribution of rotaviruses. Antibodies against the outer capsid proteins are the basis of serotypic classification of rotaviruses into G (glycoprotein, VP7) and P (protease-sensitive, VP4) serotypes. For technical reasons, P serotyping reagents are infrequently available, and classification is based on the P genotype (provided in brackets). Worldwide, most human infections are caused by five types of group A rotavirus; P[8]G1 is by far the most common (approximately 53% of strains), followed by P[8]G3, P[4]G2, P[8]G9, and P[8]G4. In some developing areas like India, Brazil, and Africa, P[6]G9, G5, and G8 rotaviruses, respectively, are most frequently encountered. Some human rotavirus strains may have arisen after reassortment with bovine or porcine rotaviruses. A high prevalence of G12 viruses has recently been observed in several countries, thereby suggesting that this serotype may be an emerging rotavirus strain.

PATHOBIOLOGY

Norovirus

Histo-blood group antigens (HBGAs) are the receptors for noroviruses and determine susceptibility to disease in a strain-specific manner. The HBGAs are complex carbohydrate oligosaccharides linked to proteins or lipids that are expressed on the mucosal epithelia of the digestive tract. All three major families of HBGA, the ABO, Lewis, and secretor families, are involved in binding noroviruses. The secretor status of a person is controlled by the fucosyltransferase 2 (*FUT2*) gene. Secretor-negative individuals are specifically resistant to infection with the Norwalk virus (GI.1) and some GII viruses.

Although norovirus RNA has been detected in the blood stream of up to 15% of patients with norovirus gastroenteritis, the site of primary viral replication is most probably in the gastrointestinal tract. Consistent with the strong association of vomiting with norovirus disease, gastric emptying is delayed. Proximal jejunal biopsy specimens show blunting of the villi with crypt cell hyperplasia and cytoplasmic vacuolation, sometimes with an increase in epithelial cell apoptosis. A functional alteration of the epithelial barrier is likely to occur. Unknown at present is the effectiveness and persistence of immunity in the context of natural infection, in which the infectious dose is generally quite low.

Rotavirus

Rotaviruses replicate in the villus tip cells of the small bowel, where the pathologic process includes shortening and atrophy of the villi, mononuclear infiltration in the lamina propria, and distention of the cisternae of the endoplasmic reticulum. However, the severity of clinical disease is not directly related to the extent of intestinal disease; rather, it is related to levels of viral RNA in stool.

During the initial phases of the disease, altered intestinal secretion, motility, and permeability contribute to the pathophysiologic mechanism of diarrhea. Later in the course of disease, malabsorption can occur. Rotaviral NSP4 is a viral enterotoxin that mediates, at least in part, the early secretory components of the diarrhea. It has also been postulated that viral infection increases intestinal motility by stimulating the enteric nervous system, possibly through NSP4. Whether and to what degree the enterotoxic effect of NSP4 is clinically relevant in children or other animal species remains to be determined. Infected individuals have a short period of viremia, but its clinical consequences are unclear other than correlating with the level of fever.

Rotavirus serum IgA levels measured shortly after natural infection in children generally correlate with intestinal IgA levels and appear to correlate with protection. One explanation for recurrent rotavirus (and norovirus) infections is that protection from reinfection is mediated by intestinal IgA, which is not long-lasting in humans. Another explanation is that protection is dependent on neutralizing antibodies to one or both of the highly variable outer rotaviral proteins. However, a monovalent P[8]G1 vaccine induces significant protection against strains with different serotypes, thereby supporting the conclusion that protective immunity to rotavirus infection is, in part, heterotypic.

CLINICAL MANIFESTATIONS

Norovirus

The clinical manifestations of norovirus infection are variable and depend in part on the age of the individual infected. About one third of infections are asymptomatic, but symptoms include diarrhea, nausea, vomiting, abdominal cramps, fever, and malaise that generally persist for 2 to 3 days. In children younger than 11 years, disease typically begins with the sudden onset of vomiting and can last 4 to 6 days. Virus can be shed in low titers for up to 8 weeks from otherwise healthy individuals and for more than a year in patients with severe immunodeficiency syndromes. In neonates and premature infants, vomiting often is not a symptom, and infection has been associated with necrotizing enterocolitis. To support the diagnosis of norovirus outbreaks, the following four criteria have been proposed: (1) vomiting in more than half of affected persons; (2) mean (or median) incubation period of 24 to 48 hours; (3) mean (or median) duration of illness of 12 to 60 hours; and (4) absence of bacterial pathogens in stool culture.

Rotavirus

Rotavirus diarrhea and dehydration tend to be more severe than illness caused by the other childhood enteric pathogens. Rotavirus diarrhea is watery, persists for approximately 5 days, is often preceded by the sudden onset of vomiting, and is frequently accompanied by fever and dehydration. The incubation period of rotavirus is estimated to be less than 48 hours. Viral excretion in feces persists for 10 days in the majority of children and rarely can persist for up to 57 days. Excretion times are longer on examination by sensitive PCR-based assays rather than solid-phase immunoassay. By the age of 5 years, virtually all children have acquired immunity to rotavirus, and severe disease after this age is uncommon.

DIAGNOSIS

Norovirus

Reverse transcription–PCR (RT-PCR) is currently the procedure of choice to detect norovirus in clinical specimens, in food, and in water. Although enzyme-linked immunosorbent assays (ELISAs) to detect noroviruses are available in Europe, their sensitivity is genotype dependent, and diagnostic

specificity and sensitivity vary on the basis of the diversity of the circulating strains in the population. Moreover, these immunoassays are not easily adaptable for detection of new strains. Norovirus RNA is detected by RT-PCR in stool samples of up to 16% of healthy individuals, a finding that complicates the diagnosis of norovirus gastroenteritis. Although the relationship between disease symptoms and viral load has not been fully established, a quantitative real-time RT-PCR has been proposed to establish a relative threshold of positivity for attributing disease to norovirus.

Rotavirus

Before the introduction of the rotavirus vaccine in developed countries, well above 50% of the moderate to severe diarrheal episodes in young children during the rotavirus "season" were due to rotavirus. In tropical countries, the presence of other enteric pathogens and the absence of seasonal occurrence of rotaviral disease make it more difficult to determine which diarrheal episodes are caused by rotavirus without a diagnostic assay. Numerous ELISAs for rotavirus are commercially available, and these are generally sensitive, specific, and easy to use under most conditions. PCR has increased sensitivity for detection of rotavirus and has permitted easy typing of viruses. With PCR-based methods, however, up to 29% of healthy children younger than 1 year may be rotavirus positive, so it is difficult to associate the detection of the virus with gastroenteritis. Thus, ELISA or quantitative RT-PCR (using a threshold level as for norovirus) is preferable for diagnosis of rotavirus gastroenteritis.

PREVENTION

Norovirus

The development of a norovirus vaccine for humans is a challenge owing to the great degree of antigenic heterogeneity among circulating strains, the propensity of noroviruses to undergo antigenic drift, and the lack of known correlates of protection. High percentage alcohol-based sanitizers (99.5% ethanol) and 10% povidone-iodine antiseptics are superior to other alcohol-based sanitizers at reducing norovirus contamination. Simple household antimicrobial hand soap and handwashing with tap water also decrease viral contamination.

Rotavirus

Rotavirus vaccines have been based on two different approaches. One type of vaccine uses a mixture of reassortant viruses, each part human rotavirus and part animal rotavirus, to provide attenuation.[1,2] Another approach uses a single attenuated human virus.[3,4] Neither type of vaccine prevents subsequent rotavirus infection or mild illness, but both types prevent severe illness.

The first vaccine (Rotashield, Wyeth-Lederle), which used a mixed rhesus-human rotavirus, was effective and licensed for use in the United States, but it was subsequently withdrawn from the market because of its association with intussusception. Subsequently, two second-generation vaccines were shown in large studies to be safe without detectable risk of intussusception, effective, and cost-effective in developed and developing countries. RotaTeq (Merck) is a modified pentavalent vaccine made of bovine and human virus. Rotarix (GlaxoSmithKline) is a monovalent attenuated human virus vaccine.

Protection rates in developed and middle-income countries for each vaccine are similar, varying from 70 to 80% against any rotavirus disease to 90 to 100% against severe gastroenteritis.[5,6] These two vaccines may be only about 50% efficacious against severe diseases in the poorest developing countries.[5] However, even with the reduced effectiveness, the two licensed vaccines are still cost-effective. The World Health Organization now recommends the routine use of these vaccines.

TREATMENT

Rx

Because both norovirus and rotavirus disease resolves within days without treatment, the basic therapeutic goal is to prevent acute dehydration. The recommended oral rehydration salts solution, which now has an osmolarity of 331 mmol/L, is as effective as higher osmolarity solutions.[6] After rehydration, rapid age-appropriate refeeding is recommended. Rotavirus disease induces self-limited intestinal lactase deficiency, but lactose-containing products, particularly maternal milk, should not be withheld.

Passive oral immunotherapy with diverse preparations of immunoglobulins can shorten the duration of rotavirus infection but probably is economically feasible only for immunodeficient patients or low-birthweight infants. *Lactobacillus*, a bacterium present in yogurt, is safe and, in limited studies, appears moderately effective for treatment of acute rotavirus gastroenteritis. Nonetheless, different preparations of lactobacilli vary greatly in dose of bacteria, and a general recommendation on their use has not been issued. Several studies in developing countries have shown that zinc supplementation (10 mg/day for infants younger than 6 months and 20 mg/day for older children) is useful for the treatment and prevention of diarrhea, but further studies are needed to determine whether treatment will be useful in all developing and developed countries.

At present, no pharmacologic treatment of rotavirus or norovirus diarrhea is recommended. Racecadotril (4.5 mg/kg per day), an enkephalinase inhibitor that acts on the enteric nervous system, has been shown to be useful as an adjunct to treat rotaviral diarrhea in several small studies. Ondansetron (0.15 mg/kg per day), a serotonin antagonist, is effective in reducing the emesis from gastroenteritis during the phase of oral rehydration. In several small studies, nitazoxanide (15 mg/kg per day) was helpful in the treatment of rotavirus gastroenteritis. More studies are needed before any of these various preparations can be generally recommended for treatment of rotavirus diarrhea.

389

VIRAL HEMORRHAGIC FEVERS

DANIEL G. BAUSCH

DEFINITION

Viral hemorrhagic fever is an acute systemic illness classically involving fever, a constellation of initially nonspecific signs and symptoms, and a propensity for bleeding and shock. It may be caused by more than 25 different viruses from four taxonomic families, Filoviridae, Arenaviridae, Bunyaviridae, and Flaviviridae (Table 389-1), although not every virus in these families causes the syndrome. Hemorrhagic fever viruses are often named after the site of the first recognized case. All are single-stranded RNA viruses with small genomes (10 to 19 kilobases). The individual viruses have negative, positive, or ambisense polarities, depending on the specific virus. Pathogenicity varies widely

TABLE 389-1 PRINCIPAL VIRUSES CAUSING HEMORRHAGIC FEVER

VIRUS	DISEASE	PRINCIPAL RESERVOIR/ VECTOR	GEOGRAPHIC DISTRIBUTION OF DISEASE	ANNUAL CASES	DISEASE TO INFECTION RATIO	HUMAN TO HUMAN TRANSMISSIBILITY	CASE-FATALITY
FILOVIRIDAE							
Ebola	Ebola HF	Fruit bat (Egyptian fruit bat or *Rousettus aegyptiacus*, perhaps others)	Sub-Saharan Africa, Philippines	—[1]	1 : 1	High	25-85%, depending on species[2]
Marburg	Marburg HF	Fruit bat (Egyptian fruit bat or *Rousettus aegyptiacus*, perhaps others)	Sub-Saharan Africa	—[1]	1 : 1	High	25-85%
ARENAVIRIDAE[3]							
Old World							
Lassa	Lassa fever	Rodent (multimammate rat or *Mastomys natalensis*)	West Africa	30,000-50,000	1 : 5-10	Moderate	5-50%
Lujo[4]	Lujo HF	Unknown; presumed rodent	Zambia	Unknown	Unknown	Moderate to high	80%
New World							
Junin	Argentine HF	Rodent (corn mouse or *Calomys musculinus*)	Argentine Pampas	<50	1 : 1.5	Low	15-30%
Machupo	Bolivian HF	Rodent (large vesper mouse or *Calomys callosus*)	Beni department, Bolivia	<50	1 : 1.5	Moderate	15-30%
Guanarito	Venezuelan HF	Rodent (cane mouse or *Zygodontomys brevicauda*)	Portuguesa State, Venezuela	<50	1 : 1.5	Low	30-40%
Sabiá[5]	Brazilian HF	Unknown; presumed rodent	Rural area near São Paulo, Brazil?	—[5]	1 : 1.5	Low?	33%
Chapare[6]	Chapare HF	Unknown; presumed rodent	Cochabamba, Bolivia	Unknown	Unknown	Unknown	Unknown
BUNYAVIRIDAE							
Old World Hantaviruses							
Hantaan, Seoul, Puumala, Dobrava-Belgrade, others	HF with renal syndrome	Rodent (Hantaan: striped field mouse or *Apodemus agrarius;* Seoul: Norway rat or *Rattus norvegicus;* Puumala: bank vole or *Clethrionomys glareolus;* Dobrava-Belgrade: yellow-necked field mouse or *Apodemus flavicollis*)	Hantaan: northeast Asia Seoul: urban areas worldwide Puumala and Dobrava-Belgrade: Europe	50,000-150,000	Hantaan: 1 : 1.5 Others: 1 : 20	None	<1-50%, depending on specific virus

New World Hantaviruses							
Sin nombre, Andes, Laguna negra, others	Hantavirus pulmonary syndrome	Rodent (sin nombre: deer mouse or *Peromyscus maniculatus;* Andes: long-tailed rat or *Oligoryzomys longicaudatus*; Laguna negra: vesper mouse or *Calomys laucha*)	Sin nombre: North America, Andes Laguna negra: Southern South America	50,000-150,000	Sin nombre: 1 : 1 Others up to 1 : 20	None except for Andes virus	<1-50%, depending on specific virus
Rift Valley fever	Rift Valley fever	Domestic livestock/mosquitoes (*Aedes* and others)	Sub-Saharan Africa, Saudi Arabia, Yemen[7]	100-100,000[8]	1 : 100	None	50%
Crimean-Congo HF	Crimean-Congo HF	Wild and domestic vertebrates/tick (primarily *Hyalomma* species)	Africa, Balkans, southern Russia, Middle East, India, Pakistan, Afghanistan, western China	~500	1 : 1-2	High	15-30%
FLAVIVIRIDAE							
Yellow fever	Yellow fever	Monkey/mosquito (*Aedes aegypti,* other *Aedes* and *Haemagogus* spp)	Sub-Saharan Africa, South America up to Panama	5000-200,000[8]	1 : 2-20	No	20-50%
Dengue	Dengue HF	Human/mosquito (*Aedes aegypti* and *albopictus*)	Tropics and subtropics worldwide	Dengue HF: 100,000-200,000[8]	1 : 10-100, depending on age, previous infection, genetic background, and infecting serotype	None	Untreated: 10-15% Treated: <1%
Kyasanur Forest disease	Kyasanur Forest disease	Vertebrate (rodents, bats, birds, monkeys, others)/tick (*Haemaphysalis* species and others)	Karnataka State, India; Yunnan Province, China; Saudi Arabia[9]	~500	Unknown	Not reported, but laboratory infections have occurred	3-5%
Omsk HF	Omsk HF	Rodent/ticks (primarily *Dermacentor* and *Ixodes* species)	Western Siberia	100-200	Unknown	Not reported	1-3%

[1]Although some endemic transmission of the filoviruses (Ebola > Marburg) and Rift Valley fever virus occurs, these viruses have most often been associated with outbreaks. Filovirus outbreaks are typically fewer than 100 cases and have never been more than 500.
[2]Five species or subtypes of Ebola virus with varying associated case-fatality ratios are recognized: Ebola Zaire, 85; Ebola Sudan, 55%; Ebola Bundibugyo, 25%; Ebola Cote d'Ivoire, 0% (only one recognized case); Ebola Reston, 0% (not pathogenic to humans). All are endemic to sub-Saharan Africa, with the exception of Ebola Reston virus, which is found in the Philippines.
[3]In addition to the arenaviruses listed in the table, Flexal and Tacaribe viruses have caused human disease as a result of laboratory accidents. Another arenavirus, Whitewater Arroyo, has been noted in sick persons in California, but its role as a pathogen has not been clearly established.
[4]Discovered in 2008 in an outbreak of five cases (four of them fatal) in South Africa. The index case came to South Africa from Zambia.
[5]Discovered in 1990. Only three cases (one fatal) of Sabiá virus infection have been noted, two of them from laboratory accidents.
[6]Discovered in 2003 from a "small outbreak" in Cochabamba, Bolivia. Blood was obtained from one fatal case and Chapare virus isolated, but few other details from the outbreak have been reported.
[7]Although Rift Valley fever virus can be found throughout sub-Saharan Africa, large outbreaks usually occur in East Africa.
[8]Based on estimates from the World Health Organization. Significant underreporting occurs. Incidence may fluctuate widely, depending on epidemic activity.
[9]Numerous variants of Kyasanur Forest disease virus have been identified, including Nanjianyin virus in Yunnan Province, China, and Alkhumra virus (also spelled Alkhurma in some publications) in Saudi Arabia and Egypt.
HF = hemorrhagic fever.

by the specific virus and sometimes among strains of the same virus. Many of the hemorrhagic fever viruses have been placed on the Centers for Disease Control and Prevention select agents list of pathogens that pose a potential bioterrorism threat (Chapter 20).

EPIDEMIOLOGY

Maintenance in Nature and Transmission to Humans

With the exception of dengue virus, for which humans can now be considered the reservoir, hemorrhagic fever viruses are zoonotic, maintained in nature in mammalian reservoirs (see Table 389-1). The viruses may be transmitted to humans through direct contact with the reservoir or, in the case of the flaviviruses and most of the bunyaviruses, by an arthropod vector. Although viral hemorrhagic fever can be found worldwide, the endemic area of any given hemorrhagic fever virus is restricted by the distribution of its natural reservoir or arthropod vector. With the exception of dengue, human infection is generally rare, and humans are dead-end hosts who play no role in the natural maintenance of the viruses. The infectious dose for most hemorrhagic fever viruses appears to be low, sometimes on the order of just a few virions.

Bat-Borne Viruses

The filoviruses (from the Latin *filo,* "thread," referring to their filamentous shape), Marburg and Ebola, are perhaps the most feared of all hemorrhagic fever viruses. Fruit bats appear to be the filovirus reservoir, with transmission to humans likely from exposure to infected bat excreta or saliva. Nonhuman primates, especially gorillas and chimpanzees, and other wild animals may become infected, presumably from similar bat exposure, and transmit filoviruses to humans through contact with blood and body fluids of these animals, usually in association with hunting. Nonhuman primates are also dead-end hosts who develop severe and usually fatal disease, similar to that seen in humans, and are likely to be easier prey for hunters. Because hemorrhagic fever viruses are rapidly inactivated by heating, infection probably occurs by exposure during butchering and preparation. Ebola Reston virus has been isolated from pigs in the Philippines, presumably from exposure to bats.

Rodent-Borne Viruses

Arenaviruses (from the Latin *arena,* "sand," referring to their sandy appearance on electron microscopy) are divided into two groups: the Old World (or lymphocytic choriomeningitis/Lassa) complex and the New World (or Tacaribe) complex. Lassa virus and the recently discovered Lujo virus are found in Africa, whereas Junin, Machupo, Guanarito, Sabiá, and Chapare viruses are found in South America. Although there may be subtle differences among the syndromes produced by the New World arenaviruses, they are usually grouped simply as the South American hemorrhagic fevers.

The genus Hantavirus of the Bunyaviridae family is similarly divided into Old and New World groups. The Old World hantaviruses, such as Hantaan, Seoul, and Puumala, among many others, cause hemorrhagic fevers with prominent renal involvement across Europe and Asia. New World hantaviruses, such as sin nombre and Andes, among many others, cause a viral hemorrhagic fever named hantavirus pulmonary syndrome, sometimes also called hantavirus cardiopulmonary syndrome to emphasize the significant cardiogenic component of this disease.

Arenaviruses and hantaviruses are maintained in nature through chronic asymptomatic infection in rodents of the Muridae family, with a strict pairing between the specific virus and rodent species. Transmission between rodents may be by vertical or horizontal transmission or both, depending on the specific virus. Transmission to humans occurs through exposure to rodent excreta, either from aerosols produced when rodents urinate or by direct inoculation to the mucous membranes. The relative importance of these modes of transmission is unknown. Secondary aerosol generation is notoriously inefficient, so disturbing shed urine is a less likely mechanism of infection. In West Africa, Lassa virus is sometimes contracted when rodents are trapped and prepared for consumption or, more rarely, through a rodent bite. Experimental data suggest that humans may be infected with arenaviruses by the oral route.

The rodents that transmit Lassa, Machupo, and many of the Old World hantaviruses commonly invade the peridomestic environment, thereby putting housewives, children, and others who spend time at home at risk. In contrast, the reservoirs for Junin, Guanarito, and most of the New World hantaviruses typically inhabit agricultural fields, wood lots, or other rural habitats, thereby putting outdoor workers, campers, and hikers at risk.

Mosquito-Borne Viruses

Rift Valley fever virus is maintained in domestic livestock, such as cattle, buffalo, sheep, goats, and camels, in which it often provokes spontaneous abortion. The virus may be transmitted to humans by direct exposure to these animals, especially during parturition, or by mosquitoes. Farmers, abattoir workers, and veterinarians are at particular risk.

Yellow fever virus is maintained in a cycle between monkeys and forest canopy mosquitoes. Sporadic cases occur when humans are bitten by these mosquitoes. Larger outbreaks occur when humans bring the virus back to more settled environments, where the urban mosquito *Aedes aegypti* can spread the virus directly between humans. *Ae. aegypti,* which typically lay eggs in artificial containers around the home and bite during the day, become infective a few weeks after feeding on a viremic monkey or human. Sanitation and mosquito control measures have virtually eliminated urban yellow fever in the Americas, but urban outbreaks continue to occur in Africa.

Although nonhuman primates are also a reservoir for sylvatic strains of dengue, the virus is now largely maintained in humans, with a regular transmission cycle akin to urban yellow fever. Despite the presence of dengue virus in the tropics worldwide, less than 10% of infected persons develop hemorrhagic fever, primarily children between the ages of 4 and 12 years.

Tick-Borne Viruses

Kyasanur Forest disease and Crimean-Congo and Omsk hemorrhagic fever viruses are maintained in small mammals, such as rodents, hares, and hedgehogs, among which the viruses are spread by ticks. Humans are infected either by tick bites or by exposure to contaminated blood or excreta of the reservoir animals. Ticks also spread Crimean-Congo hemorrhagic fever virus to large mammals, including cattle and other domestic livestock, whose transient and asymptomatic viremia puts farmers, abattoir workers, and veterinarians at risk.

Human to Human Transmission

Secondary human to human transmission occurs with many of the hemorrhagic fever viruses, but tertiary transmission is unusual and often associated with milder disease. Secondary attack rates for hemorrhagic fever viruses are generally low (15 to 20% for Ebola Zaire virus), probably because transmission between humans requires direct contact with contaminated blood or body fluids. Human to human infection probably usually occurs through oral or mucous membrane exposure, most often in the context of providing care to a sick family member (community) or patient (nosocomial transmission). Large outbreaks are almost always fueled by nosocomial transmission, usually in resource-poor regions. Funeral rituals that entail the touching of the corpse before burial have also played a significant role in transmission of the filoviruses. Infection through fomites cannot be excluded.

With the exception of hantaviruses and some of the flaviviruses, infectivity generally parallels the clinical state. Persons are generally most infectious late in the course of severe disease, especially when bleeding. Transmission during the incubation period or from asymptomatic persons is negligible.

PATHOBIOLOGY

Microvascular instability and impaired hemostasis are the hallmarks of viral hemorrhagic fever. Although the pathophysiologic mechanism varies with the specific virus, mortality usually results not directly from exsanguination but rather when an intense inflammatory process akin to septic shock results in insufficient effective circulating intravascular volume that leads to hypotension, cellular dysfunction, and multiorgan system failure. In fact, external bleeding is seen in a minority of all cases. Cardiac inotropy may be directly or indirectly inhibited, especially in Lassa fever.

After inoculation, virus first replicates in dendritic cells and other local tissues, with subsequent migration to regional lymph nodes and then dissemination through the lymph and blood monocytes to a broad range of tissues and organs, including the liver, spleen, lymph nodes, adrenal glands, lungs, and endothelium. Migration of tissue macrophages results in secondary infection of permissive parenchymal cells.

The interaction of virus with immune cells, especially macrophages and endothelial cells, results in cell activation and the unleashing of an inflammatory and vasoactive process consistent with the systemic inflammatory response syndrome. Although lymphocytes remain free of infection, they may be destroyed in massive numbers during the course of illness through apoptosis, as seen in other forms of septic shock. The synthesis of cell surface tissue factor triggers the extrinsic coagulation pathway. Impaired hemostasis

TABLE 389-2 PATHOBIOLOGIC AND CLINICAL ASPECTS OF VIRAL HEMORRHAGIC FEVERS

[1]Data are insufficient to distinguish between the syndromes produced by the various Old and New World arenaviruses.
[2]Hemorrhagic fever, encephalitis, and retinitis may be seen in Rift Valley fever independently of each other.
CNS = central nervous system; HF = hemorrhagic fever; 0 = sign not typically noted/organ not typically affected; + = sign occasionally noted/organ occasionally affected; ++ = sign commonly noted/organ commonly affected; +++ = sign characteristic/organ involvement severe.

may entail endothelial cell, platelet, or coagulation factor dysfunction. Disseminated intravascular coagulopathy (DIC) is frequently noted, especially with Ebola, Marburg, and Crimean-Congo hemorrhagic fever virus infections.

Tissue damage may be mediated through direct necrosis of infected cells or indirectly through apoptosis of immune cells. The most affected organs vary with the virus (Table 389-2). For example, renal tubular necrosis and retroperitoneal edema are seen in hemorrhagic fevers with renal syndrome, whereas interstitial pneumonitis and myocardial depression are the hallmarks of hantavirus pulmonary syndrome. The liver is particularly affected in yellow fever, with fatty degeneration, coagulative midzonal necrosis of hepatocytes, and the presence of Councilman bodies. The brain and meninges are particularly affected in Kyasanur Forest disease and Omsk hemorrhagic fever and often in the South American hemorrhagic fevers as well. Reticuloendothelial proliferation is seen in Kyasanur Forest disease, with marked erythrophagocytosis in the spleen.

With the exception of disease caused by the hantaviruses and some of the flaviviruses, the pathogenesis of viral hemorrhagic fever appears to be unchecked viremia, with most fatal cases failing to mount a significant antibody response. Inflammatory cell infiltrates are usually mild. In some viral hemorrhagic fevers, such as Ebola, virus replication and dissemination are facilitated by virus-induced suppression of the host adaptive immune response.

In contrast to this process, hantavirus, yellow fever virus, and dengue virus are usually cleared from the blood before the most severe phase of the disease. The host immune response is thought to play a detrimental role. The unique process of antibody-mediated immune enhancement, in which secondary infection with a different dengue virus serotype is more severe than the primary one, may play a role in the pathogenesis of dengue hemorrhagic fever.

CLINICAL MANIFESTATIONS

Viral hemorrhagic fever is seen in both genders and all age groups, with a spectrum from relatively mild or even asymptomatic infection to severe vascular permeability resulting in shock, multiorgan system failure, and death. Although the clinical presentation may differ for each viral hemorrhagic fever as it progresses, the limited data do not permit clear distinctions in most cases, especially in the early phases of disease. Dengue and Rift Valley fever viruses cause a range of syndromes, including rash and central nervous system involvement (Chapters 390 and 391). Hemorrhagic fever occurs in a minority of infections with these viruses.

Most patients present with nonspecific signs and symptoms difficult to distinguish from a host of other febrile illnesses (see Table 389-2). Illness typically begins with fever and constitutional symptoms, including general malaise, anorexia, headache, chest or retrosternal pain, sore throat, myalgia, arthralgia, lumbosacral pain, and dizziness. Relative bradycardia and orthostatic hypotension may be noted. The pharynx may be erythemic or, less frequently, exudative, especially in Lassa fever, and incorrectly lead to a diagnosis of streptococcal pharyngitis. Gastrointestinal signs and symptoms readily ensue, including nausea, vomiting, epigastric and abdominal pain, abdominal tenderness (especially over the liver in filovirus infection), and diarrhea. Bleeding, including from the gastrointestinal tract, may be profuse in some viral hemorrhagic fevers, especially with Crimean-Congo hemorrhagic fever, Ebola (Fig. 389-1), and Marburg viruses. Significant internal bleeding from the gastrointestinal tract may occur even in the absence of external hemorrhage.

Viral hemorrhagic fever has sometimes been mistaken for acute appendicitis (Chapter 144) or other abdominal emergencies. A dry cough, sometimes accompanied by a few scattered rales on auscultation, is common, but prominent pulmonary symptoms are uncommon early in the course of the disease, except with hantavirus pulmonary syndrome. Conjunctival injection or hemorrhage is frequent but is not accompanied by itching, discharge, or rhinitis (Fig. 389-2). Various forms of rash, including morbilliform, maculopapular, petechial, and ecchymotic, may be seen. A maculopapular rash on the torso or face may be one early and relatively specific although insensitive indicator of Ebola or Marburg hemorrhagic fever. Rash almost always occurs in fair-skinned persons with Lassa fever but, for unclear reasons, rarely in blacks.

In severe cases, patients progress to vascular instability, which may be manifested by conjunctival injection and hemorrhage, facial flushing, edema, bleeding, hypotension, shock, and proteinuria. Swelling in the face and neck is sometimes seen in Lassa fever and is relatively specific to this disease (see Fig. 389-2). The likelihood of clinically discernible hemorrhage varies with the infecting virus, but it is seen in a minority of cases and almost never in the first few days of illness. Hematemesis, melena, hematochezia, metrorrhagia, petechiae, purpura, epistaxis, and bleeding from the gums and venipuncture sites may develop, but hemoptysis and hematuria are infrequent. Large ecchymoses are characteristic of Crimean-Congo hemorrhagic fever.

TABLE 389-3 INDICATED CLINICAL LABORATORY TESTS AND CHARACTERISTIC FINDINGS IN PATIENTS WITH VIRAL HEMORRHAGIC FEVER

TEST	CHARACTERISTIC FINDINGS AND COMMENTS
Leukocyte count	Early: moderate leukopenia, sometimes with atypical lymphocytes (except for the VHFs caused by hantaviruses, in which early leukocytosis is typical) Later: leukocytosis with left shift
Hemoglobin and hematocrit	Hemoconcentration (especially noted in hantavirus pulmonary syndrome)
Platelet count	Mild to moderate thrombocytopenia
Electrolytes	Sodium, potassium, and acid-base perturbations, depending on fluid balance and stage of disease
Lactate	A level >4 mmol/L (36 mg/dL) may indicate persistent hypoperfusion and sepsis
BUN/creatinine	Renal failure may occur late in disease
AST, ALT, amylase	Increased, usually AST > ALT
Coagulation studies (PT, PTT, fibrinogen, fibrin split products, platelets, D-dimer)	DIC common except in hantavirus pulmonary syndrome
Urinalysis	Proteinuria common
Blood culture	Useful early to exclude VHF and later to evaluate for secondary bacterial infection
Stool culture	Useful to exclude VHF (in favor of hemorrhagic bacillary dysentery)
Thick and thin smears or other assay for malaria	Negative in VHF unless coinfection with malaria
Febrile agglutinins or other assay for *Salmonella typhi*	Negative in VHF unless coinfection with *S. typhi*

ALT = alanine aminotransferase; AST = aspartate aminotransferase; BUN = blood urea nitrogen; DIC = disseminated intravascular coagulation; PT = prothrombin time; PTT = partial thromboplastin time; VHF = viral hemorrhagic fever.

Central nervous system manifestations, including disorientation, tremor, gait anomalies, convulsions, and hiccups, may be noted in end-stage disease, especially in Kyasanur Forest disease, Omsk hemorrhagic fever, and the South American hemorrhagic fevers, particularly Argentine hemorrhagic fever. Nevertheless, the cerebrospinal fluid findings are usually normal, with the exception of patients who have meningoencephalitis due to Kyasanur Forest disease and Omsk hemorrhagic fever, in which an elevated protein level is common. Renal insufficiency or failure is common, especially in hemorrhagic fever with renal syndrome. Pregnant women often present with spontaneous abortion and vaginal bleeding. Maternal and fetal mortality may approach 100% in the third trimester. With the exception of yellow fever, jaundice is not typical.

Biphasic illnesses are classically noted for the flavivirus hemorrhagic fevers, in which a quiescent period of days (yellow fever and dengue) to weeks (Kyasanur Forest disease and Omsk hemorrhagic fever) is followed by the most severe manifestations, including hemorrhage, shock, renal failure, and meningoencephalitis. Distinct phases of disease and recovery are classically described for hemorrhagic fever with renal syndrome (prodrome, hypotension, oliguria, diuresis) and yellow fever (infection, intoxication, recovery), although not seen in all cases. The initial manifestations for hantavirus pulmonary syndrome may be mild and nonspecific, but the disease may progress to require mechanical ventilation and pressor support within 24 hours; sinus bradycardia and ventricular tachycardia or fibrillation may occur. Encephalitis and retinitis may develop in Rift Valley fever independently of the presence or absence of viral hemorrhagic fever.

A variety of clinical laboratory findings are seen (Table 389-3) but are nonspecific. Radiographic and electrocardiographic findings also are generally nonspecific and usually correlate with the physical examination. Bilateral noncardiogenic interstitial pulmonary edema consistent with the adult respiratory distress syndrome (ARDS) is the hallmark of hantavirus pulmonary syndrome, although chest radiographs may be normal early in the disease even when the patients complain of shortness of breath. Only about 30% of patients with hantavirus pulmonary syndrome have radiographic evidence of pulmonary edema on initial evaluation, although it develops in virtually all persons within 48 hours.

DIAGNOSIS

The nonspecific presentation of most viral hemorrhagic fevers makes them extremely difficult to diagnose clinically, especially early in the course of the disease, when hemorrhage is usually absent. The differential diagnosis includes a broad array of febrile illnesses that may vary by geographic region (Table 389-4). A diagnosis of viral hemorrhagic fever should be considered in patients with a clinically compatible syndrome who, within 3 weeks before disease onset, traveled in areas where a viral hemorrhagic fever is known or suspected to be endemic, had potential direct contact with blood or body fluids of a person or animal with viral hemorrhagic fever during the acute illness, had contact with live or recently killed wild animals (especially nonhuman primates), recently arrived from an area where a viral hemorrhagic

TABLE 389-4 DIFFERENTIAL DIAGNOSIS OF VIRAL HEMORRHAGIC FEVER

DISEASE	DISTINGUISHING CHARACTERISTICS AND COMMENTS
PARASITES	
Malaria (Chapter 353)	Classically shows paroxysms of fever and chills; hemorrhagic manifestations less common; malaria smears or rapid test result usually positive; responds to antimalarials
Amebiasis (Chapter 360)	Hemorrhagic manifestations other than bloody diarrhea generally not seen; amebic trophozoites identified in the stool; responds to antiparasitics
Giardiasis (Chapter 359)	Diagnostic findings in stool; responds to antiparasitic medications
African trypanosomiasis (acute phase) (Chapter 354)	Acute stages may mimic VHF if neurologic syndrome not prominent
BACTERIA	
Typhoid fever (Chapter 316)	Hemorrhagic manifestations other than bloody diarrhea generally not seen; responds to antibiotics
Bacillary dysentery (including shigellosis, campylobacteriosis, salmonellosis, and enterohemorrhagic *Escherichia coli* and others) (Chapter 291)	Hemorrhagic manifestations other than bloody diarrhea generally not seen; responds to antibiotics
Meningococcemia (Chapter 306)	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; large ecchymoses typical of meningococcemia are unusual in the VHFs except for Crimean-Congo HF; may respond to antibiotics
Staphylococcemia (Chapter 296)	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; may respond to antibiotics
Septicemic plague (Chapter 320)	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; large ecchymoses typical of plague are unusual in the VHFs except for Crimean-Congo HF; may respond to antibiotics
Streptococcal pharyngitis (Chapter 298)	May mimic the exudative pharyngitis sometimes seen in Lassa fever
Tularemia (Chapter 319)	Ulceroglandular and pneumonic forms more common; responds to antibiotics
Acute abdominal emergencies (Chapter 144)	Appendicitis and peritonitis
Pyelonephritis and post-streptococcal glomerulonephritis (Chapters 123 and 292)	May mimic HF with renal syndrome
Anthrax (inhalation or gastrointestinal) (Chapter 302)	Prominent pulmonary manifestations in inhalational form; may respond to antibiotics
Psittacosis (Chapter 326)	Pulmonary symptoms often not present until late in the illness; responds to antibiotics
VIRUSES	
Influenza (Chapter 372)	Prominent respiratory component to clinical presentation; no hemorrhagic manifestations; influenza rapid test result may be positive; may respond to anti-influenza drugs
Arbovirus infection (including dengue and West Nile fever) (Chapters 390 and 391)	Encephalitis unusual but when present may mimic the VHFs with significant neurologic involvement (Kyasanur Forest disease, Omsk HF); usually less severe than VHF; hemorrhage not reported
Viral hepatitis (including hepatitis A, hepatitis B, hepatitis E, Epstein-Barr, and cytomegalovirus) (Chapter 150)	Jaundice atypical in HF except yellow fever; test results for hepatitis antigens positive
Measles (Chapter 375)	Rash may mimic that seen in early stages of some VHFs; prominence of coryza and upper respiratory symptoms in measles should help differentiate; vaccine preventable
Rubella (Chapter 376)	Rash may mimic that seen in early stages of some VHFs; usually a mild disease; vaccine preventable
Hemorrhagic or flat smallpox (Chapter 380)	Diffuse hemorrhagic or macular lesions; in contrast to the VHFs, the rash may involve the oral mucosa, palms, and soles; smallpox in the wild has been eradicated
Alphavirus infection (including chikungunya and o'nyong-nyong) (Chapter 390)	Joint pain often prominent
SPIROCHETES, RICKETTSIA, EHRLICHIA, AND COXIELLA	
Relapsing fever (Chapter 330)	Recurrent fevers and influenza-like symptoms, with direct neurologic involvement and splenomegaly; spirochetes visible in blood while febrile; responds to antibiotics
Leptospirosis (Chapter 331)	Jaundice, renal failure, and myocarditis in severe cases; responds to antibiotics
Spotted fever group rickettsioses (including Rocky Mountain spotted fever, boutonneuse fever, African tick bite fever) (Chapter 335)	Necrotic lesion (eschar) at site of tick bite in some forms; responds to antibiotics
Typhus-group rickettsioses (including murine- and louse-borne typhus) (Chapter 335)	History of exposure to lice; interstitial pneumonia on a chest radiograph; responds to antibiotics
Q fever (Chapter 335)	Pneumonia may be prominent; responds to antibiotics
Ehrlichiosis (Chapter 335)	Responds to antibiotics
NONINFECTIOUS CAUSES	
Idiopathic and thrombotic thrombocytopenic purpura (ITP/TTP) (Chapter 175)	Presentation usually less acute than VHF; may have prominent neurologic symptoms in TTP; coagulation factors normal and DIC absent; often respond to corticosteroids (ITP) or plasma exchange (TTP)
Acute glaucoma (Chapter 431)	May mimic the acute ocular manifestations of Rift Valley fever
Leukemia (Chapter 189)	May resemble the leukemoid reaction occasionally seen in HF with renal syndrome

DIC = disseminated intravascular coagulopathy; HF = hemorrhagic fever; VHF = viral hemorrhagic fever.

fever is endemic, worked in a laboratory or animal facility where hemorrhagic fever viruses are handled, or had sexual relations with someone recovering from a viral hemorrhagic fever in the last 3 months. Acts of bioterrorism (Chapter 20) must be considered if clusters of cases are seen in the absence of such risk factors. ARDS or other respiratory compromise in a person living in an endemic area for New World hantaviruses should prompt consideration of hantavirus pulmonary syndrome. Risk of tick infection, including physical examination for an eschar, should be assessed if a tick-borne viral hemorrhagic fever is suspected. However, most viral hemorrhagic fevers are rare even in persons possessing one of the risk factors, so alternative diagnoses should always be aggressively sought, especially malaria and typhoid fever in areas where they are endemic. All confirmed cases of viral hemorrhagic

fever should be reported immediately to local, state, and federal health authorities.

Laboratory Testing

No commercial assays are available except for the serologic diagnosis of dengue and hantavirus pulmonary syndrome. Specialized testing can be arranged through the U.S. Centers for Disease Control and Prevention (001-404-639-1115). The enzyme-linked immunosorbent assay is the mainstay of diagnosis, with sensitivities and specificities usually above 90%. Immunofluorescent antibody tests are not as routinely sensitive or specific. Serologic diagnosis of flavivirus infection is often complicated by cross-reactions. Reverse transcription–polymerase chain reaction (RT-PCR) is also useful, although careful attention must be paid to the potential for false-positive results due to laboratory contamination. The most definitive test is viral culture, but the time to diagnosis (2 to 10 days for the virus to grow, depending on the specific virus and titer in the test sample), variability, and need for high containment facilities render this technique more of a confirmatory test and research tool.

TREATMENT

Rx

Patients with viral hemorrhagic fever should generally be treated in intensive care units or the highest level of care available. A broad range of clinical laboratory parameters should be monitored (see Table 389-3).

General Supportive Measures

Severe microvascular instability, often complicated by vomiting, diarrhea, and decreased fluid intake, normally requires aggressive fluid replacement. However, overaggressive and unmonitored rehydration may lead to significant third-spacing and pulmonary edema, especially in hantavirus pulmonary syndrome. Because of the risk of bleeding at intravascular insertion sites, hemodynamic status should be monitored by blood pressure cuff and other noninvasive means.

Fluid and blood pressure management is as for septic shock (Chapter 108). Crystalloids (lactated Ringer's solution or normal saline) and, if necessary, vasopressors (Chapter 108) should be infused to maintain central venous pressure between 8 and 12 mm Hg or mean arterial blood pressure above 65 mm Hg. Early use of vasopressors, especially dopamine and norepinephrine, may diminish the risk of fluid overload, and dobutamine should be added if these measures and blood transfusion fail to maintain the target blood pressure and adequate organ perfusion (Chapter 108). Extrapolating from data on septic shock, transfusions, preferably with packed red blood cells, should be used to maintain a hematocrit above 30% while avoiding volume overload.

Electrolyte values should be monitored closely. Vomiting and diarrhea frequently result in hypokalemia, so potassium supplementation may be needed (Chapter 119).

The possibility of DIC (Chapter 178) should be assessed and treatment (see Table 178-2) implemented in patients with consistent laboratory parameters (see Table 389-3) *and* active bleeding. Transfusion of platelet concentrate (1 to 2 units/10 kg) should be considered when the platelet count is less than 50,000/μL in a bleeding patient or less than 20,000/μL without bleeding. The platelet count should generally rise by at least 2000/μL per unit of platelets transfused, although a lesser response may occur if there is ongoing DIC and platelet consumption. Impaired platelet aggregation may promote hemorrhage in some viral hemorrhagic fevers, especially Lassa fever, even when platelet counts are not drastically low. Transfusion of fresh-frozen plasma (FFP; 15 to 20 mL/kg) should be considered when bleeding is present and fibrinogen levels are less than 100 mg/dL. Fibrinogen concentrates (total dose, 2 to 3 g) or cryoprecipitates (1 unit/10 kg) may be administered instead of FFP, although FFP has the theoretical advantage of containing all coagulation factors and inhibitors deficient in DIC but no activated coagulation factors. Vitamin K (10 mg on 2 consecutive days) may be given, especially if underlying malnutrition or liver disease is suspected.

With the exception of hantavirus pulmonary syndrome, impaired gas exchange is not typically a prominent feature of viral hemorrhagic fever, especially in the absence of iatrogenic pulmonary edema. Intubation and mechanical ventilation (Chapter 105) should be avoided because of the risk of barotrauma and pleural-pulmonary hemorrhage, except in hantavirus pulmonary syndrome, in which patients should be immediately covered with appropriate broad-spectrum antibacterial or antiparasitic therapy, with specific consideration of antimalarial agents for malaria (Chapter 353) and doxycycline for tick-borne rickettsial diseases, until a diagnosis of viral hemorrhagic fever can be confirmed (see Table 389-4). If patients have persistent or new fever after about 2 weeks of illness, secondary bacterial infection should be suspected.

Acetaminophen (500 to 1000 mg every 4 to 6 hours), tramadol (50 to 100 mg every 4 to 6 hours), opiates (see Table 29-4), or other analgesics should be used as needed for pain control. Salicylates and nonsteroidal anti-inflammatory drugs should not be used, and intramuscular and subcutaneous injections should be avoided because of the risk of bleeding. Prophylactic therapy for stress ulcers with H_2-receptor antagonists (e.g., ranitidine, 50 mg intravenously every 8 hours; see Table 140-1) is appropriate.

Seizures sometimes occur in late-stage viral hemorrhagic fever but can usually be managed with benzodiazepines or phenytoin (Chapter 410). The use of sedatives and neuromuscular blocking agents should be minimized, but haloperidol (0.5 to 5 mg, two or three times daily) or a benzodiazepine (e.g., lorazepam, 1 to 10 mg orally daily in two or three divided doses) may be used.

Uterine evacuation appears to lower maternal mortality and should be seriously considered, although only with extreme caution to avoid nosocomial transmission of hemorrhagic fever viruses. Peritoneal dialysis and hemodialysis are often used in patients with hemorrhagic fever with renal syndrome without major complications, but there is little published experience in other viral hemorrhagic fevers.

Antiviral Therapy

Intravenous ribavirin (a loading dose of 30 mg/kg, maximum 2 g; followed by 15 mg/kg, maximum 1 g, every 6 hours for 4 days; followed by 7.5 mg/kg, maximum 500 mg, every 8 hours for another 6 days) for 10 days decreases mortality in severe Lassa fever from 55% to 5% when it is begun within the first 6 days of illness, although it is not approved by the Food and Drug Administration for this indication. The drug should be diluted in 150 mL of 0.9% saline and infused slowly, with the dose diminished in persons with a creatinine clearance of less than 50 mL/min (Chapter 368).

Ribavirin reduces mortality in hemorrhagic fever with renal syndrome if it is administered within 4 days of onset. It also appears to be efficacious in the South American hemorrhagic fevers and Crimean-Congo hemorrhagic fever, although randomized trials have not been performed for these diseases. There are no published data on the clinical efficacy of ribavirin for Rift Valley fever, although the drug has in vitro activity against the virus. Ribavirin is not efficacious in Ebola or Marburg hemorrhagic fevers. Until more data are available, ribavirin should not be used for dengue and yellow fever virus infections.

Convalescent Immune Plasma

Transfusion of appropriately titered convalescent plasma within the first 8 days of illness reduces the case-fatality of Argentine hemorrhagic fever from 15 to 30% to less than 1%. However, this therapy has been associated with a convalescent phase neurologic syndrome characterized by fever, cerebellar signs, and cranial nerve palsies in 10% of treated patients. Convalescent plasma also has been used in Lassa fever. Immune plasma also appears to be efficacious for Crimean-Congo hemorrhagic fever and Rift Valley fever, although there are no controlled data, but it should not be used for Ebola and Marburg hemorrhagic fevers.

Immune Modulators

Immune modulators have not shown conclusive benefit in the viral hemorrhagic fevers. Intravenous corticosteroids (e.g., hydrocortisone, 200 to 300 mg/day divided into three or four doses for 7 days) should not be administered unless adrenal insufficiency is demonstrated, target blood pressure is not maintained despite adequate fluid repletion and vasopressors, or (in conjunction with mannitol) cerebral edema is suspected.

Activated protein C (24 μg/kg/hr constant infusion) is efficacious for some patients with septic shock (Chapter 108) and reduces mortality in Ebola virus–infected monkeys but is still experimental for viral hemorrhagic fever in humans. An experimental recombinant inhibitor of the tissue factor/factor VIIa coagulation pathway (rNAPc2) also decreases mortality in Ebola virus–infected monkeys and has completed a phase I trial in humans.

PREVENTION

Infection control of the hemorrhagic fever viruses relies on classic public health principles of isolation of infected persons. All patients with a clinically compatible syndrome should be presumed infectious and kept isolated until a specific diagnosis is made. If it is available, a negative airflow room is prudent, but hermetically sealed isolation chambers are not required. Access to the patient should be limited to a small number of designated staff and family members with specific instructions and training on infection control guidelines and the use of personal protective equipment. Insecticide-treated bed nets and room screens should be used in open-air settings to prevent transmission of arthropod-borne viruses.

Personal Protection and Nursing Precautions

Although specific viral hemorrhagic fever isolation precautions (surgical mask, double gloves, gown, protective apron, face shield, and shoe covers) are advised for added security, routine strict barrier nursing is protective in most cases. Positive airway pressure masks and other small-particle aerosol

precautions should be used in performing procedures that may generate aerosols, such as endotracheal intubation.

Items that were in direct contact with a patient with viral hemorrhagic fever should be decontaminated with household bleach. A 1 : 100 (1%) solution of ordinary 5% chlorine bleach should be used for reusable items, and a 1 : 10 (10%) solution for disinfection of excreta, corpses, and items to be discarded.

Contact Tracing

The early nonspecific presentation of the viral hemorrhagic fevers poses a serious challenge to effective epidemiologic surveillance. Fortunately, the low secondary attack rates afford a measure of reassurance even when cases go unrecognized as long as proper barrier nursing is maintained. Furthermore, because mild cases, which may be still more difficult to recognize, are usually not very infectious, missed or delayed diagnosis of these patients is unlikely to pose a problem from an infection control standpoint.

Persons with unprotected direct contact with a patient during the symptomatic phase of a person to person communicable hemorrhagic fever virus should be monitored daily for evidence of disease for the duration of the longest possible incubation period starting after their last contact (see Table 389-2). Contacts should check their temperature daily and record the results in a log. Despite the lack of evidence for transmission during the incubation period, it is usually recommended that exposed persons avoid close contact or activities with household members that might result in exposure to body fluids, such as sex, kissing, and sharing of utensils. Hospitalization or other confinement of asymptomatic persons is not warranted, but persons who develop fever or other signs and symptoms suggestive of viral hemorrhagic fever should immediately be isolated until the diagnosis can be excluded.

Reservoir and Vector Control

Avoiding contact with bats, primarily by avoiding entry into caves and mines in endemic areas, is a key prevention measure for Ebola and Marburg viruses. Personal protective equipment may be indicated for miners and other persons who work in these environments. Humans should also avoid exposure to fresh blood, body fluids, or meat of wild animals, especially nonhuman primates.

For rodent-borne viruses whose reservoirs often colonize human dwellings, prevention is best accomplished by improving "village hygiene," such as eliminating unprotected storage of garbage and foodstuffs and plugging holes that allow rodents to enter homes. Prevention of the mosquito-borne hemorrhagic fever viruses hinges on controlling *Aedes* mosquitoes in and around the home, primarily by elimination of clean standing water containers that serve as larval habitats and by use of screened windows and doors, insecticide-treated bed nets, protective clothing, mosquito repellent, and aerosol bomb insecticides in enclosed spaces. Analogous measures can help protect against tick bites.

Vaccines

The only widely licensed, validated, and available vaccine for a viral hemorrhagic fever is the yellow fever 17D (YF-17D) live attenuated vaccine. The vaccine is highly efficacious; a single 0.5-mL injection confers protection in more than 95% of recipients within 10 days. Immunity is probably lifelong, although revaccination is recommended every 10 years and required by International Health Regulations published by the World Health Organization. Hence, confirmed previous vaccination with YF-17D should strongly suggest a diagnosis other than yellow fever unless the patient was immunocompromised at the time of vaccination (see later).

YF-17D is indicated for persons 9 months of age and older who are traveling to or living in areas with risk of yellow fever transmission. The overall safety profile of YF-17D is excellent, with mild adverse events (low-grade fever, headache, myalgia) occurring in 10 to 30% of cases. However, severe and fatal vaccine-associated neurotropic and viscerotropic disease has been increasingly reported in the last decade, especially in persons older than 60 years, in whom the actual risk of exposure must be carefully weighed. YF-17D is contraindicated in persons allergic to eggs or chicken, breast-feeding women, and immunocompromised persons. Physicians are advised to consult state and federal health departments when considering vaccination of persons with relative contraindications.

A live attenuated vaccine called Candid #1 decreases the morbidity and mortality of Argentine hemorrhagic fever and may also protect against Bolivian hemorrhagic fever, although it does not appear to cross-protect against Guanarito or Sabiá viruses or any of the Old World arenaviruses. The vaccine is not approved in the United States, however, and supplies are insufficient even in Argentina, the sole country in which the vaccine is produced.

A formalin-inactivated vaccine for Rift Valley fever (TSI-GSD-200) is efficacious in humans but is not widely available and requires yearly boosters. It is sometimes available for high-risk groups, such as veterinarians working in endemic areas and laboratory workers. A number of other Rift Valley fever vaccines are in development. Vaccines for Kyasanur Forest disease and hemorrhagic fever with renal syndrome are available in India and northeast Asia, respectively, but their efficacy has not been extensively evaluated, and they are not generally licensed or available outside these regions. The vaccine for hemorrhagic fever with renal syndrome is based on hantaviruses found in Asia and is unlikely to protect against the viruses that commonly cause this disease in Europe. A mouse brain–derived vaccine for Omsk hemorrhagic fever has been used for those at risk of environmental exposure but is not widely available.

A number of experimental approaches also show promise; a live recombinant vesicular stomatitis virus vector engineered to express the key immunogenic proteins of the hemorrhagic fever viruses has shown protective immunity in animal models for Ebola, Marburg, and Lassa virus infection. Furthermore, these vaccines also are effective when they are given by the nasal or oral route. A DNA plasmid vaccine for Ebola hemorrhagic fever has been shown to be safe and immunogenic in a phase I trial, as has a recombinant vaccine for dengue fever.

Postexposure Prophylaxis

Postexposure prophylaxis with oral ribavirin (loading dose of 35 mg/kg, maximum 2.5 g; followed by 15 mg/kg, maximum 1 g, three times daily for 10 days) may be considered for persons with distinct and direct unprotected contact with blood or body fluids from a person with a confirmed infection with arenaviruses, Crimean-Congo hemorrhagic fever virus, and perhaps Rift Valley fever virus, although there are no data on efficacy, dose, or duration of administration of the drug for this purpose. Persons who are exposed to an arenavirus and who develop manifestations of viral hemorrhagic fever should be immediately converted to intravenous ribavirin. Convalescent plasma is as efficacious as postexposure prophylaxis for Argentine hemorrhagic fever. Various experimental therapies show potential promise as postexposure prophylaxis for the filoviruses. Prophylaxis should never be given if the only exposure was during the incubation period.

PROGNOSIS

The clinical course of viral hemorrhagic fever unfolds quite rapidly. In fatal cases, death usually occurs within 7 to 10 days after the onset of hemorrhagic fever symptoms in filovirus infection and in about 2 weeks with the arenaviruses and some of the other viruses. Common indicators of a poor prognosis include shock, bleeding, neurologic manifestations, high levels of viremia, elevated levels of aspartate aminotransferase (>150 IU/L), and pregnancy, especially during the third trimester. However, mild and even asymptomatic cases have been reported even for what are considered the most virulent viral hemorrhagic fevers. Reasons for this heterogeneity are largely unknown.

Viremia clears rapidly in survivors of viral hemorrhagic fever, who can be discharged without concern of subsequent transmission at home. However, clearance of virus may be delayed for weeks to months from a few immunologically protected sites, such as the kidney, chambers of the eye, and gonads. Sexual transmission can occur months after recovery from acute disease, especially with Ebola, Marburg, and Lassa viruses.

Persons who survive viral hemorrhagic fever usually suffer no obvious long-term sequelae. Notable exceptions include deafness in up to 30% of patients after Lassa fever and sometimes after Venezuelan hemorrhagic fever and optic retinopathy with vision loss in Rift Valley fever. Convalescence may be prolonged, especially for Ebola and Marburg hemorrhagic fevers, with the potential for persistent myalgia, arthralgia, anorexia, weight loss, alopecia, pancreatitis, uveitis, and orchitis up to a year after infection. The psychological effects of viral hemorrhagic fever may also be significant, with some patients experiencing depression or post-traumatic stress.

Clinical management during convalescence includes the use of warm packs, acetaminophen, nonsteroidal anti-inflammatory drugs, cosmetics, hair growth stimulants, anxiolytics, antidepressants, nutritional supplements, and nutritional and psychological counseling as indicated. Uveitis in patients recovering from Ebola hemorrhagic fever responds to topical steroids and atropine. Because of the risk of sexual transmission during convalescence, abstinence or condom use is recommended for 3 months after acute illness. Similarly, breast-feeding should be avoided during convalescence unless

there is no other way to support the baby. Transmission through toilet facilities or eye secretions has not been noted, but simple precautions to avoid contact with these potentially infected body fluids are prudent, including separate toilet facilities, if possible, and regular handwashing.

ARBOVIRUSES CAUSING FEVER AND RASH SYNDROMES

STANLEY J. NAIDES

COLORADO TICK FEVER

DEFINITION

Colorado tick fever (mountain fever, American mountain fever) is an acute, often self-limited, typically biphasic febrile illness that is common in the Rocky Mountain areas, the Sierra Nevada and Wasatch ranges, and the Black Hills mountain areas. The virus is transmitted through the bite of the hard-shelled tick *Dermacentor andersoni* (Rocky Mountain wood tick), and the disease's range corresponds to the vector's range. Other coltiviruses, such as the Salmon River, Eyach, Banna, Beijing, and Gansu viruses, have also been implicated in human disease.

The Pathogen

The causative agent, Colorado tick fever virus, is a member of the genus Coltivirus, family Reoviridae. Coltiviruses have a genome consisting of 12 double-stranded RNA segments. Colorado tick fever virus is the prototype member.

EPIDEMIOLOGY

D. andersoni is found at elevations of 4000 to 10,000 ft. Seasonal temperatures tend to influence the range, with the vector being found at higher elevations in warmer seasons and at lower elevations in colder seasons. Human exposure usually occurs during outdoor recreational activities in these areas. Occasional exposure occurs in nonendemic areas from ticks exported out of the endemic region in clothes, hiking equipment, or baggage. Infections generally take place between March and September, when the adult tick is most plentiful. Ticks are most abundant in south-facing dry and rocky slope habitats that favor small rodents (e.g., chipmunks, ground squirrels, marmosets), with underbrush cover, burrows, and humidity for the ticks. Colorado tick fever virus is found in nymphal and adult ticks that overwinter on the rodent host, in which viremia persists for weeks to months. In the endemic area, as many as 14% of *D. andersoni* ticks carry Colorado tick fever virus. Humans are an incidental host. Fewer than 50 cases have been reported annually in Colorado beginning in 1992. The actual number of cases is probably significantly larger and includes subclinical, mild, and unreported cases.

The geographic range of Colorado tick fever may be larger than the well-recognized endemic mountain areas. Serologically confirmed cases in California have been attributed to the Colorado tick fever–related virus S1-14-03, which is transmitted by *Dermacentor variabilis* (American dog tick). Salmon River virus causes a Colorado tick fever–like illness in rafters on the Salmon River in Idaho. Another similar virus, Eyach virus, has been implicated in neurologic illness in France and Germany and has been isolated from the deer ticks *Ixodes ricinus* and *Ixodes ventalloi*.

PATHOBIOLOGY

Colorado tick fever virus replicates in $CD34^+$ stem cells in bone marrow and leads to mild to moderate leukopenia and thrombocytopenia. The virus also replicates in committed erythrocyte precursors and may be detected in circulating erythrocytes up to 4 weeks after infection.

CLINICAL MANIFESTATIONS

Patients report a tick bite or exposure in 90% of cases, but there is no notable local reaction to the tick bite. After a mean incubation of 3 to 4 days (range, 0 to 14 days), sudden-onset fever develops in association with malaise, chills, myalgia, weakness, headache, photophobia, retro-orbital pain, and cutaneous hyperesthesia. Conjunctival and oropharyngeal injection, palatal enanthem, lymphadenopathy, and splenomegaly may be present. The absence of prominent respiratory and gastrointestinal symptoms helps exclude other febrile illnesses. A petechial or maculopapular exanthem, found in 15% of patients, may be confused with the rash of Rocky Mountain spotted fever (Chapter 335). The illness has a "saddleback" fever pattern consisting of resolution of the initial fever within 1 week and recrudescence after a 2- to 3-day hiatus. A third fever episode may occur.

Leukopenia develops 5 to 6 days after onset of the illness. Mild thrombocytopenia and anemia may occur.

Myocarditis, pneumonitis, hepatitis, orchitis, and epididymitis may complicate adult infection, and aseptic meningitis or encephalitis may occur in up to 10% of childhood infections.

DIAGNOSIS

Clinical diagnosis is confirmed by demonstration of the Colorado tick fever viral genome or specific acute phase IgM antibody. The viral genome may be detected up to 6 weeks after infection by nucleic acid–based methods such as reverse transcription–polymerase chain reaction (RT-PCR) on blood or stored blood clots. Virions in circulating erythrocytes may be detected by immunofluorescent antibody labeling. Anti–Colorado tick fever virus IgM antibody is detected by antibody capture enzyme-linked immunosorbent assay (ELISA) or complement fixation. Neutralization assays using Vero or BHK-21 cells have been helpful.

Differentiating Colorado tick fever from Rocky Mountain spotted fever (Chapter 335) may be difficult before the appearance of the typical rash of the latter. However, Rocky Mountain spotted fever does not have a saddleback fever pattern and is 20 times less common than Colorado tick fever in the western endemic area.

TREATMENT

Rx

Treatment is supportive. Aspirin is contraindicated to avoid complicating thrombocytopenia.

PROGNOSIS

Extreme weakness and malaise may persist for weeks to months after final resolution of the fever. Older patients have a prolonged recovery. Seventy percent of patients older than 30 years may still have fatigue 3 weeks after the fever, whereas children and adolescents may recover completely within a week. Rare instances of maternal-fetal transmission have been reported. Full

recovery eventually occurs, except when the disease course is complicated by neurologic insult. Patients should refrain from donating blood for 6 months.

DENGUE

DEFINITION

Dengue is an acute febrile illness characterized by severe muscle and joint pain, rash, malaise, and lymphadenopathy. The severity of the musculoskeletal complaints gave rise to the sobriquet *breakbone fever*. Dengue occurs in the tropical and subtropical climes of the Caribbean, Central and South America, Asia, and Africa. The mosquito range extends into the southeastern part of the United States, where dengue reemerged in the 1980s. After World War II, a spreading global pandemic has been associated with erosion of mosquito control programs, human populations that have spread into rural settings, accelerated population movement as a result of travel by airplane, and large areas that have experienced deterioration in public health infrastructure. Approximately 40% of the world's population lives in endemic areas; tens of millions of individuals are infected annually.

The Pathogen

Dengue virus is a member of the Flaviviridae family, which consists of single-stranded RNA viruses with a lipid envelope approximately 50 nm in diameter. There are four serotypes of dengue: DEN-1, DEN-2, DEN-3, and DEN-4. No cross-protection is seen among the serotypes, so dengue can develop after infection with another serotype. Infection with a second serotype places the individual at risk for the development of hemorrhagic fever (Chapter 389).

EPIDEMIOLOGY

Dengue is transmitted to humans by the bite of female *Aedes aegypti* and *Aedes albopictus* mosquitoes. *A. albopictus* has become the dominant pest mosquito in many urban centers. Members of the two mosquito species acquire dengue virus by biting humans, typically during the day. Zoonotic life cycles involving nonhuman primates (i.e., chimpanzees, gibbons, and macaques) and canopy-dwelling forest *Aedes* species have been demonstrated in western Africa and Malaysia. The mosquitoes nest in stagnant water around human dwellings; they are not typically encountered in the forest. In the human host, dengue virus may reach a titer of greater than 10^8 median infectious doses per milliliter. The mosquito becomes infected when taking its meal from a viremic host. The virus continues replication in the midgut epithelium and salivary glands of female mosquitoes, which remain infectious for life. Within 8 to 12 days of the initial infection, the mosquito's salivary glands become infected and virus is shed with saliva during the next blood meal. A given mosquito may infect multiple individuals, especially in view of its skittishness during feeding—slight movement of the host interrupts its meal, after which it returns to the original or another host.

The incubation period is typically 4 to 7 days but may range from 3 to 14 days. During outbreaks in the southeastern United States and Puerto Rico, the risk for infection may be as high as 79% in naïve hosts, and clinical disease may develop in up to 20%. Immunity against the infecting serotype is probably lifelong, but individuals remain susceptible to the remaining serotypes. Peak transmission occurs after increased rainfall, when rainwater collected in household containers allows expansion of mosquito populations. Epidemics tend to occur in 3- to 5-year cycles, but interepidemic cases occur regularly.

Dengue is a particular risk to visitors to the tropics and is a leading cause of pediatric morbidity and mortality in endemic areas. Globalization and climate change have contributed to expansion of the geographic range. Dengue accounts for approximately 2% of the febrile illnesses in travelers returning to the United States.

PATHOBIOLOGY

Dengue hemorrhagic fever (Chapter 389) and dengue shock syndrome are forms of dengue reinfection characterized by capillary leakage and hemorrhage. Previous infection with an alternative serotype allows antibody to the previously encountered serotype to combine with the newly infecting serotype. Although the first exposed serotype antibody is not neutralizing, it does allow enhanced antibody-mediated macrophage uptake, thereby leading to macrophage activation and increasing viral replication and viral load. Excretion of vasoactive inflammatory mediators by macrophages results in vascular leakage; severe vascular leak causes shock. Endothelial cell swelling and perivascular edema may occur. Rarely, dengue shock syndrome may occur with primary infection. Variation in a strain's ability to generate enhancing antibody, as well as differences in virulence, may account for differences in clinical behavior.

CLINICAL MANIFESTATIONS

Dengue infection is often subclinical. When symptomatic, dengue may be manifested as classic dengue, dengue hemorrhagic fever, or dengue shock syndrome. Patients may also have mild illness characterized by nonspecific fever, anorexia, and headache.

Classic dengue, which typically occurs in nonindigenous older children and adults, is characterized by sudden-onset fever, severe frontal headache, retro-orbital pain, myalgia, and in many cases, nausea, vomiting, rash, lymphadenopathy, and arthralgia. Patients may experience generalized weakness, altered taste, rigors, and cutaneous hyperesthesia. Classic dengue is self-limited, but some patients progress to dengue hemorrhagic fever or dengue shock syndrome, which is characterized by capillary leakage, hypotension, narrowed pulse pressure, and shock. Dengue in pregnancy may be severe.

Physical examination demonstrates fever, relative bradycardia, scleral injection, ocular pressure tenderness, and pharyngeal injection. A transient macular rash appears on days 1 or 2 of illness. On days 2 and 3 of illness, fever and other symptoms may improve. The fever is typically, but not consistently biphasic. After a hiatus of typically 2 days, fever and other symptoms recrudesce, though less severely. Generalized, nontender lymphadenopathy of the posterior cervical, epitrochlear, and inguinal regions may develop. Rash also recurs and appears as 2- to 5-mm speckles of pallor surrounded by erythema and occasionally accompanied by burning dysesthesia of the palms and soles. The rash may desquamate.

DIAGNOSIS

An adequate travel history and knowledge of occurrence of disease in the community can lead to consideration of dengue in the differential diagnosis. Viremia is of adequate intensity in infections with DEN-1, DEN-2, and DEN-3 to allow viral isolation. Viremia in DEN-4 infections is often less intense and more difficult to detect through inoculation of mosquito cells in vitro. Specific IgM antibody appears 3 to 5 days after infection. IgG antibody appears 9 to 10 days after infection. Cross-reactivity with other flaviviruses prevents serotype-specific diagnosis. Neutralization testing with hemagglutination inhibition is more specific, and complement fixation testing for IgG in paired sera is helpful. PCR-based assays are available.

Leukopenia develops by the second day of fever, reaches 2000 to 4000 cells/mL by day 4 or 5, and is associated with granulocytopenia. In dengue hemorrhagic fever, thrombocytopenia of less than 100,000 cells/mL and a prolonged prothrombin time are characteristic. Mild to moderate proteinuria and a few casts may be detected. Aspartate transaminase levels may be increased.

TREATMENT AND PROGNOSIS

Rx

Classic dengue resolves abruptly in 5 to 7 days, but fatigue and depression may linger for weeks; survival is uniform. The prognosis of patients with dengue hemorrhagic fever (Chapter 389) and dengue shock syndrome depends on early diagnosis and the introduction of supportive measures. Treatment is supportive and consists of antipyretics and analgesics. Initial resuscitation of patients with shock syndrome (Chapter 108) with crystalloid and colloidal solutions is indicated in those with moderately severe dengue shock syndrome. Fresh-frozen plasma and blood products are used as necessary.

WEST NILE FEVER VIRUS

DEFINITION

West Nile fever is an acute febrile illness associated with malaise, rash, headache, myalgia, and lymphadenopathy. Infection involves a bird-mosquito-human cycle. Viremia develops in all varieties of birds. Bats, cats, chipmunks, domestic rabbits, horses, skunks, squirrels, dogs, sheep, llamas, and alpacas may be infected.

The Pathogen

West Nile fever virus, which is the most widely distributed flavivirus, is transmitted by a variety of mosquito species. The mosquito vector varies: *Culex univittatus*, *Culex pipiens*, and *Culex molestus* in the Middle East and Africa; *Mansonia metallicus* in Uganda; and *Culex tritaeniorhynchus* in Asia. After introduction into the New York City area in 1999, *C. pipiens* became the most

important vector in the United States. Other mosquito species may carry the virus.

EPIDEMIOLOGY

Viral transmission involves mosquitoes and wild birds, with mammals, including humans, being incidental end-stage hosts. In endemic areas, more than 60% of young adults have antibodies, thus suggesting a high prevalence of inapparent or undifferentiated febrile illness in children. There is no gender predominance.

Between 0.5 and 1% of infected individuals experience a more severe illness. Incubation is typically 3 to 14 days but may be as short as 1 day.

West Nile virus emerged in the United States in New York and has spread throughout the continental United States, Canada, Mexico, the Caribbean, and Central and South America. In America, birds of the Corvidae family (e.g., crows, jackdaws, ravens) are often infected, and recognition of increased death in crow populations continues to serve as a sentinel for the presence of West Nile virus. In addition to mosquito transmission, the virus has been transmitted by a transplanted organ, via blood transfusion, transplacentally, and in the laboratory.

Zika virus, a flavivirus related to dengue and West Nile virus, has emerged in Africa, Asia, and the Yap Islands of the southwestern Pacific. It causes outbreaks of fever, rash, arthralgia, and conjunctivitis.

PATHOBIOLOGY

West Nile virus grows in a variety of cells in vitro and produces cytopathic effects in *A. albopictus* cells. Individuals in whom encephalitis develops show evidence of diffuse brain inflammation and neuronal degeneration, with virus detected early in multiple sites. The virus probably replicates in skin dendritic cells, which then migrate to local lymph nodes and initiate the innate immune response.

CLINICAL MANIFESTATIONS

Approximately 80% of infections are asymptomatic, and most of the remaining infections are mild and manifested by fever, malaise, headache, nausea, anorexia, generalized lymphadenopathy, and myalgia. Aseptic meningitis or encephalitis (Chapter 391) may occur in the elderly and, less commonly, in the very young. Severe neurologic disease, including meningitis, myelitis, encephalitis, and flaccid paralysis of the limbs and respiratory muscles, can develop. Like Colorado tick fever and dengue, West Nile fever may be biphasic. Nonpruritic, maculopapular, or roseolar rash occurs on the chest, back, and arms in half the patients, beginning during or with resolution of the fever. The rash persists for up to 1 week and then resolves with desquamation. Patients may experience vomiting, diarrhea, abdominal pain, and pharyngitis. Anterior myelitis or hepatitis may also occur. Disease is usually milder in children than in adults.

DIAGNOSIS

West Nile virus may be isolated from up to 77% of patients with West Nile fever on the first day of illness, but viral isolation is less common in patients with encephalitis (Chapter 391). Low-titer viremia may persist for the first 5 days of illness. Tests for virus-specific antibody using ELISA or immunofluorescence are available. RT-PCR may detect viral RNA in human samples and in avian and insect specimens.

TREATMENT Rx

Treatment is supportive. The clinical value of antiviral agents is unknown. Infection is controlled by the endogenous development of neutralizing antibodies to protein E, the viral envelope protein.

PROGNOSIS

Illness generally persists 3 to 6 days before rapid recovery. The prognosis is excellent, but mortality rates of 10% or higher occur in patients with encephalitis (Chapter 391).

PHLEBOTOMUS FEVER

DEFINITION

Phlebotomus fever (i.e., sandfly fever, pappataci, and 3-day fever) is an acute, mild, self-limited febrile illness transmitted through the bite of *Phlebotomus* flies.

The Pathogen

Phlebotomus fever viruses are members of the genus Phlebovirus, family Bunyaviridae. The latter consists of a group of single-stranded RNA viruses that are 80 to 120 nm in diameter, possess a lipid envelope, and have three segments in the genome. A related virus, the Toscana virus hosted by *Phlebotomus perniciosus*, causes a similar illness in central Italy, Cyprus, Spain, and Portugal. Punique virus, a related virus, has been found in blood pools in Sicily.

EPIDEMIOLOGY

The virus's distribution parallels the distribution of *Phlebotomus* flies found throughout the Mediterranean basin, Middle East, and western India and Pakistan. In Central America, *Lutzomyia* fly species may transmit the virus. These tiny sandflies pass through mosquito netting to feed in the early evenings. Virus is maintained by transovarial and trans-stadial transmission. During outbreaks, humans may serve as a reservoir. Human infection is more common in rural areas during the summer months. The incubation period is 2 to 6 days. Sandflies spread by hopping, thus limiting their travel range. Use of insect sprays locally is effective in decreasing risk.

CLINICAL MANIFESTATIONS

Sandfly fever virus causes an acute febrile illness associated with malaise, headache, photophobia, ocular pain, altered taste, myalgia, and arthralgia. The myalgias may be localized to specific regions (e.g., the chest) and simulate regional syndromes such as pleurodynia. A macular or urticarial rash may appear. Examination may show relative bradycardia after the first day, conjunctival injection, mild papilledema, or small palatal vesicles. Fever lasts 2 to 4 days and then subsides. Weakness and malaise may persist during convalescence. About 15% of patients experience recrudescence in 2 to 12 weeks. Aseptic meningitis may occur with mild cerebrospinal fluid pleocytosis. Peripheral leukopenia and lymphopenia may be present early in the illness. However, leukopenia may be delayed in some patients until the third day of illness, and a rebound relative lymphocytosis may be encountered.

DIAGNOSIS

The diagnosis of phlebotomus fever is confirmed by isolation of virus after intracerebral inoculation of suckling mice, detection of the viral genome by RT-PCR, or detection of specific IgM antibody by ELISA.

TREATMENT AND PROGNOSIS Rx

Treatment is supportive, and recovery is complete. Ribavirin (Chapter 368) has been proposed as a therapeutic option.

RIFT VALLEY FEVER

Rift Valley fever, which is an acute-onset, febrile illness, is often associated with epizootic waves of spontaneous abortion in livestock.

DEFINITION

The Rift Valley fever virus is a member of the family Bunyaviridae, genus Phlebovirus, but unlike other members of the genus, it is transmitted by *Aedes* mosquitoes.

EPIDEMIOLOGY

Rift Valley fever occurs throughout most of Africa, with the majority of epizootic outbreaks occurring in eastern and southern Africa. Rift Valley fever was documented in Saudi Arabia and Yemen in 2000. The principal initial vectors are probably the *Aedes* species associated with flooding. Shallow pools along rivers and streams play an important role as mosquito breeding sites. Feeding on nearby livestock allows a local epizootic outbreak and amplification of the virus in local mosquito populations, including *C. pipiens* in Egypt and *Culex theileri* in eastern Africa.

Hemorrhagic fever in humans is typically seen 1 to 2 weeks after a wave of abortion in livestock. Initial human cases usually occur in those who have close contact with livestock. The virus is highly transmissible through aerosolization. Although the risk for severe human infection is less than 1%, the extensive exposure associated with outbreaks can lead to significant morbidity and mortality. For example, in the 1977-1978 Egyptian outbreak associated with movement of camels from Sudan, an estimated 200,000 people

were infected, with 600 deaths. Zinga virus, isolated in central Africa and Madagascar and shown to be responsible for mild human illness, is a strain of Rift Valley fever virus.

PATHOBIOLOGY

Rift Valley fever virus grows well in a variety of cell cultures and has cytopathic effects. After infection by a mosquito bite, virus is transported through the lymphatics to regional lymph nodes, where replication allows amplification of the input inoculum and development of viremia with systemic spread. Viral replication in liver, spleen, lymph node, adrenal, lung, and kidney tissues is highly cytopathic. In severe cases, hepatic necrosis and, rarely, focal brain necrosis may occur. Encephalitis is not associated with viremia, thus suggesting that this sequela is immune mediated rather than a direct viral effect. Inflammatory cell infiltration is associated with focal necrosis in the brain. Spontaneous abortion is common in livestock, but fetal loss in humans is not clearly correlated with viral infection.

CLINICAL MANIFESTATIONS

Most human infections are mild, with an abrupt onset of fever, chills, malaise, and arthralgia following a 2- to 6-day incubation. Despite the development of neutralizing antibodies, however, about 1 to 2% of infections progress to more severe disease, including a severe hemorrhagic fever associated with hepatic necrosis and disseminated intravascular coagulopathy. Recovery is complicated by retinal vasculitis or encephalitis, which occurs in less than 0.5% of patients 1 to 4 weeks after recovery and is associated with recurrent fever. In severe cases, focal brain necrosis and encephalitis may lead to hallucinations, stupor, coma, and death.

DIAGNOSIS

Intense viremia allows detection of virus by quantitative real-time RT-PCR. Specific IgM and IgG are detectable by ELISA applied to acute and convalescent (after 1 to 2 weeks) paired sera.

TREATMENT, PREVENTION, AND PROGNOSIS

Rx

Treatment is supportive. Ribavirin (Chapter 368) has been proposed as a therapeutic option but exhibits limited penetration of the blood-brain barrier. In endemic areas, vaccination of livestock is the most effective preventive measure.

The prognosis is good in the absence of retinitis or encephalitis. A high viral load at initial evaluation is a prognostic indicator for a poor outcome.

CHIKUNGUNYA FEVER

DEFINITION

Chikungunya fever is a febrile arthritis that occurs in sporadic cases and in epidemics.

The Pathogen

Chikungunya, an enveloped, single-stranded RNA virus 60 to 70 nm in diameter, is a member of the family Togaviridae, genus Alphavirus. Chikungunya virus is transmitted by mosquitoes, principally *Aedes* species, but also by *Mansonia africana* and other genera. Known animal reservoirs are monkeys, baboons, and in Senegal, *Scotophilus* bat species. During outbreaks, humans are the major reservoir.

EPIDEMIOLOGY

Chikungunya, which is endemic in sub-Sahara Africa, India, the Philippines, and Southeast Asia, spread in 2005 to the Seychelles, Mauritius, and Mayotte Islands with a genotype better adapted to *A. albopictus*. This genotype then spread to India, where the outbreak continues with millions being affected. In 2007, an outbreak occurred in Italy. Outbreaks typically develop after heavy rains. In urban settings, outbreaks are explosive. In endemic areas, seroprevalence rates may be as high as 90%, thus suggesting that time required for loss of herd immunity is the reason for the prolonged absence of cases in a region after an outbreak. Globalization may contribute to increasing propensity for spread. An outbreak in Malaysia from 1998 to 1999 was attributed to migrant workers from endemic areas. After inoculation, the incubation period is typically 2 to 3 days but ranges from 1 to 12 days.

PATHOBIOLOGY

Intense viremia develops within 48 hours of the mosquito bite and wanes 2 to 3 days later. Onset of hemagglutination inhibition and neutralizing antibodies clears the viremia. Superficial capillaries in rash-involved skin demonstrate erythrocyte extravasation and perivascular cuffing. The virus adsorbs to human platelets and causes them to aggregate. Synovitis probably results from direct chikungunya viral infection of synovium.

CLINICAL MANIFESTATIONS

Chikungunya fever is characterized by an explosive onset of fever and severe arthralgia. Constitutional symptoms, fever to 40° C, rigors, headache, photophobia, retro-orbital pain, conjunctival injection, pharyngitis, anorexia, nausea, vomiting, abdominal pain, tense lymphadenopathy, and myalgia are common. A maculopapular rash located on the torso, extremities, and occasionally the face, palms, and soles occurs in most patients 1 to 10 days after onset of the illness. Appearance of the rash is often associated temporally with initial defervescence; the rash may recur with fever and may be pruritic. Isolated petechiae and mucosal bleeding may occur, but significant hemorrhage is rare. Desquamation may take place when the rash resolves. The initial acute illness may last 2 to 3 days (range, 1 to 7 days). Fever may recrudesce after a 1- to 2-day hiatus. The polyarthralgia is migratory and predominantly affects the small joints of the hands, wrists, feet, and ankles, with less prominent involvement of the large joints. Previously injured joints may be more severely affected. Stiffness and swelling may occur, but large effusions are uncommon. Synovial fluid shows decreased viscosity with poor mucin clot and 2000 to 5000 white blood cells per milliliter. Symptoms, including arthralgia, arthritis, and tenosynovitis, may persist for months. Maternal-fetal transmission may result in severe neonatal infection.

DIAGNOSIS

Chikungunya fever must be differentiated from dengue and o'nyong-nyong fever. Chikungunya virus may be isolated from blood during the initial 2 to 4 days of illness. In some patients, viral antigen may be detected in acute sera by hemagglutination assay as a result of the intensity of the viremia. Commercially available real time RT-PCR assays on acute phase serum may be used to confirm the diagnosis. Specific IgM antibody may be detected for 6 months or longer. Hemagglutination inhibition and neutralization antibodies develop as the viremia is cleared. Complement fixation antibodies are positive by the third week and slowly decrease over the subsequent year.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive. Nonsteroidal anti-inflammatory agents are useful. During the acute arthritis, range-of-motion exercises lessen the stiffness. In most cases, mild joint symptoms may persist for months. Destructive arthropathy is rare and may be associated with low-titer rheumatoid factor, thus suggesting an unrelated, underlying inflammatory arthritis. Approximately 10% of patients have joint symptoms 1 year after infection. In children, arthralgia and arthritis are milder and briefer in duration.

O'NYONG-NYONG FEVER

DEFINITION

O'nyong-nyong means "joint breaker" in the Acholi dialect of northwestern Uganda, where o'nyong-nyong fever first appeared in February 1959.

The Pathogen

O'nyong-nyong fever is clinically similar to chikungunya fever, and the viruses share antigenic similarity. O'nyong-nyong virus is also a member of the family Togaviridae, genus Alphavirus.

EPIDEMIOLOGY

Within 2 years of its appearance in 1959, the o'nyong-nyong fever virus spread through Uganda and eastern Africa and affected 2 million people. Serologically determined attack rates ranged from 50 to 60%, with case rates of 9 to 78%. Disease spread at a rate of 2 to 3 km daily. After the epidemic, the virus was not detected again until it was isolated from *Anopheles funestus* mosquitoes in Kenya in 1978. *Anopheles gambiae* also serves as a vector. Serologic surveys suggested that o'nyong-nyong virus is endogenous, but cases were not detected again until 1996-1997, during an outbreak in south central Uganda. An outbreak in western Côte d'Ivoire occurred in 2003. The

nonhuman vertebrate reservoir for o'nyong-nyong virus is not known. The incubation period lasts at least 8 days. O'nyong-nyong fever virus vectors include *A. funestus*, *A. gambiae,* and other species.

Igbo-ora (meaning "the disease that breaks your wings") virus is a variant of o'nyong-nyong, with 98.5% homology between the two at the genomic level. Igbo-ora is serologically similar to the chikungunya and o'nyong-nyong viruses. In 1984, an epidemic of fever, rash, arthralgia, and myalgia occurred in four villages on the Ivory Coast. The virus was isolated from *A. funestus* and *A. gambiae* mosquitoes and from affected individuals.

PATHOBIOLOGY

Little is known about the pathobiology of o'nyong-nyong fever.

CLINICAL MANIFESTATIONS

Illness begins with a sudden onset of polyarthralgia and polyarthritis. Between 4 and 7 days later, rash begins with improvement in joint symptoms. The rash is uniform in nature, begins on the face, and then spreads to the torso and extremities and occasionally to the palms. The rash lasts 4 to 7 days before fading. Fever is not prominent, but postcervical lymphadenopathy may be marked. Arthralgia is incapacitating in most patients for up to a week, but residual joint pain may persist for months.

DIAGNOSIS

O'nyong-nyong fever is difficult to differentiate from chikungunya fever and may also be mistaken for measles. Specific hemagglutination inhibition and complement fixation tests are available. Mouse antisera raised against chikungunya virus react equally well with o'nyong-nyong virus, but o'nyong-nyong antisera do not react well with chikungunya virus. O'nyong-nyong–specific RT-PCR is available in reference laboratories.

TREATMENT AND PROGNOSIS Rx

Treatment is symptomatic. Although residual joint pain often persists, there do not appear to be any long-term sequelae.

MAYARO FEVER

DEFINITION

Mayaro fever is an acute febrile illness characterized by fever, rash, arthralgia, and arthritis. Mayaro virus was first recognized in Trinidad in 1954. It has caused recorded outbreaks in Bolivia and Brazil and is endemic in the rain forest region where Bolivia, Brazil, and Peru share borders. Mayaro virus has a monkey reservoir and is transmitted to humans by *Haemagogus* mosquitoes dwelling in the tropical rain forest canopy.

The Pathogen

Mayaro virus is a member of the family Togaviridae, genus Alphavirus.

EPIDEMIOLOGY

Mayaro virus was responsible for an outbreak in Belterra, Brazil, in 1988. Eight hundred of 4000 exposed latex gatherers became infected, with a clinical attack rate of 80%. Cases of imported Mayaro virus infection have been documented in the United States after travel from the endemic Brazil-Bolivia-Peru interborder region. Mayaro virus has been isolated from a bird in Louisiana, thus raising the specter of emergence of Mayaro virus in North America.

PATHOBIOLOGY

Viremia occurs during the first 1 to 2 days of illness.

CLINICAL MANIFESTATIONS

Illness is characterized by a sudden onset of fever, headache, dizziness, chills, and arthralgia in the small joints of the hands and feet. About 20% of patients have joint swelling. Unilateral inguinal lymphadenopathy is seen occasionally. Leukopenia is common. Fever resolves after 2 to 5 days, but a maculopapular rash then develops on the trunk and extremities of about two thirds of patients and lasts about 3 days.

DIAGNOSIS

Mayaro virus may be isolated from blood by growth in Vero or C6/36 cells. RT-PCR with ELISA is available. A specific IgM is also available as an antibody capture ELISA.

TREATMENT AND PROGNOSIS Rx

Recovery is complete, although some patients have persistent arthralgia 2 months later.

ROSS RIVER FEVER VIRUS (EPIDEMIC FEBRILE POLYARTHRITIS)

Ross River fever virus causes an acute-onset, febrile illness characterized by rash and arthralgia. Ross River virus is a member of the family Togaviridae, genus Alphavirus.

EPIDEMIOLOGY

Epidemics of fever and rash have been observed in Australia since 1928. Isolation of Ross River virus from mosquitoes, its serologic association with epidemic polyarthritis, and isolation of the virus from epidemic polyarthritis patients in Australia confirmed Ross River virus as the etiologic agent of epidemic polyarthritis. Seroprevalence has been observed in endogenous populations in Papua New Guinea, western New Guinea, the Bismarck Archipelago, Rossel Island, and the Solomon Islands. An outbreak in the Fiji Islands affected more than 40,000 individuals in 1979 to 1980. A similar epidemic occurred in the Cook Islands early in 1980. Antibodies to Ross River virus are not found in individuals west of Weber's line, a hypothetic line separating the Australian geographic zone from the Asiatic zone. Endemic cases and epidemics occur in tropical and temperate regions in Australia. Queensland and New South Wales have a particularly high annual incidence associated with higher rainfall. High rainfall usually precedes epidemic periods, with cases subsequently occurring from spring through fall. Seroprevalence may reach just 6 to 15% in temperate coastal zones but is 27 to 39% in the plains of the Murray Valley river system. In Queensland, annual rates of disease range from 31.5 to 288.3 per 100,000 person years. From 1992 to 2006, 55,000 cases of Ross River virus infection were reported in Australia.

Aedes vigilax is the major vector on the eastern coast of Australia and *Aedes camptorhynchus* in the salt marshes of southern Australia. *Culex annulirostris* is a freshwater breeding vector. Other Australian *Aedes* species and *Mansonia uniformis* may also serve as vectors. In outbreaks on the Pacific islands, *Aedes polynesiensis*, *A. aegypti*, *A. vigilax*, and *C. annulirostris* may have contributed to transmission. Domestic animals, rodents, and marsupials may serve as intermediate hosts. Virus may persist in *Aedes* mosquitoes.

Most infected individuals become symptomatic. Although male and female infection rates are similar, there is a predominance of women among infected individuals. Children have a case attack rate ratio lower than that of adults. The incubation period is 7 to 11 days.

Barmah Forest virus, another alphavirus found in Australia in 1986, may be manifested in a fashion similar to epidemic febrile polyarthritis. The number of cases reported annually has been increasing since its initial discovery.

PATHOBIOLOGY

Ross River viral antigen may be detected in monocytes and macrophages early in infection, but intact virus is not identifiable by electron microscopy or cell culture. Dermal vessels show mild perivascular mononuclear cell infiltrates, mostly T lymphocytic, in erythematous and purpuric areas. Vessels in purpuric areas also show erythrocyte extravasation. Antigen can be demonstrated in epithelial cells in erythematous or purpuric skin and in the perivascular zone in erythematous skin. However, viral antigens have not been found in normal skin. Synovium undergoes lining cell hypertrophy and sublining vascular proliferation and mononuclear cell infiltration. Viral RNA can be identified by RT-PCR. Synovial fluid cell counts range from 1500 to 13,800 cells/mL and consist of monocytes, vacuolated macrophages, and a few neutrophils. Animal models of infection indicate that Ross River virus targets bone, joint, and skeletal muscle and elicits an inflammatory response mediated by the innate immune system.

CLINICAL MANIFESTATIONS

Arthralgia typically occurs abruptly, followed in 1 to 2 days by a macular, papular, or maculopapular rash that may be pruritic. Three fourths of patients have severe, incapacitating arthralgia in an asymmetrical and migratory distribution. Commonly affected joints are the metacarpophalangeal joints, finger interphalangeal joints, wrists, knees, and ankles. The shoulder, elbow,

toe, spine, hip, and temporomandibular joints may also be affected. Arthralgias are worse in the morning and after periods of inactivity. A third of patients have synovitis. Polyarticular swelling and tenosynovitis are common. Up to a third of patients have paresthesias or palm or sole pain. Classic carpal tunnel syndrome may occur.

In some individuals, rash may precede or follow the joint symptoms by 11 or 15 days, respectively. Occasionally, vesicles, papules, or petechiae are seen. The trunk and extremities are typically involved, but the palms, soles, and face may also be affected. The rash resolves by fading to a brownish discoloration or by desquamation. Fever tends to be mild to moderate and lasts 1 to 3 days. Headache, nausea, and myalgia are common. Mild photophobia, respiratory symptoms, and lymphadenopathy may occur.

DIAGNOSIS

In the Australian epidemics before 1979, patients were antibody positive at the time of initial evaluation. However, in the Pacific island epidemics of 1979 to 1980, patients remained viremic and serologically negative for up to a week after the onset of symptoms. Virus in serum is stable for up to a month at 0 to −10° C. Current testing in Australia is performed with an indirect ELISA. The presence of specific IgM or evidence of seroconversion to IgG positivity supports a recent infection.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive. Nonsteroidal anti-inflammatory drugs provide relief of joint pain. Half of all patients return to activities of daily living within 4 weeks despite residual polyarthralgia. Joint symptoms may recur, but episodes gradually resolve. In some patients, joint symptoms may persist for up to 3 years. Mild exercise tends to improve the joint symptoms.

SINDBIS

Sindbis virus causes a sudden-onset, febrile illness associated with arthralgia and rash. It is known as Ockelbo disease in Sweden, Pogosta disease in Finland, and Karelian fever in the Karelian Isthmus of Russia. *Aedes*, *Culex*, and *Culiseta* mosquitoes transmit the virus to humans, with birds serving as intermediate hosts. Sindbis virus is the prototype alphavirus used for molecular virology studies of its genus.

EPIDEMIOLOGY

The virus was first isolated from *Culex* mosquitoes in the Egyptian village of Sindbis in 1952. Outbreaks frequently occur in the forested areas of Sweden, Finland, and the Karelian Isthmus, but sporadic cases and small outbreaks have occurred in Uganda, South Africa, Zimbabwe, central Africa, and Australia. Individuals involved in outdoor activities or occupations are at greatest risk.

PATHOBIOLOGY

Skin lesions show perivascular hemorrhage, lymphocytic infiltrates, edema, and areas of necrosis. Virus has been isolated from skin lesions. Antiviral IgM may persist for years, thus raising the possibility that Sindbis virus arthritis is associated with viral persistence and a direct viral effect on the synovium. Autophagy, an evolutionarily conserved intracellular mechanism for recycling cytoplasmic material to lysozymes for degradation during times of stress, may be disrupted in neurons by Sindbis virus infection, thereby leading to programmed cell death or apoptosis.

CLINICAL MANIFESTATIONS

Arthralgia and rash are the initial symptoms, although one may precede the other by a few days. Arthralgia and arthritis involve the small joints of the hands and feet, wrists, elbows, ankles, and knees. Occasionally, arthralgia affects the spine. Tendinitis is common and often involves the Achilles and hand extensor tendons. Fever, if present, tends to be mild to moderate. Constitutional symptoms, headache, fatigue, malaise, nausea, vomiting, pharyngitis, and paresthesias may be present but are not usually severe. Macular rash typically begins on the torso and then involves the arms, legs, palms, soles, and occasionally the head. Macules evolve to papules that have a tendency to vesiculate. Vesiculation is prominent on pressure points, including the palms and soles. As the eruption fades, a brownish discoloration is left. Vesicles on the palms and soles may become hemorrhagic. Rash may recur during convalescence.

DIAGNOSIS

Specific IgM detected by enzyme immunoassay supports a diagnosis of Sindbis virus infection. IgM titers may wane over a period of 3 to 4 years.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive. Nonerosive chronic arthropathy is common in Sweden and Finland, with up to half of all patients having joint symptoms 2.5 years after infection. In a few cases, symptoms may persist for up to 6 years.

ARBOVIRUSES AFFECTING THE CENTRAL NERVOUS SYSTEM

THOMAS P. BLECK

Arboviruses, which are also termed *arthropod-borne viruses,* can affect the central nervous system (CNS). These viruses share a number of clinical and epidemiologic similarities and have an RNA genome, but they do not form a formal virologic taxonomic group. Arboviruses generally have avian or small mammalian reservoirs and are transmitted to humans and other large mammals incidentally when an infected mosquito or other arthropod obtains a blood meal.

EPIDEMIOLOGY

Most human disease is subclinical; a few patients have a brief febrile illness resembling influenza, and a small percentage, usually at the extremes of age, suffer meningitis or encephalitis. The diseases (Table 391-1) reflect the quotidian and seasonal characteristics of their insect vectors. Other viruses of the same genera cause hemorrhagic fever (Chapter 389), and other less frequently encountered arboviruses are also capable of producing encephalitis.

Many of these agents cause notifiable disease in the United States: St. Louis, West Nile, Powassan, eastern equine, western equine, and the California serogroup encephalitis viruses. Case definitions and additional information are available at *http://www.cdc.gov/ncidod/dvbid/arbor/index.htm*.

The diseases described here are zoonoses (Chapter 336), that is, illnesses caused by viruses transmitted from animals to humans. They are more prevalent in the tropics and subtropics and are usually localized because of ecologic restrictions on their transmission.

PATHOBIOLOGY

Two pathologic processes are common to the arboviral encephalitides: neuronal and glial damage mediated by intracellular viral infection; and migration of immunologically active cells into the perivascular space and brain parenchyma. Endothelial cell swelling and proliferation, destruction of myelin sheaths in deep white matter areas, and vasculitis are present in some arboviral encephalitides.

After a bite by an infected arthropod, viral replication occurs in local tissues and regional lymph nodes. Viremia, which seeds extraneural tissues, occurs and persists, depending on the extent of replication in extraneural sites, the rate of viral clearance by the reticuloendothelial system, and the appearance of humoral antibodies. The sites of extraneural infection vary among the viruses. Many alphaviruses and flaviviruses involve striated muscle and endothelium, whereas Venezuelan encephalitis virus is associated with

TABLE 391-1 ARTHROPOD-BORNE VIRUSES ASSOCIATED WITH HUMAN ENCEPHALITIS

myeloid and lymphoid tissue invasion. During viremia, the neural parenchyma may be invaded, but the mode of penetration of virus across the blood-brain barrier is not completely understood. Possible mechanisms include passive movement of virus across vascular membranes and viral replication in the cerebral capillary endothelium. Factors increasing vascular permeability promote nervous system invasion. In experimental animal infection, flaviviruses enter the CNS through the olfactory epithelium.

The immature brain is more susceptible to damage by western equine, Venezuelan equine, and California serogroup encephalitis viruses (Table 391-2). St. Louis encephalitis and West Nile encephalitis principally affect the elderly, whereas Japanese encephalitis and eastern equine encephalitis have a bimodal incidence and strike both children and elderly persons. In endemic areas, immunity accumulated with increasing age may reduce the incidence of disease in older persons for some viruses; however, the reasons for the increased severity of illness with other viruses remain unknown.

CLINICAL MANIFESTATIONS

Clinical symptoms and signs vary among the viral causes (see later), although all share common signs and symptoms of encephalitis (Chapter 422).

DIAGNOSIS

Diagnosis depends on a careful history that includes exposure to vertebrate animals and arthropod vectors, age, season, and travel, including the geographic site of exposure. Laboratory confirmation of infection is essential. The virus may be isolated from acute phase serum or whole blood in laboratory animals or in tissue culture. Neutralization, complement fixation (CF), hemagglutination inhibition (HI), fluorescent antibody, and enzyme-linked immunosorbent assay (ELISA) of acute and 3-week convalescent sera can also produce the correct diagnosis. Antigen detection and IgM capture ELISA often permit diagnosis on initial evaluation and within a week of the onset of illness in most cases. Sensitive nucleic amplification assays using reverse transcription–polymerase chain reaction (RT-PCR) are under development for a number of the arboviruses and may lead to earlier diagnosis.

Differential Diagnosis

The most important initial consideration is to differentiate arboviral encephalitides from other acute CNS infections, including infections other than encephalitis (Chapters 420 and 421), treatable causes of encephalitis (Chapter 422), and paraneoplastic and autoimmune encephalitis (Chapters 420 and 422). The early prodrome resembles influenza (Chapter 372).

Bacterial meningitis (Chapter 420; especially early or partially treated), infective bacterial endocarditis (Chapter 76), brain abscess (Chapter 421), subdural empyema (Chapter 421), and cerebral thrombophlebitis may mimic viral encephalitis, and the cerebrospinal fluid (CSF) profile is sometimes similar. Other infections that occasionally cause meningoencephalitis that may resemble arthropod-borne viral encephalitis include tuberculosis (Chapter 332), cryptococcosis (Chapter 344), histoplasmosis (Chapter 340), coccidioidomycosis (Chapter 341), Rocky Mountain spotted fever (Chapter 335), leptospirosis (Chapter 331), falciparum malaria (Chapter 353), trichinosis (Chapter 365), *Naegleria* meningitis (Chapter 420), typhoid fever (Chapter 316), Lyme disease (Chapter 329), and *Mycoplasma* pneumonia (Chapter 325).

Acute meningoencephalitis may result from infections with other viruses, including herpesviruses (Chapter 382), human immunodeficiency virus (Chapter 394), mumps virus (Chapter 377), enteroviruses (Chapter 387), lymphocytic choriomeningitis virus (Chapter 420), rabies (Chapter 422), influenza (Chapter 372), and the exanthematous viral infections of childhood (Chapters 375 and 376). The exposure history, the presence of similar disease in the community, and the summer-fall occurrence are principal clues to an arboviral etiology. Enteroviruses (Chapter 387) also cause summer-fall outbreaks, but the predominant syndrome is aseptic meningitis, and the concomitant occurrence of rash or pleurodynia is a helpful clue. Herpes simplex encephalitis (Chapter 422) presents an important diagnostic challenge because effective therapy is available and should be started quickly. The presence of localizing neurologic signs, localizing findings on computed tomography (CT) or magnetic resonance imaging (MRI), and detection of herpes simplex DNA in CSF by PCR help distinguish herpes simplex encephalitis from the arboviral encephalitides.

Noninfectious diseases of the CNS such as stroke (Chapter 414) may rarely be confused with viral encephalitis. Subarachnoid hemorrhage (Chapter 415) produces meningismus, fever, headache, and neurologic signs that mimic an infectious etiology. Metabolic encephalopathies occasionally have features suggesting infectious encephalitis. Neoplastic or granulomatous diseases involving the CNS and a variety of diseases of uncertain etiology (Behçet's disease [Chapter 278], Reye's syndrome, acute multiple sclerosis [Chapter 419], and systemic lupus erythematosus [Chapter 274]) must be considered in the differential diagnosis as well.

PREVENTION

Control can be achieved by interruption of the cycle, including vaccination of reservoir animals, vector control, and education on vector avoidance. Practical measures include wearing long-sleeved clothing, using insect repellents, limiting outdoor activities during peak mosquito season, and eliminating standing pools of water. Vaccines are currently available for Japanese encephalitis.

TREATMENT Rx

Treatment is symptomatic and may include bedrest, antipyretics, and analgesics. Early empirical treatment of herpes simplex encephalitis (Chapter 382) may be appropriate while the diagnostic evaluation to document arboviral encephalitis proceeds.

EASTERN EQUINE ENCEPHALITIS

EPIDEMIOLOGY

Human disease is relatively rare, with fewer than 10 cases occurring each year in the Gulf Coast and Atlantic states, usually in association with an equine epizootic involving 100 to 300 animals. Outbreaks generally occur during the late summer and early fall. The occurrence of equine cases or outbreaks of fatal encephalitis in penned exotic birds precedes the appearance of human cases by several weeks or more. Epizootics of eastern equine encephalitis have been reported in the Caribbean (Hispaniola) and South America.

In temperate areas, eastern equine encephalitis virus circulates between wild birds and *Culiseta melanura* mosquitoes in a freshwater swamp habitat. Equine epizootics and associated human cases result from extension of the transmission cycle to involve *Aedes* and *Coquillettidia* mosquitoes, which feed on horses and humans.

PATHOBIOLOGY

The brain is grossly edematous and congested, and the inflammatory response is predominantly polymorphonuclear. The areas most affected are the basal ganglia, thalamus, hippocampus, and frontal and occipital cortices. Focal vasculitis, endothelial cell swelling, intravenous and arteriolar thrombus formation, demyelination, necrosis, neuronolysis, and neuronophagia are prominent.

CLINICAL MANIFESTATIONS

Onset is abrupt, with high fever, vomiting, and somnolence. Stupor, coma, myoclonus, and generalized convulsions appear within 24 hours to as long as 10 days later. Autonomic disturbances (sialorrhea) may be prominent, and respiratory difficulty and cyanosis are frequent. In children, facial, periorbital, or generalized edema may be present.

A striking peripheral leukocytosis with immature neutrophils occurs frequently in patients with eastern equine encephalitis. CSF examination reveals 500 to 2000 white blood cells/μL (predominantly neutrophils). As the total cell count falls, neutrophils may persist as a significant fraction. Red blood cells may be present, protein concentration is elevated, and the glucose level is normal.

DIAGNOSIS

Brain CT and MRI are frequently abnormal and reveal lesions in the basal ganglia, thalami, and brain stem. The virus can rarely be isolated from blood or CSF. Serologic diagnosis by demonstration of a rise in antibody titer in appropriately timed paired sera is the most practical and available test. Because of the rapid course of the clinical disease, sera should be obtained at 2- to 3-day intervals during the acute phase of illness.

PREVENTION

An experimental formalin-inactivated chick embryo cell culture vaccine is used to protect laboratory and field workers. Reduction of mosquito populations by appropriate use of insecticides may be effective in threatened or established outbreaks.

TREATMENT Rx

Treatment is supportive. Control of fever, intracranial pressure, seizures, fluid and electrolyte disturbances, and the airway is critical. Although attempts at immunologic therapy have been reported, no controlled data are available.

PROGNOSIS

The case-fatality rate is 50 to 70%. Mortality, like incidence, is highest in children younger than 15 years and in persons older than 55 years, with no gender predilection. Death usually occurs during the first week; in surviving patients, recovery begins during the second week and may progress rapidly. Good functional recovery is associated with a long prodromal course and absence of coma. Residual damage, found in 30 to 50% of patients, is often severe, especially in children, and is characterized by mental retardation, spastic paralysis, and radiographic evidence of brain atrophy.

WESTERN EQUINE ENCEPHALITIS

EPIDEMIOLOGY

Few cases of western equine encephalitis have been reported in the past decade; the most recent epidemic occurred in Colorado in 1987. Epidemics occur in early or mid summer and may follow heavy snow melt or flooding, conditions favorable for breeding of mosquitoes. Cases of encephalitis in equines often precede the appearance of human disease. The illness principally affects residents of rural communities, and the incidence is higher in males than in females.

The ratio of inapparent to apparent infection is also age dependent and ranges from about 1 : 1 in infants younger than 1 year, to 58 : 1 in children 1 to 4 years old, to more than 1000 : 1 in persons older than 14 years. Western equine encephalitis virus also occurs in South America. Equine epizootics in Argentina have been associated with human cases.

Western equine encephalitis virus circulates between wild birds and *Culex tarsalis* mosquitoes. *C. tarsalis* is responsible for infection of humans and equines, which have low or undetectable viremia and do not perpetuate the chain of transmission. In temperate areas, transmission ceases during the winter months.

PATHOBIOLOGY

Pathologic examination of the brains of infants reveals massive parenchymal destruction; children dying months or years after the acute insult often have large cystic lesions in many areas of the brain. In older children and adults, acute western equine encephalitis is characterized by focal necrosis and perivascular cuffing, predominantly in the basal ganglia and thalami but also in deep cerebral white matter.

CLINICAL MANIFESTATIONS

The disease usually begins with an influenza-like illness consisting of fever, headache, malaise, and myalgia lasting 1 to 4 days. Somnolence, lethargy, photophobia, vomiting, and neck stiffness may follow; neurologic involvement may rapidly progress to stupor, coma, and seizures. Pareses, cranial nerve deficits, tremors, and abnormal reflexes may be present. In fatal cases, patients die 1 to 2 days after coma develops. Congenital infections have been documented and result in severe and progressive neurologic deterioration.

Leukocytosis and a shift to the left are common. The CSF contains fewer than 500 white blood cells/μL (at first polymorphonuclear, then mononuclear) and an elevated protein concentration (usually 90 to 110 mg/dL).

DIAGNOSIS

Viral isolation from blood or CSF is almost never successful. Diagnosis is achieved by demonstration of a rise in HI, fluorescent antibody, CF, ELISA, or neutralizing antibody titers in appropriately timed (10 to 14 days apart) paired sera. Demonstration of IgM antibodies in serum or CSF by ELISA provides a presumptive diagnosis.

PREVENTION

An experimental formalin-inactivated vaccine grown in chick embryo cell culture has been used to protect laboratory workers but is not indicated for others. In threatened or ongoing epidemics, residents should be advised to use protective clothing, insect repellents, and window screens and to restrict outdoor activity in the early morning, late afternoon, and evening (times of greatest mosquito activity). Public health measures include spraying insecticides aimed at the adult *C. tarsalis* vector.

TREATMENT Rx

There is no specific therapy for western equine encephalitis. Supportive therapy is similar to that discussed earlier for eastern equine encephalitis.

PROGNOSIS

Western equine encephalitis is most severe in infants and young children. The case-fatality rate is between 3 and 5%. Survivors generally experience sudden and rapid recovery. However, about a third of surviving infants suffer mental retardation, cerebellar damage, choreoathetosis, and spastic paralysis. Children with protracted illnesses in whom convulsions develop during the acute stage are more likely to suffer long-term neurologic sequelae. Adults may have a prolonged convalescent syndrome, but objective residua are rare.

VENEZUELAN EQUINE ENCEPHALITIS

Six antigenic subtypes of Venezuelan equine encephalitis virus (I to VI) with several antigenic variants of subtypes I and III are recognized serologically. Subtypes IAB and IC are responsible for epidemics involving humans and equines. In Florida, subtype II is enzootic and produces sporadic human disease. Methods of transmitting Venezuelan equine encephalitis virus as a biologic warfare agent were developed in the 1960s; an epidemic of Venezuelan equine encephalitis, especially if humans and horses become ill simultaneously, could represent an attack rather than naturally occurring illness.

EPIDEMIOLOGY

Before 1973, large equine epizootics occurred at 5- to 10-year intervals in Venezuela, Colombia, Ecuador, and Peru and involved many thousands of animals with mortality rates as high as 40%. Associated human morbidity was also great (up to 32,000 clinical cases). The disease was quiescent for several years but has reemerged in the past decade. The last major outbreak occurred in Venezuela and Colombia in 1995, with more than 85,000 human cases. Laboratory infections are common in unvaccinated persons working with the virus or infected animals.

A large variety of mosquito vectors, including species of the genera *Aedes, Psorophora,* and *Mansonia,* transmit subtypes IAB and IC during epizootic epidemics. Equines are the principal viremic hosts. Virus may be present in the pharyngeal excretions of human patients; contact or aerosol person to person spread, although possible, is not epidemiologically important.

The other members of the Venezuelan equine encephalitis viral complex, including subtype II in Florida, have enzootic transmission cycles involving *Culex* mosquitoes and small forest rodents and marsupials. Human disease is sporadic and relatively uncommon.

PATHOBIOLOGY

Pathologic changes in the CNS include edema, congestion, meningeal and perivascular inflammation, intracerebral hemorrhage, neuronal degeneration, and vasculitis. In addition, hepatocellular degeneration and necrosis, widespread lymphoid depletion and follicular necrosis, and interstitial pneumonitis are frequent. Congenitally infected fetuses demonstrate massive and widespread necrosis of brain tissue, hemorrhage, and resorption of brain material resulting in hydranencephaly.

CLINICAL MANIFESTATIONS

The predominant syndrome is a self-limited influenza-like illness; encephalitis develops in only about 4% of infected persons, principally children younger than 15 years. Subclinical infections are rare.

After an incubation period of 2 to 5 days, there is a sudden onset of fever, chills, malaise, and headache, followed by myalgias, nausea, vomiting, and occasionally diarrhea. Physical examination reveals fever, tachycardia, conjunctival injection, and, in some cases, nonexudative pharyngitis. The acute illness generally subsides in 4 to 6 days, and convalescent symptoms may last up to 3 weeks. A biphasic course has sometimes been noted; acute symptoms can reappear after a brief remission, within a week after initial onset.

When it occurs, severe encephalitis is characterized by meningeal signs, seizures, tremor, stupor, coma, spastic paralysis, abnormal reflexes, cranial nerve palsies, and central respiratory failure. Residual neurologic damage occurs in severe cases. Infections of pregnant women acquired during the first and second trimester may result in fetal encephalitis and death.

The peripheral leukocyte count is often low, with a decrease in both lymphocytes and neutrophils, or normal with relative lymphopenia. In patients with CNS signs, the CSF contains up to 500 cells/μL, predominantly lymphocytes. Serum lactate dehydrogenase and aspartate aminotransferase concentrations may be elevated.

DIAGNOSIS

In contrast to the other arboviral encephalitides, Venezuelan equine encephalitis virus can be isolated from blood or from throat swabs or washings during the first 3 or 4 days of illness. Serodiagnosis is usually more practical and is achieved by testing appropriately timed paired sera by HI, CF, ELISA, neutralization, or IgM immunoassay.

PREVENTION

An experimental live attenuated vaccine made from subtype IAB is used for adult laboratory personnel. It provides solid immunity to subtypes IAB and IC but incomplete protection against heterologous Venezuelan equine encephalitis viruses. Epidemics and epizootics can be prevented by effective vaccination of equines. Spraying insecticides to reduce adult (infective) mosquito populations is the only means of immediate control in the face of an ongoing epidemic. Individual protection against mosquitoes is advised.

TREATMENT Rx

No specific therapy is available, and treatment of encephalitis cases is supportive.

PROGNOSIS

The case-fatality rate in children 5 years or younger with encephalitis is approximately 35%, but it is less than 10% in older persons.

JAPANESE ENCEPHALITIS

EPIDEMIOLOGY

Japanese encephalitis virus causes epizootics of clinical encephalitis in equines. The disease occurs throughout Asia, including Japan, the Korean

peninsula, Taiwan, the People's Republic of China, Okinawa, Vietnam, the Philippines, Burma, Malaysia, Bangladesh, east and south India, Sri Lanka, Thailand, and Indonesia. More than 30,000 clinical cases occur annually, about one third of which are fatal. Japanese encephalitis is a summertime disease in temperate areas but occurs sporadically year-round in the tropics. Epidemics are most frequent at the northern fringe of the tropical zone. It is a predominantly rural disease, and the incidence in males is often higher than in females. In hyperendemic areas, more than 70% of adult populations surveyed have antibodies, and children younger than 15 years are principally affected by the disease. In areas without a high prevalence of background immunity (e.g., northern India), however, all age groups are affected. In Japan, where schoolchildren have been protected by vaccination campaigns targeted at this age group, encephalitis has become prominent in the elderly. The ratio of clinically inapparent to apparent infection is higher than 500 : 1 in children and decreases with age; in Korea, the ratio in American servicemen was estimated at 25 : 1.

PATHOBIOLOGY

Neuropathologic changes and the distribution of lesions are similar to those described for St. Louis encephalitis (see later).

CLINICAL MANIFESTATIONS

Manifestations of Japanese encephalitis include abrupt fever, headache, and gastrointestinal symptoms. Meningeal irritation develops within 24 hours and is followed on the second or third day by the appearance of irritability, impaired consciousness, seizures (especially in children), muscle rigidity, parkinsonian findings, ataxia, coarse tremor, involuntary movements, cranial nerve deficits, paresis, hyperactive deep tendon reflexes, and pathologic reflexes. Weight loss and dehydration are often striking findings. In mild cases, fever subsides after the first week, and neurologic signs resolve by the end of the second week after onset. In severe cases, hyperpyrexia, progressive neurologic dysfunction, and coma result in death, usually between the seventh and tenth days. About 25% of patients undergo a prolonged recovery, with permanent sequelae often remaining. The occurrence of such sequelae correlates with severity of the acute stage of illness, and young children are most susceptible. Cardiorespiratory complications are frequent during the acute stage in these patients. A poor prognosis is associated with protracted high fever, frequent or prolonged seizures, high protein content in CSF, Babinski signs, and early respiratory depression. Fetal death from transplacental Japanese encephalitis infection has been reported.

DIAGNOSIS

Moderate peripheral leukocytosis and neutrophilia occur early in the disease. Pleocytosis (predominantly lymphocytic), protein elevation, and normal glucose concentration in CSF are usual findings.

MRI in Japanese encephalitis reveals edema in the basal ganglia, thalami, and focal area of the cerebral cortex; evidence of hemorrhage in these areas may likewise be present. Enhancement may also be noted in the meninges, brain stem, and spinal cord.

Virus is rarely isolated from blood. Virus is also rarely recovered from the CSF of patients who live but may be recovered from the CSF of a third of patients who die. HI and neutralizing antibodies appear during the first week, and CF antibodies appear during the second week. Cross-reactions with other flaviviruses make serodiagnosis difficult. Specific IgM antibodies in serum or CSF are detectable by immunoassays in more than three fourths of patients at the time of hospital admission.

PREVENTION

The inactivated, partially purified mouse brain vaccines produced in Japan are safe and effective in preschool- and school-aged children.■ A vaccine produced in Japan is available to U.S. citizens traveling to high-risk areas. However, generalized urticaria and angioedema may occur in 0.3% of recipients, and anecdotal cases of encephalomyelitis have been reported; as a result, the precise indications for vaccination of travelers are unclear. Because two or three doses of the inactivated vaccine are used and approximately 1 month is required to confer protection, vaccination is not a practical measure in the event of an ongoing epidemic. Two Japanese encephalitis (JE) vaccines are licensed in the United States. An inactivated mouse brain–derived vaccine (JE-MB) was licensed to prevent Japanese encephalitis in persons older than 1 year, but it is not currently in production. The remaining stores of JE-MB are reserved for children. A newer inactivated Vero cell culture–derived vaccine (JE-VC; ICS1, or IXIARO) is licensed for use in persons older than 17 years■ and has recently been shown to be safe in children. Reduction of vector mosquito populations by the application of insecticides may help abort outbreaks. Immunization of swine is an ancillary control strategy.

TREATMENT

Rx

Treatment is supportive (see Eastern Equine Encephalitis). A randomized trial of interferon alfa showed no benefit.

PROGNOSIS

The case-fatality rate is probably about 25%. Sequelae such as mental impairment, emotional lability, choreoathetosis, tremor, parkinsonism, autonomic disturbances, paralysis, and psychiatric disturbances have been reported in up to 75% of patients.

WEST NILE FEVER AND ENCEPHALITIS

Before 1996, the predominant clinical manifestation of West Nile virus was a brief influenza-like illness, sometimes with a rash (Chapter 390) but infrequently with neurologic manifestations. Epidemics since then in Romania, Israel, and North America have added meningitis, meningoencephalitis, and myelitis to the list of disorders attributable to the virus. Sequence analyses of various isolates of the virus indicate two lineages. The first includes viruses from North America, Europe, Israel, western Africa, India, Russia, and Australia; the second includes viruses from sub-Saharan Africa and Madagascar.

EPIDEMIOLOGY

See Chapter 390. The incidence of neuroinvasive West Nile disease varies in different parts of the United States but can be seen nearly everywhere (Fig. 391-1).

CLINICAL MANIFESTATIONS

The majority of infected people are asymptomatic. Fever develops in about 20%, and CNS manifestations are seen in less than 1%, although this percentage is higher in the elderly (Chapter 390). In those in whom clinical manifestations develop, an incubation period of 1 to 6 days is followed by the abrupt onset of symptoms, usually without a prodrome. The temperature rises quickly to 38.3° to 40.0° C, with rigors in a third of patients. Symptoms include drowsiness, severe frontal headache, ocular pain, myalgia, and pain in the abdomen and back. A small number of patients have dryness of the throat, anorexia, and nausea. Cough is common. Examination shows facial flushing, conjunctival injection, and coating of the tongue. Generalized lymphadenopathy had been a prominent feature in past epidemics but is no longer commonly reported. The spleen and liver are occasionally slightly enlarged. The temperature curve may be biphasic. A pale roseolar maculopapular rash, predominantly on the trunk and upper part of the arms, may appear from the second to fifth day but is now less common as well; it may be evanescent (several hours) or persist until defervescence, and it does not desquamate. Vesicular lesions occur rarely. The illness lasts 3 to 5 days in 80% of patients.

In the past decade, the incidence of CNS disease has increased in several epidemics, apparently because of a true increase in the invasiveness and neurovirulence of the virus. The virus causes a syndrome resembling poliomyelitis (Chapter 423), with prominent lower motor neuron dysfunction (acute flaccid paralysis with asymmetrical weakness and decreased deep tendon reflexes but preserved sensory function), which may be seen independently or with signs of meningoencephalitis. In some patients, prolonged, possibly permanent ventilatory failure requiring mechanical ventilation develops. A parkinsonian syndrome has also been noted, but it generally remits after months. Some patients may have seizures, cranial nerve involvement, ataxia, tremors, or myoclonus. Acute inflammatory polyneuropathy (e.g., Guillain-Barré syndrome; Chapter 428) has also been reported. Other rare complications include myocarditis, pancreatitis, and hepatitis. Convalescence is often prolonged, lasting several weeks with prominent symptoms of fatigue. Lymph node enlargement requires several months to regress. Laboratory findings often include leukocytosis, whereas 10 to 15% of patients have leukopenia.

DIAGNOSIS

CSF examination may reveal a lymphocytic pleocytosis (<1800 cells/μL) with some increase in protein but a normal glucose concentration. Although

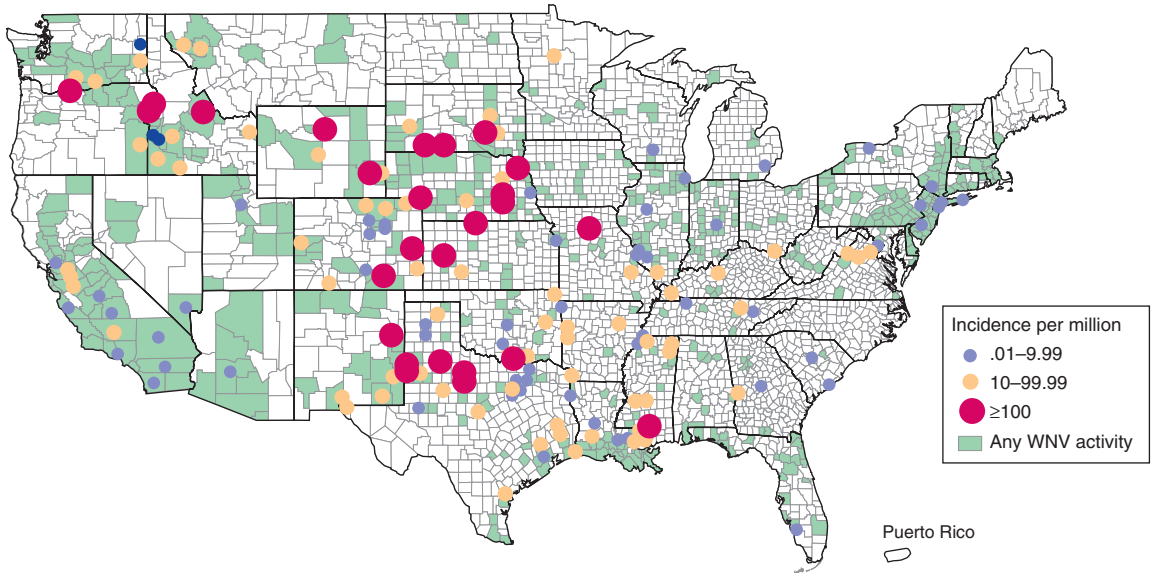

FIGURE 391-1. Incidence of human neuroinvasive West Nile disease in 2009. (Available at http://www.cdc.gov/ncidod/dvbid/westnile/images/2009BL_300410.jpg. Accessed May 27, 2010.)

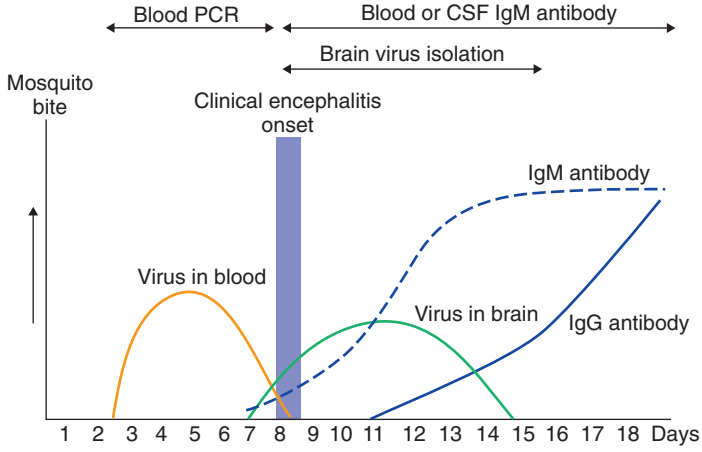

FIGURE 391-2. Typical time course for development of West Nile virus in blood and brain and occurrence of IgG and IgM antibodies in humans after West Nile virus infection. CSF = cerebrospinal fluid; PCR = polymerase chain reaction. (Reproduced from Davis LE, Beckham JD, Tyler KL. North American encephalitic arboviruses. *Neurol Clin.* 2008;26: 727-757.)

West Nile virus may be isolated from the blood of three fourths of patients with West Nile fever on the first day of illness (Chapter 390), patients with West Nile encephalitis appear less likely to be viremic, and isolation of virus from CSF is infrequent. Viral RNA is detected in CSF by RT-PCR in about 50% of cases (Fig. 391-2). IgM antibody capture immunoassay, which is the test of choice, is more sensitive than RT-PCR. IgM antibodies may remain detectable for up to 500 days after infection, so their presence should suggest acute infection only with compatible clinical manifestations. In some situations, cross-reactions with other flaviviruses, particularly St. Louis encephalitis virus, may complicate the interpretation of IgM immunoassays.

TREATMENT

Rx

Treatment is symptomatic and similar to that suggested for eastern equine encephalitis. Patients may require prolonged mechanical ventilation for either the polio-like syndrome or Guillain-Barré syndrome. The Guillain-Barré syndrome seen in West Nile patients does not appear to respond to plasma exchange. A large trial of intravenous immune globulin is under way. Ribavirin has activity against West Nile virus, but its clinical utility is unknown.

PROGNOSIS

The overall case-fatality rate is 4 to 14%, but it is higher in the elderly. Risk factors for death include more severe weakness or coma, immunocompromise, and failure to produce virus-specific IgM. The prognosis for neurologic recovery is generally good; most U.S. patients regain physical and mental function by 1 year, but about half the patients in some series still report difficulties 1 year after the illness.

ST. LOUIS ENCEPHALITIS

ETIOLOGY

St. Louis encephalitis virus, a member of the family Flaviviridae, shares close antigenic relationships with Japanese encephalitis, Murray Valley encephalitis, and West Nile viruses and is related to yellow fever (Chapter 389) and dengue (Chapter 390) viruses. Strains associated with *Culex pipiens*–borne epidemics in the eastern United States are distinct from endemic strains transmitted by *C. tarsalis* in the western states.

EPIDEMIOLOGY

The virus is present in all parts of the Western Hemisphere, but epidemics occur only in North America and some Caribbean islands. During epidemic years, the virus has been responsible for up to 80% of all reported cases of encephalitis of known etiology in the United States. Epidemics of up to 2000 cases have taken place, mainly in urban-suburban localities of the Ohio-Mississippi River basin and in eastern and central Texas and Florida. Small outbreaks have also occurred in the western United States. Epidemics generally take place between July and September but may arise later in the year in warm areas such as Florida. Previous exposure and immunity to dengue may provide a degree of cross-protection against clinical St. Louis encephalitis. The ratio of inapparent to apparent infection is 800 : 1 in children up to 9 years of age, 400 : 1 in persons aged 10 to 49 years, and 85 : 1 in persons older than 60 years.

In most of the eastern United States, St. Louis encephalitis virus circulates between wild birds and *C. pipiens* mosquitoes, which breed in polluted water. In Florida and in parts of the Caribbean, *Culex nigripalpus* is the principal vector. The cycle in the western United States also involves wild birds, but the vector is *C. tarsalis,* also that of western equine encephalitis. Because of the similar ecology of St. Louis encephalitis and western equine encephalitis viruses in the West, mixed outbreaks occur, mostly in rural, agricultural areas.

Above-average summer temperatures and conditions such as deficient rainfall, which create stagnant pools suitable for *C. pipiens* breeding, are associated with epidemics in the eastern United States. St. Louis encephalitis in the western states is favored by warm spring temperatures, heavy snow melt, and flooding.

PATHOBIOLOGY

Pathologic changes in fatal cases are limited to microscopic findings. Leptomeningitis is characterized by lymphocytic inflammation. Parenchymal changes consist of lymphocytic perivascular cuffing, cellular nodule formation, and neuronal degeneration.

CLINICAL MANIFESTATIONS

Three clinical syndromes are recognized: febrile headache, aseptic meningitis, and encephalitis. After an incubation period of 4 to 21 days, a variable period of nonspecific symptoms, including fever (temperature of 38° to 41° C), headache, malaise, drowsiness, myalgia, and sore throat, may be followed by an acute or subacute onset of meningeal or encephalitic signs, or both. Nausea, vomiting, and photophobia are common.

Neurologic abnormalities occur in up to 25% of patients. Extrapyramidal abnormalities and altered consciousness are the most significant findings. Other findings include meningismus, cranial nerve deficits (particularly the facial nerve), abnormal reflexes, tremors, myoclonic twitching, nystagmus, and ataxia. Motor abnormalities are infrequent, and sensory changes are extremely uncommon. Seizures occur in 10% of patients and are a poor prognostic sign, as is a persistent high temperature of 40° to 41° C. Signs of markedly increased intracranial pressure are unusual. A Guillain-Barré–like syndrome (Chapter 428) has occasionally been associated with St. Louis encephalitis, both as an acute manifestation and during the convalescent period.

In uncomplicated cases of St. Louis encephalitis, a moderate peripheral neutrophilic leukocytosis and shift to the left are noted. CSF pressure is elevated, protein level is mildly elevated, and glucose concentration is normal; a pleocytosis of up to 500 cells/μL is present, with an early neutrophilia predominance changing to lymphocytes within days. Serum creatine kinase, aspartate aminotransferase, and aldolase levels are frequently elevated. The electroencephalogram typically shows polymorphic delta activity, most prominently in the frontal and temporal regions; electrographic seizures are common. CT scans are normal, but MRI may show edema involving deep structures such as the substantia nigra. Hypo-osmolality, presumably as a result of the syndrome of inappropriate antidiuretic hormone secretion (Chapter 232), is noted in a third of patients.

Genitourinary tract symptoms (urgency, frequency, incontinence, and retention), microscopic hematuria, pyuria, proteinuria, and elevated blood urea nitrogen are frequent. St. Louis encephalitis viral antigen in cells of the urinary sediment has been detected by fluorescent techniques, and virus-like particles have been detected in urine by immunoelectron microscopy.

DIAGNOSIS

St. Louis encephalitis virus is rarely isolated from blood or CSF obtained during the acute phase of illness. Serologic diagnosis is achieved by demonstration of changing antibody titers; the HI, fluorescent, ELISA, and neutralizing tests demonstrate antibody within the first week after onset, and titers rise during the ensuing 2 weeks. CF antibodies appear 10 to 20 days after onset. Rapid, early diagnosis is possible by detection of IgM antibodies by ELISA in serum and CSF. Serologic cross-reactions may occur in persons with previous exposure to dengue, West Nile, and other related flaviviruses. RT-PCR provides a more specific diagnosis, but its sensitivity is uncertain.

PREVENTION

No vaccine is available for St. Louis encephalitis. Surveillance of viral activity in vectors and avian hosts is used to define the risk for human infection and to initiate vector control efforts. In an established outbreak, avoidance of mosquito bites and spraying to reduce infected adult mosquitoes are the only effective means of control.

TREATMENT

Rx

Treatment is supportive.

PROGNOSIS

A convalescent syndrome characterized by weakness, fatigue, nervousness, tremulousness, sleeplessness, irritability, depression, difficulty concentrating, and headaches occurs in 30 to 50% of older persons and clears in 80% of them within 3 years. The overall case-fatality rate is approximately 9%. Mortality is negligible in persons younger than 20 years but rises steeply after 55 years to approximately 30% in patients older than 65 years. Approximately 50% of the deaths occur during the first week, and 80% occur within 2 weeks after onset.

MURRAY VALLEY ENCEPHALITIS AND ROCIO ENCEPHALITIS

Murray Valley encephalitis and Rocio encephalitis, which are similar to Japanese encephalitis in their pathogenesis and clinical features, are caused by closely related flaviviruses. Murray Valley encephalitis has occurred in small epidemics in the Murray and Darling River valleys of Victoria and New South Wales, Australia. The virus is endemic in northern Australia and New Guinea, where it is maintained in a bird-mosquito cycle. Rocio encephalitis has caused epidemics of 1000 or more cases in São Paulo State, Brazil.

TICK-BORNE ENCEPHALITIS

PATHOGENS

A complex of six antigenically related tick-borne flaviviruses cause encephalitis: Powassan, tick-borne encephalitis, louping ill, Kyasanur Forest disease, Omsk hemorrhagic fever, and Langat viruses. The predominant syndrome is hemorrhagic fever (Chapter 389), but meningoencephalitis may be a component of the disease spectrum. Two subtypes of tick-borne encephalitis virus (central European encephalitis and Russian spring-summer encephalitis) are distinguished by serologic tests, are ecologically distinct, and differ in virulence for humans. Powassan and louping ill viruses are rare causes of encephalitis in North America and the British Isles, respectively. These viruses are easily distinguished serologically from mosquito-borne flaviviruses but induce cross-reactions within the complex.

EPIDEMIOLOGY

Tick-borne encephalitis occurs in Europe (including eastern Europe and Ukraine), southern Scandinavia, and far eastern Russia during the summer months, which corresponds to peak tick vector populations. Several hundred to more than 2000 cases are reported annually, with morbidity rates of up to 20 per 100,000 inhabitants. Adults older than 20 years are mainly affected, and persons frequenting wooded areas that are heavily tick infested are at highest risk. In Europe, the disease is relatively mild (case-fatality rate of 1 to 2%), but in the Far East, it is severe (20 to 25%).

The vector of tick-borne encephalitis is *Ixodes ricinus* in Europe and *Ixodes persulcatus* in the Far East. The tick vector also serves as a reservoir for the virus. Larval ticks parasitize small rodents, which serve as amplifying viremic hosts during the spring and summer. Large vertebrates (goats, sheep, cattle) are hosts for nymphal and adult ticks. Outbreaks have occurred in families or groups of individuals ingesting unpasteurized milk or cheese from goats or sheep.

CLINICAL MANIFESTATIONS

Inapparent infections are common. Symptomatic tick-borne encephalitis in Europe typically (but not invariably) has a biphasic course beginning 7 to 14 days after exposure with an influenza-like illness that lasts 1 week, followed by a period of clinical remission for several days and then an abrupt onset of aseptic meningitis or meningoencephalitis. The meningoencephalitis is usually benign, although severe paralytic illness, myelitis, myeloradiculitis, and bulbar forms may occur.

In the Far East, tick-borne encephalitis begins suddenly with fever, headache, and gastrointestinal symptoms, followed rapidly by the appearance of depressed sensorium, coma, convulsions, and paralysis. Bulbar paralysis and cervical myelitis are frequent findings. In fatal cases, death occurs in the first week after onset. Aseptic meningitis and milder forms of encephalitis also occur. Chronic forms of tick-borne encephalitis have been described, with active clinical and pathologic abnormalities present a year or more after onset.

DIAGNOSIS

Brain MRI in patients with tick-borne encephalitis shows evidence of edema in the basal ganglia, thalami, and brain stem in about 20% of cases. MRI of the spinal cord may show anterior horn cell lesions corresponding to lower motor neuron weakness on examination.

Isolation of virus from blood is also possible during the early phase of illness. Serologic diagnosis is achieved by the HI, CF, neutralization, or ELISA techniques.

PREVENTION

In eastern Europe and the former Soviet Union, vaccines are used in high-risk groups (forestry and agricultural workers, military personnel). In Austria,

immunization of the general population has resulted in a marked decline in incidence. Avoidance of tick exposure by wearing of protective clothing and use of repellents may be recommended in areas of high tick-borne encephalitis activity.

TREATMENT

Rx

Treatment is supportive (see Eastern Equine Encephalitis).

PROGNOSIS

In European tick-borne encephalitis, convalescence is often prolonged, and residual paralysis may follow in severe cases. In the Far East, survivors frequently have residual paralysis, especially lower motor neuron paralysis of the upper extremities or shoulder girdle as a result of spinal cord involvement.

Louping Ill Encephalitis

Louping ill causes encephalitis in sheep (rarely in cattle, horses, and swine) in Scotland, northern England, and Ireland. Sporadic human cases have been recognized. Louping ill virus is maintained in nature by *I. ricinus* ticks and a variety of hosts, including small mammals, ground-dwelling birds (grouse), and probably sheep. The clinical features of louping ill resemble the European form of tick-borne encephalitis.

Powassan Virus Encephalitis

Powassan virus encephalitis has been documented in a small number of cases in the northeastern United States and eastern Canada. The virus is not associated with animal disease. The transmission cycle of Powassan virus involves *Ixodes cookei, Ixodes marxi,* and possibly other tick species along with mammals, particularly rodents and carnivores. Powassan encephalitis is characterized by fever and nonspecific symptoms, followed by encephalitic signs, which are frequently severe. Peripheral blood and CSF changes are similar to those described for other forms of flaviviral encephalitis. The case-fatality rate is about 50%, and residual paralysis may persist in survivors.

CALIFORNIA SEROGROUP ENCEPHALITIS

At least four members of the California serogroup of the Bunyaviridae family (Bunyavirus genus)—La Crosse, California encephalitis, Jamestown Canyon, and snowshoe hare viruses—cause encephalitis. California encephalitis virus occurs in the western United States (California, New Mexico, Utah, Texas) and has been implicated in only three human cases. In contrast, La Crosse virus, distributed more widely in the eastern half of the United States and southern Canada, is a major human pathogen. Jamestown Canyon and snowshoe hare viruses have also been implicated in sporadic cases of human encephalitis in the north central United States and Canada. California serogroup viruses have been implicated in human disease in China and the former Soviet Union.

EPIDEMIOLOGY

California serogroup encephalitis occurs as an endemic rather than an epidemic disease, with individual or small clusters of cases scattered across affected areas. Seventy to 115 cases are reported each year, generally between July and September, with a peak incidence in August. The virus primarily affects persons younger than 15 years living in rural and suburban areas characterized by deciduous hardwood forests. It is most prevalent in the north central states, where it is responsible for as many as 20% of cases of acute CNS infection in children. Focal "hot spots" (communities, even backyards) of recurrent summertime viral activity are recognized. The ratio of inapparent to apparent infection has been estimated variably at between 26 : 1 and 157 : 1.

The vector of La Crosse virus is *Aedes triseriatus,* which breeds both in forest tree holes and in artificial containers, notably discarded tires. This vector also serves as a reservoir for La Crosse virus. Wild rodents (squirrels, chipmunks) contribute to the cycle of transmission as viremic hosts. Humans acquire the disease by being bitten by an infected mosquito. *Aedes communis, Aedes stimulans, A. triseriatus,* and possibly anopheline mosquitoes are involved in transmitting Jamestown Canyon virus, and deer are the principal vertebrate hosts.

PATHOBIOLOGY

Histopathologic features in the CNS are qualitatively similar to those of other viral encephalitides. However, absence of inflammatory lesions in the cerebellum, medulla, and spinal cord may be a distinguishing feature of La Crosse infection.

CLINICAL MANIFESTATIONS

The clinical spectrum of California serogroup virus infection includes nonspecific febrile illness, aseptic meningitis, and meningoencephalitis. The disease begins with fever, headache, sore throat, and gastrointestinal symptoms. In mild cases, CNS signs appear on the third day after onset and subside within 7 to 8 days. In the more severe form, neurologic signs appear within 24 to 48 hours of onset, usually in the form of generalized seizures, elevated intracranial pressure, and altered consciousness, and persist longer. Encephalitis may be severe in the acute stage, but the disease is almost always self-limited; death is extremely rare.

The peripheral white blood cell count is elevated, with a predominance of polymorphonuclear cells and a shift to the left. CSF contains up to 500 lymphocytes/μL; the protein level is normal or mildly elevated, and the glucose concentration is normal. The electroencephalogram reveals generalized slowing in the delta and theta range; focal delta wave activity related to cortical destruction and focal seizures are also common findings.

DIAGNOSIS

In contrast to the other arboviral encephalitides, brain MRI in patients with California serogroup encephalitides may show lesions involving the temporal lobe in a pattern similar to that of herpes simplex encephalitis. The virus cannot be recovered from blood or CSF obtained during the acute phase. Diagnosis is best achieved by counterimmunoelectrophoresis, HI, CF, fluorescent, ELISA, and neutralization tests for antibody in paired acute and convalescent sera. The most practical, sensitive, and reliable methods are the HI test with La Crosse viral antigen and IgM antibody capture ELISA. Viral RNA can be detected in CSF or brain tissue by RT-PCR, although the sensitivity of the test remains to be determined.

PREVENTION

There is no vaccine for California encephalitis, although research involving DNA-based vaccines appears promising. Vector control methods are of uncertain usefulness in this disease. In defined hot spots of recurrent viral activity, breeding sites for *A. triseriatus* should be eliminated, particularly by draining or eliminating standing water (e.g., discarded tires or birdbaths) and filling holes in trees. Parents should protect children by limiting exposure and using mosquito repellents.

TREATMENT

Rx

Treatment is supportive.

PROGNOSIS

The case-fatality rate is less than 1%. The risk for permanent neuropsychiatric sequelae is unclear, but hemiparesis and persistent seizure disorders have been reported.

392

EPIDEMIOLOGY OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME

THOMAS C. QUINN

HISTORICAL PERSPECTIVE

Twenty-five years after initial recognition of acquired immunodeficiency syndrome (AIDS) in the United States, the disease has become epidemic in every country of the world. Initially reported as a disease primarily affecting homosexual men, AIDS was rapidly identified in many other risk groups, and it became evident that it was caused by an infectious agent transmitted through sexual activities, parentally through blood transfusions and injecting drug use, and perinatally from mother to infant. Early investigations in the 1980s demonstrated that the etiologic agent of AIDS was human immunodeficiency virus (HIV), which existed in two types, HIV-1 and HIV-2. After the development of diagnostic assays for HIV antibody, it became possible to track and monitor the escalating spread of HIV throughout the world, definitively define the modes and probabilities of transmission, and study the natural history of HIV infection. Within years of its recognition, HIV disseminated rapidly throughout the world, caused a massive epidemic, and became one of the leading causes of death worldwide. Efforts at prevention and treatment with antiretroviral drugs have tempered the spread and decreased the fatality rate in some countries, but in developing countries where the social, demographic, cultural, and economic impact of the AIDS epidemic has been the greatest, these gains were initially too limited and too slow to reverse the escalating trend of the epidemic. More recently, with the increased availability of antiretroviral drugs in many countries, the annual rate of increase in HIV infections may have peaked and mortality has declined.

GLOBAL STATISTICS

By January 2010, approximately 75 million people had become infected with HIV since the beginning of the epidemic in 1981. Of these individuals, more than 40 million people had already died of AIDS, and it became ranked as one of the leading causes of death throughout the world. According to estimates by the Joint United Nations Program on HIV/AIDS (UNAIDS), 33.4 million people were living with HIV by December 2008 (Fig. 392-1; Table 392-1). In 2008 alone, 2.7 million people became newly infected, half of whom were young individuals between the ages of 15 and 24 years. The continuing rise in the population of people living with HIV infection reflects the combined effects of continued high rates of HIV infection and the beneficial impact of antiretroviral therapy (ART) resulting in fewer deaths.

The latest epidemiologic data indicate that globally, the spread of HIV appears to have peaked in 1996, when 3.5 million new HIV infections occurred. In 2008 the estimated number of new HIV infections was approximately 30% lower than at the epidemic's peak 12 years earlier. The epidemic appears to have stabilized in most regions, although prevalence continues to increase in Western Europe, central Asia, and other parts of Asia because of the high rates of HIV infection. Sub-Saharan Africa remains the most heavily affected region and accounted for 71% of all new HIV infections in 2008.

Nearly 90% of all new infections occurred in developing countries; 50% occurred in women; and the major mode of transmission was heterosexual transmission, although infections continue to spread at high rates among men who have sex with men (MSM). Resurgence of the epidemic among MSM in high-income countries is increasingly well documented. Differences are apparent in all regions, with some national epidemics continuing to expand even as the overall regional incidence of HIV infection stabilizes. Epidemic patterns have been changing over time. In eastern and central Asia, epidemics that were once characterized primarily by transmission among injecting drug users (IDUs) are now increasingly being characterized by significant sexual transmission, whereas in parts of Asia, epidemics are increasingly becoming characterized by significant transmission among heterosexual couples. Perinatal transmission also continues to occur in developing countries, where access to antiretroviral drugs to prevent mother-to-infant transmission is limited. In 2008, 430,000 children became newly infected, and 25 million children have been orphaned by the premature deaths of their parents from AIDS. In 2008, 2.0 million people died of AIDS, including 280,000 children.

From these epidemiologic trends it is projected that within the next 8 years an additional 25 million people could become infected with HIV in 126 low- and middle-income countries, which have the most concentrated or generalized epidemics, unless the world succeeds in mounting a drastically expanded global prevention and treatment effort. It is anticipated that more than 40% of these new infections will occur in Asia, the Pacific, and Eastern Europe, although it is apparent that the epidemic will continue to devastate nearly all countries of the African continent. During the next decade, without full access to treatment and care in many countries, millions of individuals will join the ranks of the more than 40 million people who have already died of AIDS.

DEMOGRAPHIC, SOCIAL, AND ECONOMIC IMPACT OF HIV AND AIDS

AIDS is the leading cause of death in sub-Saharan Africa and the fourth largest killer worldwide. The average life expectancy in sub-Saharan Africa is now 47 years; it would have been 62 years without AIDS (Fig. 392-2). Life expectancy at birth in Botswana has dropped to a level not seen in that country since the 1950s. Even in Haiti, life expectancy is nearly 6 years less than it would have been in the absence of AIDS. In Asia, Cambodia has experienced a reduction in life expectancy of 4 years. Current HIV prevalence levels merely hint at the greater lifetime probability of AIDS developing. In Lesotho, it is estimated that a person who is 15 years old has a 74% chance of being infected with HIV by his or her 50th birthday.

According to one report, AIDS is expected to cause a decline in life expectancy in 51 countries over the next 20 years. Seven nations in sub-Saharan Africa now have life expectancies of less than 40 years, and this number will increase by 11 countries over the next 7 years. The declining life expectancies will soon reach levels that have not existed since the 19th century. In Zimbabwe and South Africa, the infant mortality rate is higher than it was in 1990. Five African nations will experience more deaths than births by 2010, with a resultant decrease in population. Life expectancy will drop to just 27 years in Botswana and Mozambique in the next 8 years, and Swaziland will have an estimated life expectancy of 33. In Zimbabwe, Zambia, and Namibia, the expected lifespan will be 34 years. In contrast, the overall life expectancy in an African nation without AIDS would be 70 years by 2010.

THE GLOBAL RESPONSE

At a 2001 special session of the United Nations General Assembly on AIDS, 189 nations agreed that AIDS was a national and international security issue of the highest priority. The Global Fund for AIDS, Tuberculosis, and Malaria raised funds from private donations and industrialized countries to help support access to care and treatment within developing countries. This initiative was complemented by the U.S. government's Emergency Plan for AIDS Relief (PEPFAR), now committed over a 10-year period through the Bush and Obama administrations to provide treatment and care for HIV-infected individuals, as well as additional resources for enhancing prevention efforts to prevent further transmission. As of December 2008, approximately 4 million people in low- and middle-income countries were receiving ART—a 10-fold increase over a period of 5 years (Fig. 392-3). ART coverage rose from 7% in 2003 to 42% in 2008, with especially high coverage achieved in eastern and southern Africa (48%). Even though the rapid expansion of access to ART is helping lower AIDS-related death rates in multiple countries and regions, it is also contributing to increases in HIV prevalence. Scale-up in sub-Saharan Africa has been the most dramatic, with an increase from 100,000 people receiving treatment in 2003 to more than 3 million in December 2008. Sixty-three percent of all people now receiving treatment in low- and middle-income countries are living in sub-Saharan Africa, as compared with 25% in late 2003.

Effective prevention of mother-to-child transmission depends on the simultaneous support of several strategies that work synergistically to reduce the odds that an infant will become infected as a result of exposure to the mother's virus. In ideal conditions, provision of antiretroviral prophylaxis and replacement feeding or continued antiretroviral treatment with breastfeeding can reduce transmission from an estimated 30 to 35% with no intervention to 1 to 2%. Unfortunately, most countries have not yet reached all

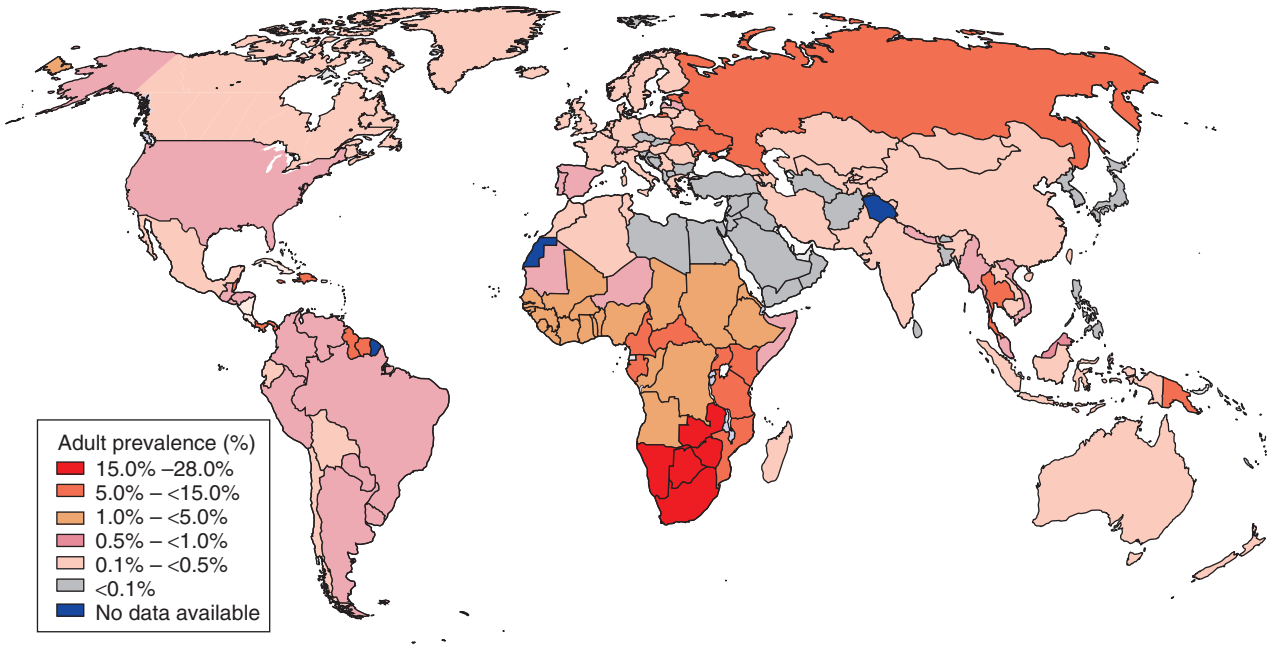

FIGURE 392-1. A total of 33.4 million people (31.1 to 38.5 million) were living with HIV infection in 2008. The adult prevalence of HIV infection is shown by country. (Data from UNAIDS.)

TABLE 392-1 REGIONAL HIV AND AIDS STATISTICS AND FEATURES AT THE END OF 2008

REGION	ADULTS AND CHILDREN LIVING WITH HIV/AIDS	ADULTS AND CHILDREN NEWLY INFECTED WITH HIV	ADULT PREVALENCE RATE*	MAIN MODES OF TRANSMISSION FOR ADULTS LIVING WITH HIV/AIDS
Sub-Saharan Africa	22,400,000	1,900,000	5.2%	Hetero
North Africa and Middle East	310,000	35,000	0.2%	Hetero, IDU
South and Southeast Asia	3,800,000	280,000	0.3%	Hetero, IDU
East Asia and Pacific	850,000	75,000	0.1%	IDU, Hetero, MSM
Oceania	59,000	3,900	0.3%	MSM, Hetero
Latin America	2,000,000	170,000	0.6%	MSM, IDU, Hetero
Caribbean	240,000	20,000	1.0%	Hetero, MSM
Eastern Europe and central Asia	1,500,000	110,000	0.7%	IDU, Hetero, MSM
Western Europe	850,000	30,000	0.3%	MSM, IDU, Hetero
North America	1,400,000	55,600	0.4%	MSM, IDU, Hetero
Total	33,400,000	2,700,000	0.8%	

*The proportion of adults (15 to 49 years of age) living with HIV infection or AIDS in 2008 using 2008 population numbers.
Hetero = heterosexual transmission; IDU = transmission through injecting drug use; MSM = sexual transmission among men who have sex with men.

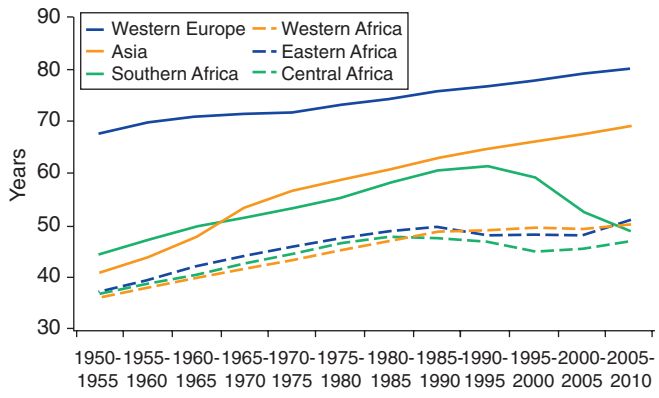

FIGURE 392-2. Impact of AIDS on life expectancy in six regions between 1950 and projected to 2010. (From the United Nations Population Division, 2004. World Population Prospects: the 2004 Revision Database.)

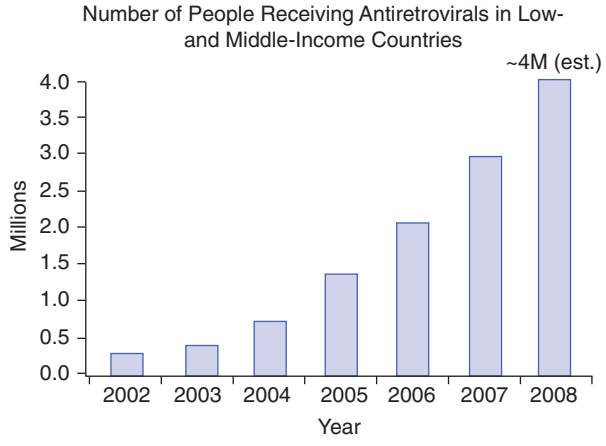

FIGURE 392-3. Estimated number of people receiving antiretroviral therapy in low- and middle-income countries from 2002 through 2008. (Data from World Health Organization and UNAIDS.)

pregnant women with these services, with estimates of only 30 to 50% of HIV-infected mothers receiving appropriate HIV care and prophylaxis for mother-to-child transmission. Despite these limitations, it has been estimated that nearly 200,000 new HIV infections have been averted in the past decade because of provision of antiretroviral prophylaxis during pregnancy and to newborn infants.

Unfortunately, not all have equal access to therapy, even within countries with middle to high prevalence. For example, an estimated 800,000 children younger than 15 years now require ART, but only 200,000 are receiving treatment. Children account for approximately 14% of AIDS deaths. Nearly 90% of children infected with HIV are African. The median proportion of HIV-infected children receiving treatment is just 25% in sub-Saharan Africa. Similarly, less than 40% of HIV-infected pregnant women in low- and middle-income countries are benefiting from antiretroviral prophylaxis despite success in certain countries such as Botswana, Brazil, and Thailand and the virtual elimination of pediatric HIV disease in the industrialized world. Likewise, in Eastern Europe and central Asia, injecting drug use accounts for more than 70% of HIV-positive persons. However, only 25% of treatment recipients in this region are IDUs. In years to come, additional resources will be required to reach the additional millions of HIV-infected people who require treatment with antiretroviral drugs, especially in light of recent recommendations to expand access to all HIV-infected adults who have a $CD4^+$ count of less than $350/mm^3$ based on the finding that early (versus standard) initiation of ART reduces mortality and incident tuberculosis.■

REGIONAL EPIDEMICS

HIV and AIDS in Sub-Saharan Africa

Sub-Saharan Africa represents the epicenter of the global HIV/AIDS pandemic (see Table 392-1). Studies in the late 1990s and early 2000s support the theory that HIV originated in Africa and that humans probably became infected sometime in the mid-20th century from a similar, related retrovirus in chimpanzees and sooty mangabey monkeys. For years, the infection remained limited to remote rural regions of Africa, but with urbanization, infected individuals migrated to major urban centers, where transmission was amplified and HIV spread to thousands of individuals within a relatively short period.

Most HIV transmissions in sub-Saharan Africa occur through sexual intercourse, with unsafe blood transfusions and unsafe injections accounting for a smaller fraction. Although sexual behavior is the most important factor influencing the spread of HIV in Africa, that behavior varies greatly across cultures, age groups, socioeconomic class, and gender. The interplay of multiple factors, biologic and behavioral, determines the spread of HIV. One study of four African cities (Cotonou, Kisumu, Ndola, and Yaounde) revealed that the most common behavioral and biologic factors in those cities with the highest HIV prevalence were young age at a woman's first sexual intercourse, young age at first marriage, age difference between spouses, the presence of herpes simplex type 2 infection and trichomoniasis, and lack of male circumcision. There is substantial evidence that sexually transmitted diseases (STDs) enhance the risk for sexual transmission of HIV, that the level of the HIV viral load in an individual enhances the probability of infectiousness, and that male circumcision is associated with a reduced risk for transmission. Although the complex interplay of factors makes it difficult to estimate the probable growth of the epidemic within the region, evidence from the past 25 years demonstrates that HIV can spread rapidly and widely from very low-prevalence levels.

Sub-Saharan Africa remains the worst affected region in the world for HIV infection. A little more than a 10th of the world's population lives in sub-Saharan Africa, but it is home to 64% of all people infected with HIV in the world. In 2008 an estimated 1.9 million people living in sub-Saharan Africa became newly infected with HIV, thus bringing the total number of people infected with HIV to 22.4 million. Sub-Saharan Africa accounted for 72% of all the world's AIDS-related deaths in 2008. Even though the rate of new HIV infections in sub-Saharan Africa has slowly declined, with the number of new infections in 2008 being approximately 25% lower than at the epidemic's peak in the region in 1995, the number of people infected with HIV has slightly increased in 2008, in part because of the increased longevity stemming from improved access to treatment.

Seventy-five percent of all women infected with HIV live in sub-Saharan Africa. In Côte d'Ivoire, home to the most serious epidemic in West Africa, HIV prevalence in females (6.4%) was more than twice as high as that in males (2.9%). In sub-Saharan Africa as a whole, women account for 60% of the estimated HIV infections. The risk of becoming infected is especially disproportionate for girls and young women. In Kenya, young women between 15 and 19 are three times more likely to be infected than their male counterparts, whereas 20- to 24-year-old women are 5.5 times more likely than men in their age cohort to be living with HIV infection. Among people aged 15 to 24 in Tanzania, females are four times more likely than males to be living with HIV. In the nine countries of southern Africa most affected by HIV, the prevalence in young women 15 to 24 was on average three times higher than that in men of the same age.

Women's vulnerability to HIV in sub-Saharan Africa stems not only from their greater physiologic susceptibility to heterosexual transmission but also from the severe social, legal, and economic disadvantages that they often confront. HIV prevalence generally tends to peak at a younger age for women than for men. The very young are often at extremely high risk for infection through mother-to-child transmission.

A third of all AIDS deaths globally occurred in sub-Saharan Africa in 2008. As noted earlier, access to ART has increased more than 10-fold since the end of 2003, and more than 3 million people now receive treatment. Unfortunately, progress is uneven, with coverage reaching or exceeding 50% in some countries (Botswana, Namibia, and Uganda) but remaining below 20% in most others.

Although some countries in sub-Saharan Africa such as Kenya, Uganda, and Zimbabwe have shown recent declines in HIV prevalence, there is no evidence of any decline in southern Africa, including the Republic of South Africa, Botswana, Namibia, and Swaziland, where exceptionally high infection levels continue. Southern Africa remains the area most heavily affected by the epidemic. The nine countries with the highest HIV prevalence worldwide are all located in this subregion, with each of these countries experiencing adult HIV prevalence greater than 10%; prevalence is as high as 26% in Swaziland, 24% in Botswana, and 23% in Lesotho. South Africa is home to the world's largest population of people living with HIV (5.7 million). In Swaziland, the national adult HIV prevalence is estimated to be 33.4%. HIV prevalence in pregnant women attending antenatal clinics rose from 4% in 1992 to 43% in 2004. In the Republic of South Africa, an estimated 5.5 million people were living with HIV in 2005. An estimated 18.8% of adults (15 to 49 years old) were living with HIV in 2005. Almost one in three pregnant women attending public antenatal clinics was infected with HIV. Although South Africa's HIV prevention efforts have not made a significant impact on the epidemic, there has been considerable progress on the treatment front as noted earlier. South Africa accounts for a large percentage of the treatment scale-up in sub-Saharan Africa, but as of 2006, nearly 80% of the 1 million South Africans in need of ART were still without treatment.

In Botswana, the national adult HIV prevalence was 24.1% in 2005. More than a third of pregnant women attending antenatal clinics and close to 50% of women 30 to 34 years of age were infected with HIV. The prevalence in pregnant women has generally remained at 34 to 37% since 2001. Similarly, Lesotho has a national adult HIV prevalence of 23.2%, with 27% documented in women attending antenatal clinics. A third of pregnant women 25 to 34 years of age were infected. In Namibia, the prevalence of HIV infection is 19.6% in all adults, with an HIV prevalence of 42% in antenatal clinics in selected areas. In neighboring Mozambique, Malawi, and Zambia, HIV prevalence has been documented to be between 16 and 17%. There is wide geographic variation, however, with HIV infection rates in pregnant women ranging from less than 10% in some places to as high as 30% in others.

In the countries of eastern Africa, HIV prevalence has either decreased or remained stable in the past several years. In Uganda, which saw a steep decline in HIV prevalence during the mid and late 1990s, adult HIV prevalence was estimated to be 6.7% in 2005. However, trends in 2006 suggest that HIV prevalence may be increasing in selected areas, in part because of a decrease in mortality with access to ART but potentially also because of increasing incident rates as a result of decreasing condom use and an increased percentage of multiple partners. In neighboring Kenya, Eritrea, Tanzania, Burundi, and Rwanda, the HIV epidemic has been stable in recent years, with prevalence rates ranging from 2% in Eritrea to 7% in Kenya, Tanzania, Burundi, and Rwanda. In Ethiopia, HIV prevalence has stabilized in urban areas but appears to be increasing in more distant rural areas, where access to treatment and care is more limited.

Western Africa is less severely affected than other parts of sub-Saharan Africa, with national adult HIV prevalence rates of 2% in several countries. The highest rate in the region is in Côte d'Ivoire: 7.1%. In Nigeria, infection levels vary radically across the country from 2.6% in the southwest to 6.1% in the north central zones. HIV continues to spread rapidly among female sex

workers and their clients, as well as in the general population. In some urban populations, more than 10% of adults are infected and the annual incidence is as high as 3%.

As of December 2008, 44% of adults and children in need of ART in the region were estimated to be receiving such services. ART coverage is notably higher in eastern and southern Africa (48%) than in western and central Africa (30%). Treatment coverage for adults (44%) remains higher than that for children (35%). Children's access to ART is especially limited in western and central Africa.

AIDS-related deaths have fallen by 29% in Kenya, and a study in Uganda found that timely initiation of ART and cotrimoxazole prophylaxis reduced mortality by 95% and produced a 93% reduction in HIV-related orphans. In Botswana, where ART coverage exceeds 80%, the estimated annual number of AIDS-related deaths declined by more than half. More than 50% of all people in need of treatment are still not receiving such services.

AIDS is now the leading cause of death and years of productive life lost throughout the continent. Excess deaths attributable to HIV are highest in the 25- to 34-year-old group, usually a group with low mortality. Nearly 90% of deaths in this age group are in excess of background rates and were attributable to HIV. Because AIDS deaths are concentrated in childhood and young adult age groups, their effects are substantial, with life expectancy reduced by more than 20 years in several countries. Demographic projections have estimated that population growth will decline more rapidly than expected and that the size of the African population in 2015 will be smaller than it would have been without AIDS. HIV or AIDS cases will put an increasing strain on health care systems, which are already overburdened, and on individual households that are trying to manage with limited economic resources. Care and support for children orphaned by AIDS will become a growing concern throughout the region.

HIV and AIDS in Asia and the Pacific

After sub-Saharan Africa, Asia and the Pacific, home to 60% of the world's population, have the second largest number of HIV-infected individuals in the world, estimated at 4.7 million. In 2008, 360,000 adults and children became newly infected, in part because of growth of the HIV epidemic in China, India, and several other countries in Southeast Asia. With the exception of Thailand, national HIV prevalence levels remain comparatively low in most countries of Asia and the Pacific, with HIV prevalence being less than 1%, to some extent being due to their large population base. Thus, because of the region's large population, Asia's comparatively low HIV prevalence translates into a substantial portion of the global HIV burden. India's national adult HIV prevalence rate of 0.3% offers little indication of the serious situation facing the country. An estimated 2.4 million people were living with HIV at the end of 2008—one of the highest figures in the world after South Africa.

Throughout the region, injecting drug use remains one of the most prominent modes of transmission of HIV. More than 50% of IDUs have already acquired HIV in Malaysia, Myanmar, Nepal, Thailand, Indonesia, Manipur, and southern China. Very high rates of needle sharing have been documented among users in Bangladesh and Vietnam, along with evidence that a considerable proportion of sex workers in Vietnam also inject drugs. More recently, the epidemic in many parts of Asia is steadily expanding into lower-risk populations through transmission to the sexual partners of the most at risk. In China, where the epidemic was previously driven by transmission through injecting drug use, heterosexual transmission has become the predominant mode of HIV transmission.

China, with a fifth of the world's population, has also witnessed a dramatic escalation of the HIV epidemic in the past decade. A total of 700,000 Chinese individuals are estimated to be living with HIV. The HIV epidemic is particularly severe among IDUs, who account for almost half (44%) of all HIV infections. To compound the tragedy of the epidemic in China, reports from Henan province in central China demonstrate that tens of thousands and possibly more rural villagers became infected by selling their blood to collecting centers that did not follow basic blood donation safety procedures. It has been estimated that 150,000 people have been infected through these practices. There are new signs of heterosexually transmitted HIV epidemics in at least three provinces—Guangdong, Guangxi, and Yunnan. Several other factors highlight the swift escalation of HIV infection in China. STDs quadrupled between 1997 and 2002, thus suggesting that unprotected sex with nonmonogamous partners is increasing in China. There is massive population mobility. Approximately 100 million Chinese are temporarily or permanently away from their registered addresses, and increasing socioeconomic disparities add to the likelihood of the spread of HIV.

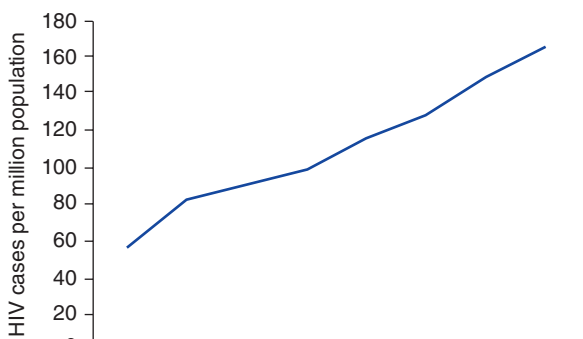

FIGURE 392-4. HIV cases per million population in Eastern Europe by year of notification, 2000 to 2007. *Note*: Data from the Russian Federation are not included. (Data from UNAIDS 2008.)

Indonesia, the world's fourth most populous country, is another example of how quickly the AIDS epidemic can emerge. After more than 10 years of negligible HIV prevalence, the infection rate in IDUs, sex workers, and blood donors in some regions is rapidly increasing. Papua New Guinea has also reported the highest HIV infection rates among the Pacific Island countries and territories. Even though the Philippines has maintained a low HIV prevalence, higher rates of STDs among Filipino sex workers, their clients, and MSM indicate low levels of condom use and the potential for rapid spread of HIV.

In some countries of Southeast Asia where HIV prevalence rose rapidly in the 1990s, strong prevention programs have limited the spread, most notably in Thailand, Cambodia, and Myanmar. Furthermore, the increased access to ART has coincided with a drastic drop in AIDS-related deaths. Despite these advances, AIDS is still a leading cause of death in Thailand, and 1.4% of the country's 63.6 million people are infected with HIV. Although STDs and heterosexual transmission have declined as a result of the government's prevention programs, HIV continues to spread rapidly among IDUs and MSM.

Treatment scale-up in Asia has been mixed. As of December 2008, 37% of those in Asia needing ART were receiving it, lower than the global average (42%) for all low- and middle-income countries. This, however, represents a seven-fold increase in access to treatment in 5 years.

HIV and AIDS in Eastern Europe and Central Asia

The HIV epidemic has increased faster in Eastern Europe and central Asia between 2000 and 2009 than in any other area of the world (Fig. 392-4). In 2008 there were an estimated 1.5 million people living with HIV, a 20-fold increase in less than a decade. In recent years, the Russian Federation has experienced an exceptionally steep rise in reported HIV infections, 90% of which have been attributed to injecting drug use. It is estimated that nearly 1% of the young people in Eastern Europe and central Asia are injecting drugs, which places these individuals and their sex partners at high risk for becoming infected with HIV. In countries such as Azerbaijan, Georgia, Tajikistan, and Uzbekistan, HIV has experienced explosive growth. Similar explosive high rates of HIV are being documented in IDUs and heterosexuals at risk for STDs in other countries of the Commonwealth of Independent States, in the Baltic states, and in Romania.

In Estonia, Latvia, and Lithuania, major HIV outbreaks are also occurring in selected populations, such as prison inmates. In one prison in Lithuania, 15% of the inmates were HIV positive, thus confirming the role of prisons in the spread of HIV in many countries of the region. The concentration of large numbers of young people in overcrowded prisons or juvenile justice facilities, often marked by an abundance of drugs but a scarcity of HIV information, clean needles, or condoms, provides fertile ground for the rapid spread of HIV among inmates and, on their eventual release, into the wider population.

Initially driven by injecting drug use in young people, heterosexual transmission of HIV has become a prominent mode of spread in Belarus and Ukraine. With an estimated adult HIV prevalence rate of 1.6%, Ukraine is one of the most severely affected countries in the region. Three fourths of HIV infections in Ukraine are related to injecting drug use, with a prevalence ranging from 38.5 to 50.3% in IDUs, but the proportion of sexually transmitted infection is increasing. Although many of these infections may occur in sex partners of IDUs, the trend may also indicate spread into the wider population of these countries. In the Russian Federation in the Ukraine, up to 30%

of female IDUs are also involved in commercial sex work. In Odessa, 67% of sex workers who inject drugs were HIV positive. The public health efforts to stem the tide of the epidemic in these countries are limited and, in some cases, nonexistent. In contrast, HIV prevalence remains low in Poland, the Czech Republic, Hungary, and Slovenia, where well-designed national HIV/AIDS programs are in operation.

A number of countries in the region have expanded access to ART, although treatment coverage remains relatively low. By December 2008, only 22% of adults in need of therapy were receiving it—a level much less than the global average. IDUs, the population most at risk for HIV in eastern Europe and central Asia, are often least likely to receive ART when they are medically eligible. If effective interventions are not implemented in the more severely affected countries, it is likely that the situation will become dramatically worse over the next 5 years.

HIV and AIDS in Latin America and the Caribbean

An estimated 2.25 million adults and children are living with HIV in Latin America and the Caribbean. Twelve countries in this region have an estimated HIV prevalence of 1% or greater in pregnant women. In several Caribbean countries, adult HIV prevalence rates are surpassed only by the rates experienced in sub-Saharan Africa, which makes this region the second most affected in the world. Haiti and the Bahamas remain the worst affected, with an estimated national prevalence higher than 2.2% in Haiti and a prevalence of 3.3% in the Bahamas. AIDS is the leading cause of death in some countries of the Caribbean basin. In Haiti, the Bahamas, and Guyana, the number of deaths in 15- to 34-year-olds is 2.5 times higher than it would have been in the absence of AIDS.

Homosexual and heterosexual transmission continues to be the major mode of transmission throughout the region, although there is evidence that spread of HIV is increasing through sharing of infected drug equipment. Population mobility, spurred by high rates of unemployment and poverty, is emerging as a significant factor in the epidemic's growth in this region. Central America's geographic position also makes it an important transit zone for people moving between the rest of the region and North American countries. Appropriately, protecting vulnerable populations on the move, including adolescent girls and young women, is now the focus of a regional prevention program in Central America. In Mexico, adult HIV prevalence in the wider population is still well under 1%, but prevalence rates are higher in specific population groups—6% in IDUs and 15% in MSM. There is significant overlap between IDUs and MSM, especially in Brazil and the southern Latin American countries, where injecting drug use is a growing social phenomenon. Injecting drug use is also a major route of HIV transmission in Argentina, Chile, and Uruguay.

Despite many constraints, the region has made progress in the provision of treatment and care. By reducing HIV-related morbidity through treatment, Brazil's treatment and care program is estimated to have avoided 234,000 hospitalizations in a 4-year period, thereby demonstrating a cost-effective approach to care. Argentina, Costa Rica, Uruguay, and Cuba now guarantee free and universal access to drugs through the public sector, and sharp reductions have recently been secured in Honduras and Panama. Treatment coverage has risen from 10% of those in need in 2004 to 54% in 2008. Similarly, pediatric antiretroviral coverage in the Caribbean was high (55%) in comparison to the global average for children of 38%. Consistent with the evolving guidelines of HIV treatment, a growing number of people living with HIV in Latin America are starting treatment earlier at $CD4^+$ cell counts of 350 or lower rather than waiting until the count drops below 200. Earlier initiation of therapy offers the possibility that medical outcomes in the region may improve further still and reduce the population-level viral load, which might result in lower transmission rates.

HIV and AIDS in Western Europe

More than 850,000 HIV-infected individuals reside in Western Europe, with trends similar to those witnessed in the United States, Australia, and New Zealand. Longer survival of people infected with HIV has led to a steady increase in the number of people living with the virus in high-income countries. In a multicountry study in Europe, Australia, and Canada, mortality rates in people living with HIV in the first 5 years after infection now approach those in the non–HIV-infected population, although excess mortality in HIV-infected people increases with the duration of infection. In the United Kingdom, half of all people living with HIV are receiving ART, with no appreciable increase in the number of patients with virologic failure or resistance to the drugs.

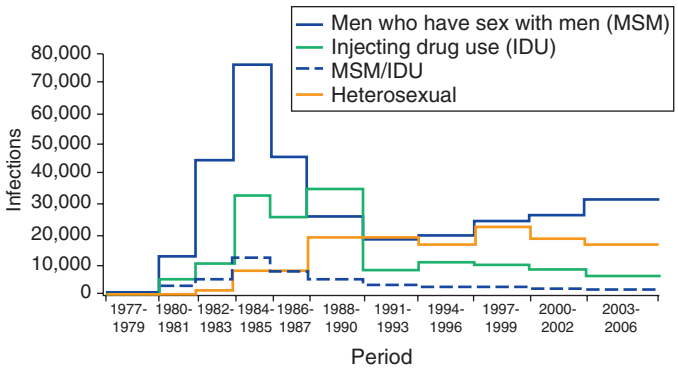

FIGURE 392-5. Estimated new HIV infections by transmission category for the United States, 1977 to 2006. Tick marks denote the beginning and end of a year. The model specifies periods within which the number of HIV infections was assumed to be approximately constant. (Data from Centers for Disease Control and Prevention and Hall HI, Song R, Rhodes P, et al. Estimation of HIV incidence in the United States. *JAMA.* 2008;300:520-529.)

The HIV epidemic in Western Europe is a result of a multitude of epidemics that differ in their timing, scale, and effects on populations. A larger proportion of new HIV diagnoses in Western European countries occur through heterosexual intercourse. More than half of the new HIV infections in the United Kingdom in 2008 resulted from heterosexual sex, as compared with 33% in 1998. In Ireland, a similar trend is visible, with numbers of heterosexually transmitted HIV infection increasing four-fold between 1998 and 2001. Unsafe sex between men remains an important factor for spread in most European countries, particularly in the United Kingdom, Germany, the Netherlands, and Spain. Injecting drug use remains a major mode of transmission in Spain, France, and Portugal, but like other countries in Europe, about a fourth of all HIV infections are now heterosexually transmitted. Most data from high-income countries demonstrate that the epidemic has shifted to the poor and marginalized sections of society. Underscoring the need for renewed prevention efforts, especially in young people, are findings of increases in high-risk behavior, less frequent condom use, and higher rates of STDs in several countries. In the United Kingdom, for example, rates of gonorrhea, syphilis, and chlamydial infections have more than doubled since 1995, and increases have been found in other Western European countries as well.

HIV and AIDS in the United States

By 2009, more people than ever were living in the United States with HIV—1.2 million (see Table 392-1). Nationally, the adult HIV prevalence was estimated to be 0.6%. This increase reflects mixed results in the U.S. effort to combat its epidemic. More people infected with HIV are living longer because of ART, but unfortunately, the early gains made in prevention have not been sustained (Fig. 392-5). The number of newly recorded HIV cases in 33 states with confidential name-based reporting has varied only slightly since the late 1990s. In 2006, the annual incidence of HIV infection was estimated at 56,300, which was approximately 40% higher than previously estimated. Half of all HIV infections diagnosed in men, women, and children in 2008 were in MSM, a rise from previous years.

Another aspect of the U.S. epidemic is that more women are being infected with HIV through unprotected heterosexual exposure and injecting drug use. Overall, nearly 20% of new HIV infections are attributable to injecting drug use. The main risk factor for women who acquire HIV during sex is the risk behavior of their male partners, such as injecting drug use, commercial sex, or sex with other men. As in Latin America, women living in impoverished and marginal circumstances appear to be at disproportionate risk for HIV infection. In North Carolina, HIV-positive women were considerably more likely to be unemployed, requiring public assistance, and exchanging sex for money and gifts.

As the U.S. epidemic evolves, it is becoming more an epidemic of African Americans and other minorities. African Americans make up 12% of the U.S. population but account for 45% of new HIV diagnoses. Hispanics represent 14% of the population but account for 18% of new HIV diagnoses. Among African Americans and Hispanics, most men infected with HIV were exposed during sex with other men (49% and 59%, respectively), whereas most women with HIV become infected heterosexually (78% and 73%, respectively). African American women are more than 10 times more likely to be infected with HIV than white women are. AIDS continues to be the leading cause of death in African American women aged 25 to 34 years and ranks in

the top three causes of death in African American men aged 25 to 54 years. African Americans are about half as likely to receive ART as other population groups, and twice as many African Americans as whites die of AIDS. In the United States, the challenge of slowing the rate of new HIV infections overlaps with the need to provide diagnosis, treatment, and care services more equitably. The number of AIDS-related deaths was 69% lower than in 1994. However, further declines in mortality will require greater success in encouraging timely diagnosis of HIV infection. An estimated 21% of people living with HIV are unaware of their HIV status. Moreover, in 36% of people in whom HIV was diagnosed, AIDS was diagnosed within 12 months. With the aim of increasing the percentage of people who receive a timely diagnosis of HIV, the Centers for Disease Control and Prevention recommends routine voluntary HIV testing in all health care settings unless the patient opts not to be tested.

With an epidemic that is nearly into its third decade, complacency has increased, and prevention efforts have dwindled as a result of declining mortality. Multiple studies illustrate that prevention efforts are not reaching the large number of at-risk individuals who engage in unsafe sex. Increased rates of sexually transmitted infections among MSM have been documented in the United States, Australia, Great Britain, Canada, and other developed countries. Rates of gonorrhea, syphilis, and chlamydia have more than doubled in the past 5 years among MSM in selected U.S. and European cities. Renewed efforts to enhance prevention efforts, particularly in HIV care clinics, are being echoed throughout all these countries.

IMMUNOPATHOGENESIS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

JOEL N. BLANKSON AND ROBERT F. SILICIANO

Human immunodeficiency virus type 1 (HIV-1) infection results in a progressive state of immune system dysregulation that ultimately leads to the acquired immunodeficiency syndrome (AIDS), a syndrome characterized by a profound depletion of $CD4^+$ T lymphocytes and the inability to control infections by opportunistic pathogens that do not cause disease in individuals with a normal immune system. Despite almost 30 years of research on this condition, the basic pathogenic mechanisms are still incompletely understood. This chapter reviews current understanding of the mechanisms involved in HIV-1 immunopathogenesis.

PRIMARY INFECTION

The natural history of HIV-1 infection is illustrated in Figure 393-1. During acute HIV-1 infection, massive viral replication occurs in $CD4^+$ T lymphocytes in the absence of an adaptive immune response. $CD4^+$ T cells in the gut-associated lymphoid tissue and other mucosal sites express high levels of the HIV coreceptor CCR5 and are thus particularly prone to infection and depletion by the commonly transmitted R5 variants of HIV-1. In animal models, it has been shown that approximately 30% of memory $CD4^+$ T cells are infected and depleted by 4 days after infection. This is in contrast to chronic infection, in which less than 1% of all $CD4^+$ T cells are infected at any given time. As a result of this massive early infection, levels of virion-associated HIV RNA of more than 1 million copies/mL are typically seen in plasma within 2 weeks of infection, and patients tend to experience a constellation of signs and symptoms known as the *acute retroviral syndrome.* There can be significant declines in peripheral $CD4^+$ T-cell counts in primary infection resulting in opportunistic infections. Within several weeks, the development of an effective HIV-1–specific cytolytic T-lymphocyte response results in the partial control of viral replication, and peak viral loads fall and reach a steady state known as the *set point.* The magnitude of the set point viral load during the second asymptomatic phase of the infection reflects a dynamic equilibrium between viral replication and the HIV-1–specific immune response. This set point determines the rate of progression to the final phase, clinical AIDS. The median set point is approximately 30,000 HIV-1 RNA copies per milliliter, and most patients who have this level of viremia will develop AIDS in a 5- to 10-year period if they are left untreated. Patients with much higher set point viral loads will tend to be rapid progressors who develop AIDS much more quickly; patients with much lower viral loads tend to be long-term nonprogressors.

HIV-1–SPECIFIC IMMUNITY

The host mounts a vigorous immune response after HIV-1 infection. The virus is thought to activate plasmacytoid dendritic cells through Toll-like receptors, resulting in the secretion of type I interferons and other inflammatory cytokines. Whereas type I interferons have direct antiviral properties and enhance the HIV-1–specific immune response, excessive secretion may play a key role in pathogenic immune activation of $CD4^+$ and $CD8^+$ T cells (Fig. 393-2). Natural killer (NK) cells are important effector cells in the innate immune response that become activated when infection of target cells by HIV-1 or other viruses results in the downregulation of HLA molecules. Patients expressing certain NK receptor alleles are more likely to become long-term nonprogressors, suggesting that these cells may play a protective role possibly by controlling early HIV-1 replication, leading to the development of an effective adaptive immune response. Myeloid dendritic cells play a key role in the presentation of HIV-1 antigens to HIV-1–specific $CD4^+$ and $CD8^+$ T cells, which results in the initiation of the adaptive immune response. They express CD4 molecules and have been shown to bind HIV-1. It is thought that in the process of presenting antigen, these cells may inadvertently transmit HIV-1 to clusters of activated $CD4^+$ T cells.

The role of the humoral response in HIV-1 infection is not clear. HIV-1–specific antibodies, which are used to diagnose HIV-1 infection, do not develop until after peak viremia occurs. There is thus a window period in primary HIV-1 infection during which viremia is present in the absence of detectable antibodies. A subset of the antibodies that eventually appear are capable of preventing infection by blocking the interaction of the HIV-1 envelope protein gp120 with CD4 and coreceptor proteins on the surface of

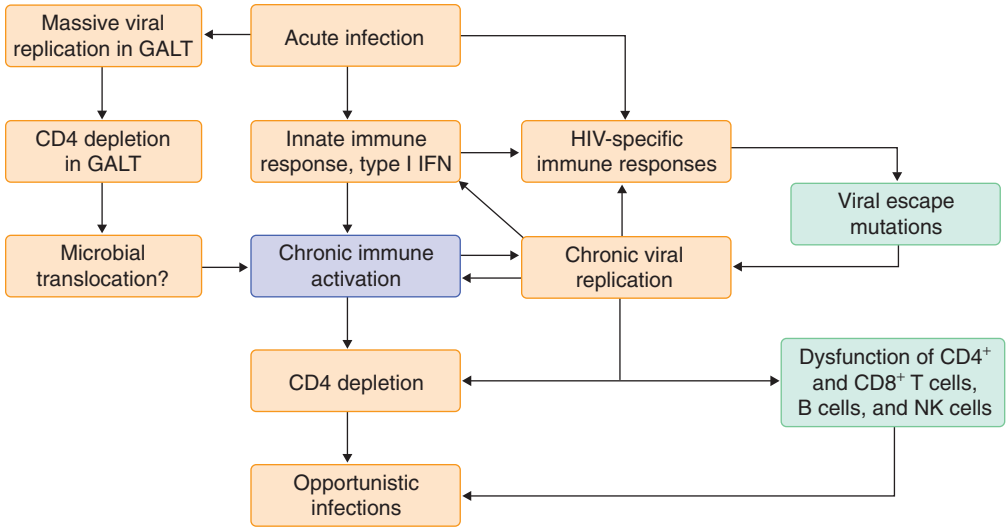

FIGURE 393-2. Parameters involved in chronic immune activation and CD4⁺ T-cell depletion. GALT = gut-associated lymphoid tissue; IFN = interferons; NK = natural killer.

target cells. These so-called neutralizing antibodies are present at relatively low titers and have limited access to the critical regions of gp120. Whereas they can exert significant selective pressure on the virus, immunologic escape is common, and the bulk of evidence suggests that these antibodies do not play a major role in the control of viral replication in most long-term nonprogressors.

The selective depletion of $CD4^+$ T cells is the main reason that HIV-1 infection results in such profound immunosuppression; these so-called helper T cells play a major role in every facet of the adaptive immune response. The ability of HIV-1–specific $CD4^+$ T cells to proliferate and to secrete key cytokines such as interleukin-2 is lost shortly after primary infection, setting up the entire HIV-1–specific response for failure.

$CD8^+$ T cells contribute to the control of HIV-1 infection by the direct lysis of infected cells and by the secretion of soluble factors like macrophage inflammatory protein 1β that bind to chemokine receptors, thereby preventing HIV-1 entry into target cells. However, the HIV-1–specific $CD8^+$ T-cell response that partially controls HIV-1 replication after peak viremia in primary infection does not achieve sterilizing immunity, partly because of a reservoir of latent virus in resting memory $CD4^+$ T cells that develops shortly after infection. These quiescent cells probably do not make HIV-1 proteins and thus are not recognized by cytolytic T lymphocytes. Furthermore, the cytolytic T-lymphocyte response in patients with progressive disease is of poor quality with limited proliferative capacity. Most important, the low fidelity of HIV-1 reverse transcriptase results in the development of mutations with each round of replication. Mutations that lead to escape from cytolytic T-lymphocyte responses have an advantage and are thus rapidly selected for.

THE EFFECT OF HIV-1 REPLICATION ON THE IMMUNE SYSTEM

Whereas the HIV-1–specific immune response helps limit the rate of viral replication, sterilizing immunity is never achieved and the virus has a negative impact on the immune system. Continuous viral replication results in chronic immune activation (see Fig. 393-2). The mechanism is not understood. The chronic immune response to the virus may lead to nonspecific inflammation, and microbial translocation resulting from the depletion of $CD4^+$ T cells in the gut-associated lymphoid tissue may also be important. Whatever the mechanism, immune activation appears to drive the depletion of $CD4^+$ T cells. The level of immune activation markers on $CD4^+$ and $CD8^+$ T cells correlates better with the rate of CD4 decline than does the magnitude of the viral load in untreated patients.

Increased levels of activation markers are seen on NK cells, B cells, $CD4^+$ T cells, and $CD8^+$ T cells. Activation is accompanied by an increase in the turnover rate of these cells. The function of NK cells is compromised, which may predispose to the poor control of other viruses. B-cell defects result in hypergammaglobulinemia and the production of autoantibodies. Poor antibody responses to vaccines are also seen as $CD4^+$ T cells decline.

Studies of viral dynamics make it clear that most productively infected cells live only a short time (~1 day) before succumbing to viral cytopathic effects or host cytolytic T lymphocytes or NK cells. Although the loss of infected $CD4^+$ T cells contributes to CD4 depletion, there is marked depletion of $CD4^+$ T cells even though at any given time during chronic infection only 1% or less of these cells are infected. Thus, it is currently thought that chronic immune activation leading to the death of noninfected $CD4^+$ T cells is the principle mechanism for CD4 depletion. Support for this idea comes from studies of the closely related simian immunodeficiency virus that replicates in natural simian hosts without causing immune activation or CD4 depletion. In addition to the quantitative loss of $CD4^+$ T cells in HIV-1 infection, marked skewing of the CD4 T-cell repertoire is seen, and there is a diminished qualitative memory response to recall antigens long before the $CD4^+$ T-cell count drops to 200 cells/μL. The chronic activation and high turnover rate of these cells eventually result in the progressive CD4 decline that is characteristic of HIV-1 infection.

There is evidence of immune exhaustion for both $CD4^+$ and $CD8^+$ T cells, and there is decline in the qualitative features of the $CD8^+$ T-cell response to other chronic viruses such as cytomegalovirus and Epstein-Barr virus. This may be the result of anergy or depletion of the $CD4^+$ T cells that are needed to sustain functional $CD8^+$ T-cell responses.

CLINICAL CONSEQUENCES OF HIV INFECTION

Clinical immunodeficiency is associated with the late stages of HIV-1 infection, when profound $CD4^+$ T-cell depletion has occurred. However, some level of immunodeficiency may be present shortly after infection because of qualitative changes in the immune response related to ongoing viral replication. As a result, patients are more susceptible to infections like *Mycobacterium tuberculosis* infection before the CD4 count reaches the 200 cells/μL threshold that defines AIDS. Patients are also much more susceptible to malignant neoplasms such as non-Hodgkin's lymphoma at any $CD4^+$ T-cell count. Other opportunistic infections arise at fairly predictable $CD4^+$ T-cell counts. *Pneumocystis jiroveci* infections occur at CD4 counts of lower than 200 cells/μL, *Cryptococcus neoformans* and *Toxoplasma gondii* infections occur at CD4 counts of lower than 100 cells/μL, and *Mycobacterium avium* complex and cytomegalovirus infections occur at CD4 counts below 50 cells/μL. Whereas these infections are a consequence of diminished cellular immunity, there is also a marked increase in invasive pneumococcal infections in HIV-1–infected patients, possibly due to defects in humoral immunity.

The Response to Antiretroviral Therapy

Treatment with selected combinations of antiretroviral drugs, which is known as highly active antiretroviral therapy (HAART), suppresses viral replication to below the limits of detection of current commercial assays (50 copies of HIV-1 RNA per milliliter of plasma). Current evidence suggests that HAART produces a complete or nearly complete arrest in viral replication in adherent patients, but trace amounts of viremia persist because of stable viral reservoirs, including the latent reservoir in resting $CD4^+$ T cells. This suppression of viral replication is usually accompanied by a substantial increase in $CD4^+$ T-cell counts. The initial rise in $CD4^+$ T-cell counts occurs mostly as a consequence of migration of cells from lymph nodes (where 98%

of all CD4 T cells reside) to the peripheral blood as inflammation diminishes in lymphoid tissue. Subsequently, there is an increase in the production of memory $CD4^+$ T cells in most individuals. Naive T cell production is also sometimes seen at lower levels. Clinical studies have shown that patients who experience significant immune reconstitution can safely discontinue prophylactic therapy for opportunistic infections. However, it is not clear whether patients who maintain undetectable viral loads while receiving HAART yet do not achieve significant CD4 T-cell immune reconstitution are still at risk for opportunistic infections. Two large studies have shown that although the use of interleukin-2 treatment in conjunction with HAART will cause a significant increase in $CD4^+$ T-cell counts in these patients, the enhanced immune reconstitution is not associated with any clinical benefit.

Just as a decline is seen in the functional $CD4^+$ T-cell response shortly after primary infection, there is a qualitative improvement in $CD4^+$ T-cell function shortly after HAART is initiated. In some cases, there are exaggerated immune responses to opportunistic infections leading to the immune reconstitution inflammatory syndrome (IRIS; Chapter 402), particularly when there is rapid control of viral replication after the initiation of HAART. IRIS usually presents as a paradoxical worsening of a disease process a few weeks after HAART is started and can occur even before there are significant changes in the absolute $CD4^+$ T-cell counts. IRIS has been reported for virtually all known opportunistic infections, and in some cases it can occur in response to previously unrecognized infections. There have not been clinical trials looking at treatment of this condition, but nonsteroidal anti-inflammatory drugs and corticosteroids have been routinely used with varying degrees of success (Chapter 402).

BIOLOGY OF HUMAN IMMUNODEFICIENCY VIRUSES

GEORGE M. SHAW

DISCOVERY OF HUMAN IMMUNODEFICIENCY VIRUSES

Identification of human immunodeficiency virus type 1 (HIV-1) as the causative agent of acquired immunodeficiency syndrome (AIDS) just 3 years after the clinical syndrome was initially described represents a remarkable scientific achievement that had its roots in earlier discoveries of animal and human retroviruses. The selective loss of $CD4^+$ helper T lymphocytes in patients with AIDS implicated an agent with T-lymphocyte tropism. HIV-1 had this property, and as expected for an etiologic agent, the virus was shown to be invariably present in subjects with AIDS and to reproduce the hallmark of the disease in tissue culture: destruction of T lymphocytes.

HUMAN IMMUNODEFICIENCY VIRUS TYPE 1

General Biologic Properties

Soon after its discovery, HIV-1 was shown to be biologically, structurally, and genetically distinct from human T-lymphotropic virus type 1 (HTLV-1) and type 2 (HTLV-2) and more like members of the lentivirus subfamily of retroviruses. Unlike the leukemia viruses, which lead to immortalization of lymphocytes in vitro and in vivo, HIV-1 produces pronounced cytopathic properties in lymphocytes and causes syncytia formation and cell death. Morphologically, HIV-1 differs from HTLV-1 and other type C oncogenic retroviruses in exhibiting a dense, cylindrical core surrounded by a lipid envelope typical of lentiviruses (Fig. 394-1).

The structural organization of HIV-1 is shown diagrammatically in Figure 394-2. Like all retroviruses, HIV-1 is a single-stranded, plus-sense RNA virus. The RNA-dependent DNA polymerase, or reverse transcriptase, is packaged within the virion core and is responsible for replicating the single-stranded RNA genome through a double-stranded DNA intermediate that serves as the precursor molecule for proviral integration within the host cell genome. The major structural core proteins of HIV-1 are the p24 capsid protein and the p18 matrix protein. Surrounding the viral core protein structures is a bilayered lipid envelope that is derived from the outer limiting membrane of the host cell as the virus buds from the cell surface during replication. Studding this outer viral membrane are the envelope glycoproteins gp120 and gp41, which are encoded by virus-specific genes and are responsible for cell attachment and entry.

The life cycle of HIV-1 is shown diagrammatically in Figure 394-3. Features of this life cycle distinguish retroviruses from all other viruses. The cell-free virion first attaches to the target cell through a specific interaction between the viral envelope and the host's cell membrane. The specificity of this interaction between virus and cell results from a high-affinity interaction between the viral gp120 envelope glycoprotein and the target cell–associated

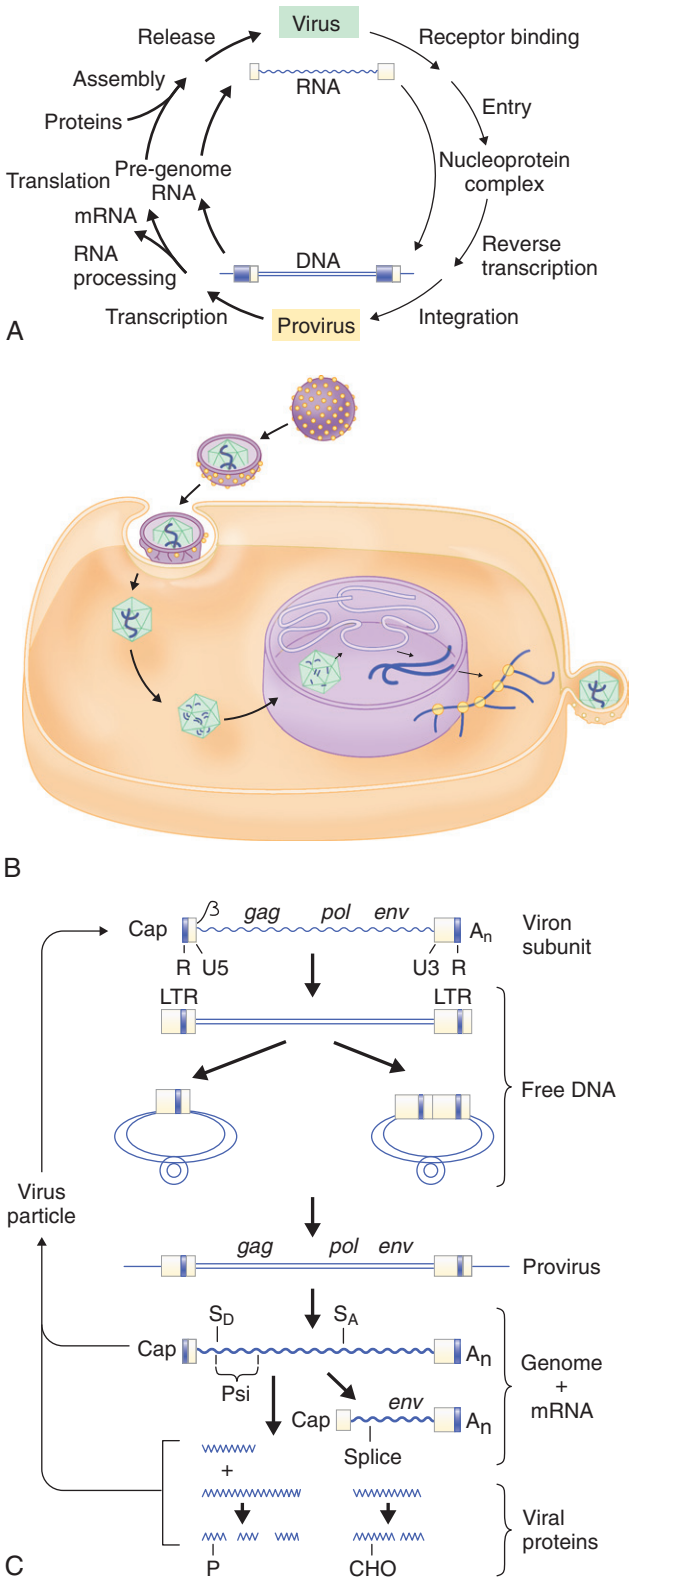

FIGURE 394-3. Different representations of the HIV-1 life cycle. CD4 molecule and leads to a conformational change in gp120 and subsequent interaction with a member of the cellular chemokine receptor family (CCR5 or CXCR4). These highly specific interactions among gp120, CD4, and CCR5/CXCR4 culminate in fusion of the viral and cellular membranes and internalization of the nucleoprotein-viral complex. Reverse transcription catalyzed by viral reverse transcriptase generates a double-stranded DNA copy of the viral RNA within the nucleoprotein complex, and this copy migrates to the nucleus, where covalent integration of viral DNA into host chromosomes leads to formation of the provirus. Subsequent expression of viral DNA is controlled by a combination of viral and host cellular proteins that interact with viral DNA and RNA regulatory elements. Transcribed viral mRNA is translated into viral proteins, and new virions are assembled at the cell surface, where genomic-length viral RNA, reverse transcriptase, structural and regulatory proteins, and envelope glycoproteins are assembled. Importantly, most of the steps in the HIV-1 life cycle can now be inhibited by antiretroviral drugs, which when used in combination, result in sustained clinical benefit. However, because the HIV-1 provirus is covalently integrated within the host cell's chromosomes, it can persist in a transcriptionally silent or latent state in unactivated memory $CD4^+$ T lymphocytes for years, only to resume productive replication should therapy be discontinued. Thus, HIV-1 latency is a viral feature that has stood in the way of curative therapy.

Molecular Structure and Function of HIV-1

The genomic organization of HIV-1 is shown diagrammatically in Figure 394-4. The HIV-1 genome, like other retroviral genomes, is diploid and consists of two identical viral RNA molecules assembled in a hydrogen-bonded 70S complex. These genomic subunits are plus strands of viral RNA in that they have the same chemical polarity as the mRNA from which the viral products are translated. Like eukaryotic mRNA, the genomic viral RNA contains a 5′-methyl-G nucleotide, a poly(A) tract of 100 to 200 nucleotides at its 3′ end, and a number of methylated(A) residues. Host cell–derived tRNA incorporated within the virion is base-paired over a stretch of 18 nucleotides to the primer-binding site of the genomic viral RNA near its 5′ terminus and serves to prime the synthesis of minus-strand DNA during the initial stages of viral replication after infection.

The HIV-1 genome is bounded by long terminal repeat (LTR) elements and contains genes encoding the structural and enzymatic proteins (gag, pol, and env) found in all other replication-competent retroviruses. In addition to these genes, HIV-1 contains genes encoding other viral functions unique to this family of viruses that are responsible for their biologic behavior. The LTR sequences of HIV-1 direct and regulate expression of the viral genome (Fig. 394-5).

The *gag* gene encodes a precursor protein (p55) of 55 kD that is cleaved into four smaller products with the linear order NH_2-p18-p24-p9-p7-COOH. These proteins constitute the core protein structure of the virus and subserve nucleic acid– and lipid membrane–binding functions. The gag proteins of HIV-1, like those of other retroviruses, are synthesized as a polyprotein precursor that is subsequently cleaved during the viral maturation process. This facilitates assembly of the different components of the viral core structure into a three-dimensional configuration that when cleaved by a specific virus-derived protease, acquires the specialized functions characteristic of the mature virion. The polymerase gene products are translated from the same genomic RNA message as the gag proteins but in a different, overlapping reading frame as a result of ribosomal frame shifting. The *pol* gene encodes three proteins that are cleaved from a larger precursor polypeptide. These genes include NH_2-protease (p13)-reverse transcriptase (p66/p51)-integrase (p31)-COOH. The HIV-1 protease plays a critical role in viral biology in that it acts specifically to cleave gag and pol precursor polypeptides into functionally active proteins. The reverse transcriptase of HIV-1 is a magnesium-requiring, RNA-dependent DNA polymerase responsible for replicating the RNA viral genome. The integrase protein is required for proviral integration into the host cell's genome.

The envelope gene *(env)* encodes a glycosylated polypeptide precursor (gp160) that is cleaved to form the exterior envelope glycoprotein (gp120) and the transmembrane glycoprotein (gp41), the latter of which anchors the envelope complex to the viral surface. The gp120/gp41 heterodimer exists as a trimeric spike complex on the virion surface and must serve two separate but essential functions: (1) mediation of viral binding and entry into cells and (2) avoidance of neutralization by virus-specific antibodies. The former task is accomplished by sequential gp120 binding to cell-associated CD4 followed by a chemokine receptor, which triggers a gp41-mediated fusion event. The latter function results from a combination of carbohydrate cloaking of the exposed viral env surface, mutation of exposed env epitopes, and masking of conserved env receptor surfaces by conformational or energetic barriers to antibody binding.

Within the HIV-1 genome, additional genes serve important viral functions and distinguish HIV-1 from oncogenic retroviruses. They include the

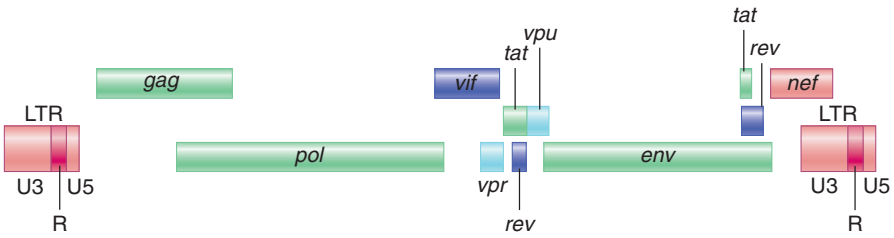

FIGURE 394-4. Genomic organization of HIV-1. LTR = long terminal repeat.

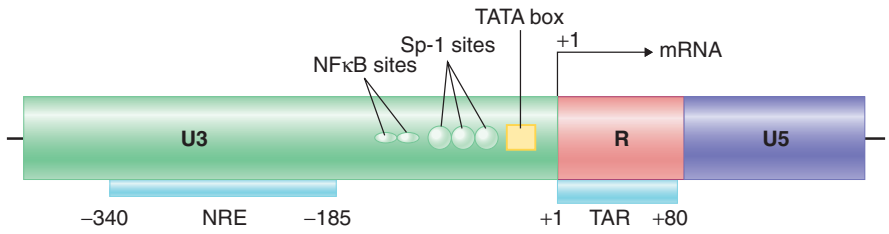

FIGURE 394-5. Regulatory regions in the long terminal repeat (LTR) of HIV-1. Deletion mutant studies of the LTR have identified at least five regions for gene expression, including the TATA box and promotor, where RNA polymerase binds and transcription is initiated (+1); a negative regulatory element (NRE) located between nucleotides –340 and –185, deletion of which increases the level of gene expression directed by the viral LTR; enhancer elements (NFκB and Sp-1) located between nucleotides –137 and –17; and a *trans*-acting responsive region (TAR) located between nucleotides +1 and +80, which represents the putative binding region for regulatory factors responsible for tat-mediated transcriptional activation.

vif, *vpr*, and *vpu* genes located between *pol* and *env*; the *nef* gene located 3′ to *env* and extending into the U3 region of the viral LTR; and the *tat* and *rev* genes, both of which exist as bipartite coding exons in the central and 3′ end of the virus. The *tat* gene encodes a 14-kD protein that upregulates HIV-1 expression at transcriptional and post-transcriptional levels and is thus essential for HIV-1 replication. The target sequence for *tat*-mediated upregulation of HIV-1 expression is the *trans*-acting responsive region (TAR) of the LTR, which interacts with cellular factors to bind and activate TAR (see Fig. 394-5). The *rev* gene encodes a 20-kD protein that is required for transport of unspliced and singly spliced viral mRNA from the nucleus to the cytoplasm. In the absence of *rev*, gag and env mRNA transcripts become multiply spliced and gag and env proteins are not made. The *vif* gene encodes a protein product of 23 kD that suppresses the antiretroviral cellular enzyme apolipoprotein B mRNA-editing enzyme-catalytic polypeptide-like 3G (APOBEC3G), thereby enabling the production of infectious virions. The *vpr* gene encodes a protein of 15 kD that induces G_2/M cell cycle arrest, thereby enhancing viral production. The *vpu* gene encodes a 16-kD protein that is involved in virus assembly and release. The *nef* gene encodes a 27-kD protein that facilitates viral pathogenesis by downregulating cell surface–bound CD4, altering T-cell activation, and interfering with major histocompatibility complex (MHC) antigen presentation.

In summary, HIV-1 encodes the usual structural and enzymatic proteins typical of other replication-competent retroviruses, including gag, pol, and env, but it also encodes a group of at least six regulatory or auxiliary proteins (vif, vpr, vpu, tat, rev, and nef) whose activities are critically important in regulating the life cycle and pathogenesis of the virus.

Cell Tropism

The hallmark of AIDS is selective depletion of $CD4^+$ helper-inducer T lymphocytes. This defect is believed to result largely from the selective tropism of HIV-1 for this population of cells based on the high affinity of the viral gp120 envelope protein for the CD4 molecule. CD4 normally serves as a ligand for MHC type II interactions, but in HIV-1 infection, it is used as the primary receptor molecule for HIV-1 targeting. This has been shown conclusively by studies demonstrating (1) direct complexing of gp120 and CD4 during viral infection, (2) inhibition of viral attachment and infection by anti-CD4 monoclonal antibodies that prevent gp120 binding, and (3) the ability of recombinant CD4 to confer susceptibility to HIV-1 infection to transfected human cells that normally do not express CD4.

CD4 expression alone is not sufficient to mediate HIV-1 entry. Coreceptors essential for viral entry include members of the chemokine receptor family, which are G protein–coupled receptors for pro-inflammatory chemokines. They include CCR5, which normally responds to the chemokines RANTES, MIP-1α, and MIP-1β, and CXCR4, which normally binds SDF-1. CCR5 and CXCR4 are differentially expressed on normal human cells that serve as targets of HIV-1 infection and are importantly involved in the cellular and tissue tropism of HIV-1 and in viral transmission and pathogenesis.

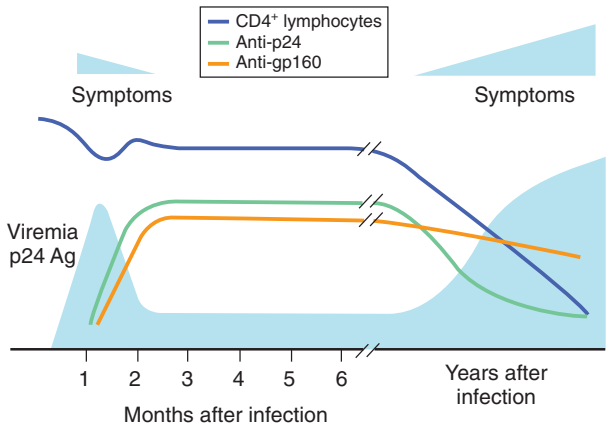

FIGURE 394-6. Natural history model for HIV-1 infection. Viremia denotes cell-free virus in plasma, p24 Ag denotes circulating viral p24 antigen in plasma, and anti-p24 and anti-gp160 correspond to antibodies to viral core and envelope proteins.

A variety of cell types other than helper-inducer T lymphocytes are known to express CD4 on their surface and are capable of replicating HIV-1. Such cells include tissue macrophages, Langerhans cells in skin, and microglial and multinucleated giant cells in the central nervous system (CNS). These cells generally express smaller amounts of CD4 on their cell surface, but in each case they express one or more coreceptor molecules. Infection of such cells is believed to play a role in the pathogenesis of AIDS. Other cell types, including neurons, glial cells, gastrointestinal epithelial cells, and kidney epithelium, can support HIV-1 infection, but the pathophysiologic significance of such findings in regard to viral pathogenesis in vivo is uncertain.

Viral Pathogenesis

Lentiviral (*lenti* = slow) diseases are typically characterized by prolonged periods of restricted viral gene expression, clinical latency, and lifelong persistence of virus in the face of substantial host immune responses and effective suppressive antiretroviral drug therapy. From cohort studies of individuals infected with HIV-1 before the era of highly active antiretroviral therapy (HAART), it was estimated that AIDS will develop in 26 to 36% of infected individuals within 7 years of infection and that lesser signs of immune dysfunction will develop in an additional 40%. This protracted clinical course suggested that expression of the HIV-1 genome in vivo is downregulated with respect to in vitro infection of lymphocytes by HIV-1, which is characterized by explosive lytic viral infection.

However, clinical quiescence can be misleading, and Figure 394-6 depicts the natural history of HIV-1 infection in humans to be one of continuous viral replication and progressive lymphocyte destruction. Initial infection with HIV-1 frequently causes an acute viral syndrome with protean manifestations

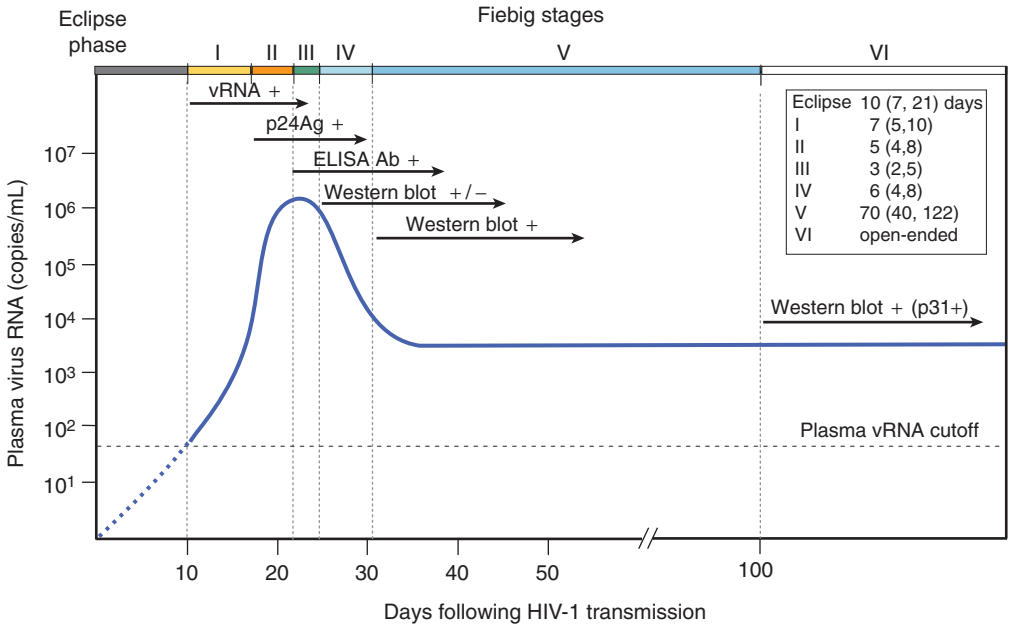

FIGURE 394-7. Laboratory markers and clinical staging of acute and early HIV-1 infection. HIV-1 transmission is followed by an orderly appearance of viral markers and host antibodies in plasma. The average duration (with 95% confidence intervals in parentheses) of each clinicopathologic stage is depicted in the *boxed inset*. (Adapted from Fiebig EW, Wright DJ, Rawal BD, et al. Dynamics of HIV viremia and antibody seroconversion in plasma donors: implications for diagnosis and staging of primary HIV infection. *AIDS*. 2003;17:1871-1879.)

but typically characterized by fever, lymphadenopathy, pharyngitis, and rash. Other symptoms and signs that may occur with acute HIV-1 infection include myalgia, arthralgia, leukopenia, thrombocytopenia, nausea, diarrhea, headache, and encephalopathy. During this primary phase of infection, $CD4^+$ lymphocytes in blood may be normal or transiently diminished, but $CD4^+$ lymphocytes in gut-associated lymphoreticular tissue and in lymph nodes become widely infected and rapidly depleted, thereby leading to a long-lasting quantitative and qualitative loss of $CD4^+$ helper T-cell function. Regardless of the presence or absence of discernible clinical symptoms during primary infection, the emergence of viral and host immune markers of infection occurs in an orderly process (Fig. 394-7). Immediately following viral transmission, there is an eclipse phase during which virus replicates in mucosal tissues, draining lymphatics, and gut-associated lymphoid tissue but neither virus nor viral-specific antibodies are detectable in plasma. This is followed by an exponential rise in viral RNA (Fiebig stage I) and viral RNA and p24 antigen (Fiebig stage II) in plasma while viral antibodies are still not detectable. Peak plasma viremia titers typically reach 10^6 to 10^8 virions/mL. Clinically, Fiebig stages I and II are important because patients are highly infectious, oftentimes symptomatic, and commonly seek medical attention, but rapid antibody tests are negative. To diagnose acute HIV-1 infection, clinicians must thus have a high index of clinical suspicion and specify HIV-1 RNA tests in addition to antibody tests. The typical "window" period during which a patient is HIV-1 antibody negative but plasma virus positive is about 12 days but ranges from 9 to 18 days. This antibody-negative, plasma viral RNA–positive period generally begins about 7 to 21 days after transmission and persists for as long as 2 weeks before HIV-1–specific antibodies are first detectable by sensitive recombinant protein-based enzyme-linked immunosorbent assay (ELISA). Confirmation of HIV-1 infection based on the appearance of antibodies to multiple viral proteins on Western immunoblot generally follows within a week or two. In rare instances, antibody seroconversion has been reported to occur as long as 3 or even 6 months after a presumed date of infection. After peak viremia, HIV-1 replication is downregulated by host defense mechanisms with resolution of the acute proinflammatory infectious state, although viral replication is not altogether abrogated. Even during the clinically quiescent stages of infection, substantial viral replication takes place and leads to progressive $CD4^+$ cell destruction. This serves as the rationale for clinical studies examining the risk-benefit ratio of antiviral therapy initiated at the earliest stages of infection, a question that has still not been answered.

The precise biologic mechanisms responsible for the cytopathic effects and immunosuppressive properties of HIV-1 in vivo are unknown. Molecularly cloned HIV-1 proviral DNA, transfected into human cells, has been shown in cell culture experiments to contain all the necessary information to generate infectious and cytopathic virus. Expression of HIV-1 proteins in activated lymphocytes leads to cell cycle arrest in G_2 and cell death within approximately 2 days. HIV-1 alone exerts direct cytopathic activity against $CD4^+$ lymphocytes in vitro and in vivo. Expression of only the HIV-1 envelope on lymphocytes is sufficient to induce fusion of cells with normal uninfected $CD4^+$ bystander cells, thus suggesting that syncytium formation mediated by gp120-CD4 interaction may contribute to cell loss in vivo. Other mechanisms of $CD4^+$ cell loss may also be operative. Cell-free HIV-1 gp120 envelope protein adsorbs to $CD4^+$ cells and may serve as an antigen for mediating antibody-dependent cell-mediated cytotoxicity and, when processed by antigen-presenting cells, be a target for direct T-cell cytotoxicity. In the CNS of infected individuals, in which the predominant cell types infected with HIV-1 are cells of the monocyte-macrophage lineage, additional mechanisms of cellular and organ dysfunction are involved. These mechanisms are believed to include the elaboration of cytotoxic factors from infected cells and interference with neurotropic factors leading to the clinically recognized AIDS dementia complex (Chapter 401).

Despite uncertainties regarding the precise mechanisms of $CD4^+$ lymphocyte destruction and immune dysfunction, the relationship between HIV-1 expression (as reflected by the plasma viral load) and disease outcome is clear. Outcome measures of death or AIDS-defining illness are related to plasma viral load at a set point beginning about 6 months after infection, and effective antiretroviral therapy that reduces viral load improves clinical outcome. It was the introduction of HAART that illuminated the extraordinary dynamics of ongoing viral replication and infected cell turnover in chronic HIV-1 infection that drive HIV-1 pathogenesis and made the case for earlier treatment intervention. Such therapy combined with a kinetic analysis of plasma virus decay curves revealed a lifespan of HIV-1 in plasma of less than 6 hours, a lifespan of activated, virus-producing $CD4^+$ lymphocytes in lymphoreticular tissue of less than 1.2 days, and a virus production rate as high as 10 billion HIV-1 particles per day released into the circulation. Steady-state plasma viral load measurements in patients directly reflect this extraordinary, incessant reiteration of the HIV-1 life cycle: cellular infection, viral production, cell death, de novo infection of cells by newly released virus, and so on. It is not surprising that clinical outcome as measured by time to diagnosis of AIDS or time to death from AIDS is significantly related to the steady-state plasma viral load, although other factors, including activated T-cell levels, are also prognostically important. With the advent of HAART, viral replication in vivo can be all but eliminated for prolonged periods lasting months and years. However, the toxicities of therapy are cumulative, and residual latently infected $CD4^+$ memory T lymphocytes (with a lifespan measured in years) remain an insurmountable obstacle to cure of infection.

Host immune and immunogenetic factors contribute to partial containment of HIV-1 replication in vivo. Neutralizing antibodies, antibody-dependent cell-mediated cytotoxicity, antibody-dependent complement-mediated cytotoxicity, MHC-restricted virus-specific cytotoxic T-lymphocyte-mediated cytotoxicity, and natural killer cell–mediated cytotoxicity all have activity against HIV-1 in vitro and may play a role in the downmodulation of viral replication. The most convincing evidence for a significant role of cytotoxic

T cells in viral containment comes from human studies in which virus escape mutants have been detected and from primate studies in which plasma viral loads increased dramatically after elimination of $CD8^+$ cells by the administration of monoclonal antibody. However, $CD8^+$, or killer, T cells lose their ability to combat HIV-1 infection over time despite their persistence in large numbers in the body of an infected patient. This "T-cell exhaustion" may be due to the enhanced activity of a T-cell receptor protein, programmed death 1 (PD-1), whose ligand (PD-L1) is located on antigen-presenting cells. This interaction diminishes the capacity of these T cells to be activated, most likely reflecting a normal pathway for dampening immune responses to prevent the consequences of uncontrolled cytotoxicity.

Genetic variability is a hallmark of HIV-1. Variability of the HIV-1 genome is characteristic of retroviruses because reverse transcription of viral RNA into proviral DNA and transcription of proviral DNA into genomic viral RNA are not subject to cellular proofreading mechanisms. The rate of nucleotide misincorporation by the viral reverse transcriptase is on the order of 10^{-4} per nucleotide per replication cycle. Because the HIV-1 genome is 10^4 nucleotides long, this high rate of nucleotide misincorporation means that virus strains that infect patients or that are isolated from patients must be described as a "quasispecies" composed of populations of viruses with highly related, but distinct viral genomes. Such variation in the HIV-1 genome leads to viral resistance to reverse transcriptase, protease, and entry inhibitors and to escape from the cellular and humoral arms of the adaptive immune system. Genetic variability can also lead to other biologic changes in the virus over time, including altered cellular tropism. Patients in whom predominant viral strains develop that use the CXCR4 coreceptor, for example, generally have an accelerated decline in $CD4^+$ cell counts and a less favorable clinical prognosis. On a population level, the variability in HIV-1 can be recognized in the phylogenetic relationships among circulating viral strains (Fig. 394-8). HIV-1 viruses are composed of four distinct groups: M, N, O, and P. Group M is responsible for more than 99% of infections worldwide. Groups N, O, and P are largely restricted to west-central Africa. It is believed that HIV-1 groups M, N, O, and P represent separate introductions of virus into the human population from African primates sometime early in the 20th century, most likely as a consequence of direct blood exposure. Group M viruses can be further subdivided by phylogeny into subtypes A through K. Although these phylogenetic distinctions allow molecular epidemiologic tracking of HIV-1 at a population level, there is little evidence to suggest that the various virus groups and subtypes differ in any clinically meaningful manner. All are pathogenic in humans.

HUMAN IMMUNODEFICIENCY VIRUS TYPE 2

After the discovery of HIV-1 as the cause of the global AIDS pandemic, patients in West Africa with AIDS-like symptoms were identified whose serum antibodies reacted not with HIV-1 but with a distantly related lentivirus isolated from captive rhesus macaques in U.S. primate centers and from wild-living sooty mangabey monkeys in West Africa. These latter two simian viruses were found to be genetically indistinguishable, and it thus became apparent that the new West African AIDS-like illness in humans had originated from zoonotic transmission of a virus from sooty mangabey monkeys (SIVsmm). The new human virus was designated HIV-2 to distinguish it from HIV-1. An extensive survey of African primate species for other related lentiviruses then led to the identification of phylogenetically distinct but related lentiviruses in approximately 40 African primate species (see Fig. 394-8).

Though originally restricted geographically to western Africa, HIV-2 has been identified in patients in Europe, the United States, South America, and India. HIV-2 is approximately 40 to 50% similar to HIV-1 in overall nucleotide sequence homology. There are two major differences in the genomic organization of HIV-1 and HIV-2. The *vpu* gene of HIV-1 is not present in HIV-2, and HIV-2 contains an additional gene, *vpx,* in its central region that is not present in HIV-1. Vpx is an 18-kD protein involved in nuclear transport of the HIV-2 preintegration complex in nondividing cells. Antigenically, HIV-2 and HIV-1 are distinct, with the greatest cross-reactivity in structural proteins and the least in envelope proteins. Licensed ELISA tests to detect HIV-1 infection include HIV-2 antigens as well.

Like HIV-1, HIV-2 selectively infects $CD4^+$ cells. Although HIV-2 has the potential to cause profound immunodeficiency and an AIDS syndrome indistinguishable from that caused by HIV-1, evidence suggests that it is less virulent than HIV-1 and causes disease in a smaller fraction of individuals and over a more protracted period. Moreover, transmissibility of HIV-2 is less than that of HIV-1, and as a consequence, the prevalence of HIV-2 is declining.

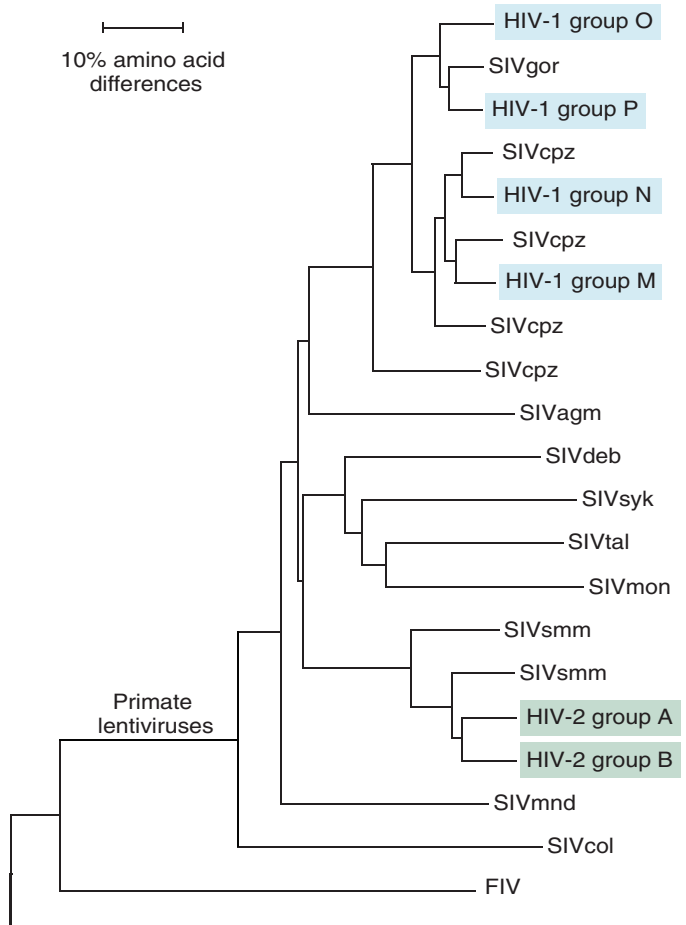

FIGURE 394-8. Phylogenetic relationships among HIV-1, HIV-2, and other lentiviruses inferred from pol protein sequences. Sequences from the HIV-1 pandemic group M ("main" group) and the less widely distributed HIV-1 group N cluster with chimpanzee viruses SIVcpz. HIV-1 groups O and P cluster with gorilla viruses SIVgor. HIV-2 groups A and B cluster with sooty mangabey viruses SIVsmm. More divergent primate lentiviruses (SIVagm = African green monkey; SIVdeb = De Brazza's monkey; SIVsyk = Sykes monkey; SIVtal = Talapoin monkey; SIVmon = Mona monkey; SIVmnd = Mandrill monkey; SIVcol = Colobus monkey) and lower vertebrate lentiviruses (FIV = feline immunodeficiency virus; EIAV = equine infectious anemia virus; BIV = bovine immunodeficiency virus; VISNA = visna virus from sheep) are also represented. Horizontal branch lengths are drawn to scale and can be used to infer the percent difference in pol protein sequences between the different viral lineages.

The discovery of two distinct types of human immunodeficiency viruses (HIV-1 and HIV-2) having closely related counterparts in African primates (SIVcpz in chimpanzees and SIVsmm in sooty mangabeys) suggested a cross-species (zoonotic) origin for HIV-1 and HIV-2. This conclusion has been confirmed by molecular epidemiologic studies that have unequivocally identified the chimpanzee subspecies *Pan troglodytes troglodytes* in west-central Africa as the source of the HIV-1 pandemic (HIV-1 group M) and the sooty mangabey *(Cercocebus atys)* in western Africa as the source of HIV-2. A recent intriguing finding is that the closest relatives to HIV-1 groups O and P are viruses that naturally infect gorillas, thus raising the possibility that this second great ape species represents a natural reservoir for HIV-1.

PREVENTION OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

CARLOS DEL RIO

Prevention of infection with human immunodeficiency virus (HIV) requires a thorough understanding of the epidemiology of HIV infection and knowledge of the science of human behavior. Only then can science-based prevention strategies be designed and implemented. HIV has been identified in virtually every body fluid and tissue, including blood, semen, vaginal secretions, saliva, tears, breast milk, cerebrospinal fluid, amniotic fluid, urine, and fluid obtained from bronchoalveolar lavage. In most instances, the virus resides in lymphocytes present within body fluids; therefore, any fluid that contains lymphocytes could theoretically be implicated in spread of the virus. Nonetheless, HIV transmission occurs primarily through exposure to blood, semen, vaginal secretions, and breast milk. HIV has also been transmitted through transplanted organs, including kidney, liver, heart, pancreas, and bone.

The advent of antiretroviral therapy has resulted in new challenges in the field of HIV prevention, and concern about reports of an upsurge in sexually transmitted infections in people known to be infected with HIV has resulted in guidelines for the incorporation of HIV prevention into the medical care of HIV-infected persons.

MODES OF HIV TRANSMISSION AND PREVENTION

Sexual Transmission

The primary mode of HIV transmission throughout the world is sexual contact. However, the geographic distribution of cases attributable to homosexual or heterosexual transmission varies markedly. In the United States, most sexually transmitted cases reported have occurred through male homosexual activity, and heterosexual transmission accounts for a smaller, albeit growing proportion of cases. In contrast, heterosexual transmission is the leading mode of transmission worldwide and is the primary mode of disease acquisition in Africa. Like other sexually transmitted diseases (STDs) (Chapter 293), HIV spreads bidirectionally and appears to be more efficiently transmitted from male to female. Sexual transmission of HIV is relatively inefficient, but behavioral and biologic factors influence the likelihood of HIV transmission in a given sexual encounter. In particular, the coexistence of an STD (most notably the presence of genital ulcerative disease) greatly increases the infectiousness as well as the susceptibility of the individual. In a study conducted in Rakai, Uganda, there were no cases of transmission between heterosexual serodiscordant couples when the infected partner had a serum HIV RNA level of less than 1500 copies/mL. The risk for acquisition of HIV per coital act has been estimated to be 5 per 10,000 for insertive unprotected penile-vaginal intercourse to 50 per 10,000 for receptive unprotected anal intercourse. However, the risk is not stable and varies depending on the stage of infection. It is highest in early HIV infection and in advanced infection, thus suggesting that the HIV viral load of the index partner is the strongest predictor of the risk for transmission, with risk being greater when the viral load is higher.

Prevention

Abstinence is the only absolute way of preventing sexual acquisition of HIV infection. Persons who have been engaged in a mutually monogamous relationship since the mid-1970s are at extremely low risk of acquiring disease; however, assurance that both partners have remained "faithful" is sometimes difficult to confirm. Strategies for the prevention of sexual transmission of HIV have focused on reducing unsafe sexual behavior, encouraging condom use, and treating STDs.

In situations in which a decision to engage in sexual activity has been made and the HIV status of the partner is positive, unknown, or in doubt, safe sexual practices ("safe sex") should be implemented (Table 395-1). Mutual masturbation is considered "safe," assuming that it is nontraumatic and not followed by the ingestion of body fluids such as semen or vaginal secretions.

TABLE 395-1 SAFE AND UNSAFE SEXUAL PRACTICES IN ORDER OF "SURENESS" OF SAFETY

SAFE
Abstinence
Monogamous relationship with a confirmed seronegative partner
Manual sex (manual masturbation)
Kissing
Intercourse with a latex condom
UNSAFE
Intercourse with a "natural skin" condom
Intercourse with a latex condom lubricated with petroleum-based products
Unprotected oral-genital sex
Unprotected vaginal intercourse
Unprotected anal intercourse

The probability of HIV transmission through saliva during oral-oral and oral-genital contact is extremely low but not zero. Condom use is the most effective means of preventing HIV infection in individuals who engage in oral, vaginal, or anal intercourse. Consistent use of latex condoms has been shown to be effective in preventing of HIV transmission at both an individual and population level. Multiple epidemiologic studies of heterosexual couples in which one partner is HIV positive and the other is HIV negative indicate that correct and consistent use of condoms can significantly reduce transmission of HIV and other STDs.

To be effective, however, the condom should be made of latex and must be used properly. Natural skin condoms should not be used because they do not prevent transmission of HIV. Petroleum-based lubricants enhance the likelihood of rupture of latex condoms and should be avoided. If needed, water-based lubricants such as K-Y jelly should be used.

Both partners should be knowledgeable about the correct use of condoms. Discussions regarding condom use should occur before the need arises, and ideally, condom placement should be practiced in advance. A new condom should be used for each act of intercourse, and each condom should be used only one time. The effectiveness of condoms in preventing heterosexual transmission of HIV has been estimated to be 87%, but it may be as low as 60% or as high as 96%. Many factors can affect the effectiveness of condoms in reducing the risk for transmission of HIV, such as condom breakage, leakage, and slippage. The effectiveness of condoms during anal intercourse is probably lower because the frequency of condom breakage and slippage may be considerably higher than during vaginal intercourse. Thus, although condom use during intercourse is considered "safer" sex, it is not absolutely safe.

Three randomized clinical trials have demonstrated a protective benefit of male circumcision, with the risk for acquisition of HIV infection through heterosexual intercourse decreasing by approximately 60%.[1-3] This benefit has not been confirmed for men who have sex with men.

Antiretroviral therapy may influence infectivity and the subsequent risk for transmission through sexual contact. Emerging data seem to suggest that the risk for transmission of HIV from a patient receiving highly active antiretroviral therapy (HAART) with a viral load below the limit of detection of the current assays (<50 copies/mL) is exceedingly low. However, even in the presence of suppression of HIV RNA in plasma, proviral DNA has been detected in the seminal cells of infected men and genital secretions of women. Thus, any protective effect of antiretrovirals on sexual transmission of HIV is not absolute, and current antiretroviral therapy does not render an individual completely noninfectious. Ongoing studies are also looking at the prospect of using antiretrovirals for prevention of HIV when administered prophylactically to HIV-uninfected, but at-risk individuals (pre-exposure prophylaxis). In a randomized trial, daily administration of co-formulated tenofovir plus emtricitabine to men who have sex with men decreased the risk of HIV infection by 44%.[4] Similarly, a tenofovir-containing vaginal gel led to a 39% reduction in the risk of HIV infection among women.[5] In addition, antiretrovirals can be given after exposure to prevent HIV acquisition (postexposure prophylaxis). In 2005 the Centers for Disease Control and Prevention (CDC) published guidelines for antiretroviral postexposure prophylaxis after sexual, injection drug use, and other nonoccupational exposures to HIV (see Suggested Readings). In these guidelines it is recommended that persons seeking care 72 hours or sooner after nonoccupational exposure to the blood, genital secretions, or other potentially infected body fluids of a person known to have HIV infection be offered a 28-day course of antiretroviral therapy. In

contrast, acyclovir was not shown to be effective for the prevention of HIV transmission.

HIV Transmission in Intravenous Drug Users

The primary mode of HIV transmission in intravenous drug users (IVDUs) is sharing of contaminated needles and syringes. Sharing of injection paraphernalia ("works") is commonplace among IVDUs and is reinforced by the cultural, economic, and legal environment in the IVDU community. The risk for transmission of HIV is highest in IVDUs who share needles and use drugs that are injected more often, such as cocaine. HIV is frequently transmitted from IVDUs to their sexual partners through heterosexual and homosexual activity, and ultimately, the virus may be transmitted to their children through perinatal exposure. Many cases of heterosexual transmission, including transmission from prostitutes, are associated with intravenous drug use.

Prevention

The primary mode of preventing HIV transmission in IVDUs is to stop the use of intravenous drugs in the first place. Education programs that are culturally sensitive and geared to young audiences have the best chance of preventing drug use. Access to treatment centers is the best approach for individuals already using intravenous drugs. However, approximately 80% of active drug users in the United States are not in substance abuse treatment because of either choice or the unavailability of treatment centers. For IVDUs who do not wish to seek treatment or who are unable to gain access to treatment, the most effective way to prevent HIV infection is to avoid sharing needles and works. Where works are in short supply, needles and syringes should be cleaned after each use, preferably with readily accessible virucidal cleansers such as chlorine bleach (diluted 1 : 10). Some communities have adopted programs that provide free needles and syringes for IVDUs, and there is strong evidence that these programs, when implemented properly, are effective in reducing HIV transmission and do not result in increased drug use among participants. As with sexual transmission, preliminary data from Vancouver, Canada, suggest that voluntary HIV testing followed by antiretroviral therapy may decrease transmission of HIV among drug users. The efficacy of many community programs is limited, however, by cultural barriers, including lack of trust, fear of prosecution, misconceptions regarding the prevalence of HIV infection within the local drug-using population, and the use of ineffective language in delivering anti-HIV messages by program staff. When combined with the relative paucity of intravenous drug treatment resources, HIV education among IVDUs that ultimately results in behavioral changes remains a challenging HIV prevention goal.

Transmission of HIV through Blood Products and Other Tissues

HIV has been transmitted through the transfusion of single-donor blood and blood products, including whole blood, fresh-frozen plasma, packed red blood cells, cryoprecipitate, clotting factors, and platelets. Confidential donor exclusion, as well as the institution of HIV antibody screening in 1985, followed by additional testing for antibodies to HIV-2 and p24 antigen in 1996 and nucleic acid testing in 2002, has reduced the risk for HIV infection through the transfusion of blood or blood products to approximately 1 in 2,135,000.

Transmission of HIV by liver, heart, kidney, pancreas, bone, and possibly skin transplantation has been reported. In contrast, relatively avascular tissues such as corneas and processed tissues have not been associated with transmission.

Prevention

The institution of HIV antibody testing of donated blood and blood products in 1985 has had the most dramatic effect on lowering the incidence of transfusion-related transmission. When combined with voluntary self-deferral and nucleic acid testing, the blood supply has become relatively free of HIV. The effectiveness of self-deferral is limited, however, by social pressures. Self-deferral programs are most effective when free, voluntary testing centers are readily available elsewhere in the community and when blood drives encourage potential donors to come to donation centers by themselves and not in groups. Heat inactivation processes for cryoprecipitate and clotting factor concentrates have virtually eliminated transmission of HIV through use of these products. Other products, such as immune globulin preparations and hepatitis B vaccines, are produced by methods that inactivate HIV and have never been associated with transmission of HIV.

Organ and tissue donors should be evaluated and serologically screened in a manner similar to blood donors. In addition, donations of semen and bone from a living donor may be quarantined until subsequent testing has definitively ruled out the possibility of delayed seroconversion in the donor.

TABLE 395-2 SUMMARY OF UNIVERSAL PRECAUTIONS

Specimens, including blood, blood products, and body fluids, obtained from all patients should be considered hazardous and potentially infected with transmissible agents.
Handwashing should be performed before and after patient contact, after removing gloves, and immediately if hands are grossly contaminated with blood.
Gloves should be worn when hands are likely to come in contact with blood or body fluids.
Gowns, protective eyewear, and masks should be worn when splashing, splattering, or aerosolization of blood or body fluids is likely to occur.
Sharp objects ("sharps") should be handled with great care and disposed of in impervious receptacles.
Needles should never be manipulated, bent, broken, or recapped.
Blood spills should be handled by initial absorption of the spill with disposable towels, cleaning the area with soap and water, followed by disinfecting the area with a 1:10 solution of household bleach.
Contaminated reusable equipment should be decontaminated by heat sterilization or, when heat is impractical, with a mycobactericidal cleanser.
Pocket masks or mechanical ventilation devices should be available in areas where cardiopulmonary resuscitation procedures are likely.
Health care workers with open lesions or weeping dermatitis should avoid direct patient contact and should not handle contaminated equipment.
Private rooms are not required for routine care; select circumstances, however, such as the presence of a concomitant transmissible opportunistic disease, may warrant respiratory, enteric, or contact isolation.

Transmission of HIV to Health Care Workers

Transmission of HIV in the health care delivery setting has been the subject of intense investigation throughout the course of the epidemic. The percentage of health care workers with AIDS who have "no identified risk" for HIV infection has remained low (<10%) and has not increased over time despite the dramatic increase in the number of AIDS cases and concomitant exposure of health care workers to patients with HIV disease. More importantly, detailed studies examining the risk associated with specific exposures, such as needlestick injuries and mucous membrane exposure, have demonstrated very low risk for acquisition of disease in the workplace. More than 3628 health care workers have been prospectively examined in carefully designed surveillance studies at 10 high-incidence medical centers. The overall risk for seroconversion after a percutaneous needlestick from a known HIV-positive source is 0.3% per exposure. A retrospective study conducted by the CDC found that the risk for transmission of HIV to health care workers is increased when the device causing the injury is visibly contaminated with blood, when the device has been used for insertion into a vein or artery, when the device causes a deep injury, or when the source patient dies within 2 months after the exposure. Although exposure of mucous membranes to HIV-positive blood has resulted in seroconversion in at least five health care workers, the risk for transmission is estimated to be 0.09%. No transmission has occurred after exposure to body fluids other than blood or fluids heavily contaminated with blood. Although the potential for HIV transmission to health care providers clearly exists, the risk for infection is inherently low and can be further minimized by following routine precautions to prevent transmission.

Prevention

In August 1987, the CDC published guidelines recommending that the principles of "universal precautions" be incorporated into health care settings to minimize exposure of health care workers to blood and body fluids that may be infected with blood-borne pathogens such as HIV. The guidelines, updated in June 2001 and in September 2005 (available at *http://www.aidsinfo.nih.gov/guidelines/*), remain the principal mode of HIV prevention among health care workers today. "Universal precautions" are based on the premise that any patient may be infected with blood-borne infectious agents and it may be difficult, if not impossible, to differentiate those with infection from their uninfected counterparts. All specimens containing blood or blood-tinged fluids obtained from *any* patient should be considered hazardous and handled as such (Table 395-2). The use of universal precautions helps minimize the transmission of many transmissible diseases in addition to HIV.

Handwashing is the cornerstone of universal precautions, as it is with all infection control practices. Gloves should be worn when spillage of blood or body fluids is likely. Gloves should *never* be washed and should be changed

TABLE 395-3 CDC RECOMMENDATIONS FOR POSTEXPOSURE PROPHYLAXIS (PEP) FOR PERCUTANEOUS AND MUCOUS MEMBRANE EXPOSURE TO HIV

EXPOSURE TYPE	HIV POSITIVE, CLASS 1*	HIV POSITIVE, CLASS 2†	HIV STATUS OR SOURCE UNKNOWN	HIV NEGATIVE
Percutaneous exposure: less severe (e.g., solid needlestick)	Recommend basic 2-drug PEP‡	Recommend expanded ≥3-drug PEP	No PEP, but should consider 2-drug PEP if source has risk factors for HIV	No PEP
Percutaneous exposure: more severe (e.g., large-bore hollow needlestick)	Recommend expanded 3-drug PEP‡	Recommend expanded ≥3-drug PEP	No PEP, but should consider 2-drug PEP if source has risk factors for HIV	No PEP
Mucous membrane exposure: small volume (e.g., few droplets)§	Consider basic 2-drug PEP	Recommend basic 2-drug PEP	Generally no PEP warranted	No PEP
Mucous membrane exposure: large volume (e.g., major blood splash or prolonged contact)	Recommend basic 2-drug PEP	Recommend expanded ≥3-drug PEP	Generally no PEP warranted, but should consider 2-drug PEP if source has risk factors for HIV	No PEP

*Asymptomatic patient with HIV infection, low viral load (<1500 copies/mL). If drug resistance is suspected, obtain expert consultation regarding the choice of antiretroviral regimen. PEP should not be delayed while awaiting consultation.
†Symptomatic patient with HIV, high viral load (>1500 copies/mL), AIDS, or acute seroconversion syndrome.
‡Basic PEP refers to dual-nucleoside therapy (e.g., zidovudine plus lamivudine); expanded PEP includes dual nucleosides combined with a potent protease inhibitor (such as lopinavir-ritonavir). PEP should be discontinued if the source patient is later determined to be HIV negative.
§Body fluids considered to be potentially infectious include blood, blood products, cerebrospinal fluid, amniotic fluid, menstrual discharge, inflammatory exudates, pleural fluid, peritoneal fluid, pericardial fluid, and any fluid visibly contaminated with blood. All other fluids are considered noninfectious.
Consider PEP indicates that PEP is optional and should be individualized for each situation based on the nature of the exposure and the opinion of the exposed health care worker and the treating clinician.
Adapted from Henderson D, Gerberding J. Occupational and nonoccupational exposure management. In: Dolin R, Masur H, Saag M, eds. *AIDS Therapy*, 2nd ed. New York, NY: Churchill-Livingstone; 2003:327-346; and Panlilo AL, Cardo DM, Grohskopf LA, et al. Updated U.S. Public Health Service guidelines for the management of occupational exposures to HIV and recommendations for postexposure prophylaxis. *MMWR Recomm Rep*. 2005;54(RR-9):1-17.

after soiling or after gross contamination, with handwashing immediately after the gloves are removed. Handwashing may be performed with soap and water or with the use of commercially available alcohol-based cleansing gels. Gowns, protective eyewear, and masks are not usually needed except in circumstances in which splattering or splashing of blood-containing fluids is likely to occur. Masks should always be worn in situations in which eyewear is required. Reusable equipment should be cleaned of visible organic material, placed in an impervious bag, and returned to central supply for decontamination. Although heat is the single best decontamination method, chemical agents that possess mycobactericidal activity are effective against hepatitis B virus and HIV and are acceptable alternatives when heat inactivation is impractical. Blood spills should be cleaned with appropriate caution. After putting on gloves and using other appropriate barrier precautions, excess blood should be removed with absorbent material (e.g., paper towels) and the area then cleaned with soap and water and disinfected with a 1 : 10 solution of sodium hypochlorite (i.e., household bleach) and water. Health care workers with denuded skin, open lesions, or active dermatitis should avoid direct patient contact and should not process contaminated equipment or materials. Private rooms are not generally required for patients known to be infected with HIV unless a concomitant opportunistic disease is present that requires respiratory, enteric, or contact isolation. Food service should be provided as usual on reusable dishware.

Because *all* blood and body fluids should be handled as though potentially hazardous and *all* patients presumed to be infected, it makes little sense to identify infected patients or their specimens with "blood and body fluid" labels. The use of such labels on known infected patients implies that unlabeled specimens or specimens from patients of unknown status are less hazardous and may be handled with less care. Studies have shown that more than half of specimens containing antibodies to hepatitis B surface antigen or HIV went to the laboratory unlabeled.

Handling of sharp instruments ("sharps") represents the greatest risk for transmission of HIV to health care workers. Although injuries from sharps cannot be eliminated entirely, the number of exposures can be reduced substantially by adhering to guidelines put forth in universal precautions. Before a sharp instrument is used, thought should be given to where the instrument will be disposed after use. Impervious containers should be readily available in all patient care areas and identified by the health care worker *before* the use of sharps. These containers should be checked frequently and should not be allowed to overfill. Used needles should never be manipulated, bent, broken, or recapped. Recapping of needles is the single most common activity that results in needlestick injuries. Technologic developments that do not rely on health care worker compliance such as self-sheathing needles have also been important in decreasing the risk for needlestick injury.

Even in the best of circumstances, accidental mucous membrane and percutaneous exposure to blood from HIV-infected patients does occur. Each institution and health care facility should adopt procedures for managing such exposure based on guidelines published by the CDC (see Suggested Readings). The essential elements of management after needlestick or mucous membrane exposure include defining the type of exposure, appropriately evaluating the donor (patient) and recipient (health care worker) at the time of exposure, and providing follow-up of the health care worker for at least 1 year after exposure.

Proposed definitions of the types of exposure are summarized in Table 395-3. Health care workers with any type of parenteral exposure should be counseled and evaluated for possible acquisition of HIV and should receive routine prophylaxis against hepatitis B virus. The source patient (donor) should be evaluated for HIV infection; if the donor's HIV status is unknown, the donor should be informed about the incident and encouraged to allow voluntary, confidential screening of blood for HIV and hepatitis B antibody. If a patient refuses or cannot give consent, that patient should be considered to be infected. In cases in which exposure to HIV is documented or presumed to have occurred, the health care worker should be evaluated serologically for the presence of HIV as soon as possible after the exposure (baseline) and again at 6 weeks, 12 weeks, 24 weeks, and 1 year after the exposure to determine whether transmission of HIV has occurred. The health care worker should report any acute illnesses that occur during the follow-up period, especially during the first 6 to 12 weeks after exposure. Exposed workers should follow the recommended guidelines for preventing HIV transmission, including using safe sexual practices; refraining from blood, semen, and organ donation; and avoiding breast-feeding. If the source patient is seronegative for HIV and has no clinical manifestations of HIV disease, no further follow-up of the exposed health care workers is necessary, although some workers prefer follow-up for their own peace of mind. Serologic testing should be made available to all health care workers who are concerned about potential on-the-job exposure.

For occupational exposure to HIV among health care workers, the CDC recommended the use of zidovudine for postexposure prophylaxis in 1990. This recommendation was further supported by a case-control study in which it was shown that the risk for HIV seroconversion after occupational exposure was decreased by approximately 81% with the use of zidovudine. Subsequent recommendations have incorporated the newer antiretroviral drugs, as well as risk stratification for the type of exposure, in the management of occupational exposure to HIV. The current CDC recommendations are different, depending on the type of exposure and the clinical status of the source patient. For less severe exposures (e.g., a solid needle or a superficial injury), two nucleosides/nucleotides are recommended (e.g., tenofovir and emtricitabine). For more severe exposures (e.g., large-bore hollow needle, deep puncture, visible blood in the device, or a needle used in a patient's artery or vein), a regimen that includes three antiretrovirals is recommended (e.g., zidovudine, lamivudine. and lopinavir/ritonavir). Postexposure prophylaxis should be initiated as soon as possible, preferably within hours of exposure, and administered for 4 weeks.

The U.S. Public Health Service has established a National Clinicians' Post-Exposure Prophylaxis Hotline (PEPline) to provide expert consultation

about the management of health care workers with potential HIV exposure. The PEPline can be accessed at 1-888-448-4911 or through the Internet at *http://www.ucsf.edu/hivcntr/Hotlines/PEPline*.

Transmission from Infected Health Care Workers to Their Patients

Transmission of HIV from a health care worker to patients has been documented in two instances: in a dental practice in Florida and from an orthopedic surgeon in France. The Florida cluster of cases was reported in July 1990. Six patients are believed to have acquired infection from the dentist based on the absence of other risk factors in the patients and the high degree of homology between the virus isolated from the dentist and those isolated from the patients. Although each patient underwent an invasive procedure in the dental office, the precise mode of transmission remains unknown. Aside from these two instances, investigation of 22,759 patients treated by 53 other HIV-infected health care workers has not identified other episodes of transmission of HIV from health care worker to patient.

PREVENTION INTERVENTIONS FOR HIV-POSITIVE INDIVIDUALS

Increases in high-risk sex practices and STDs among HIV-infected individuals have prompted considerable concern over increased risk for transmission of HIV infection and have led to initiatives to increase STD screening and risk reduction measures in the HIV-infected population. The available evidence indicates that risk reduction counseling is effective, and improved attention to risk reduction counseling in the HIV medical care setting is needed. CDC 2006 STD treatment guidelines recommend that all patients with newly diagnosed HIV infection undergo screening for gonorrhea, chlamydial infection, hepatitis B and C virus infection, and syphilis. Screening for curable STDs (gonorrhea, chlamydial infection, and syphilis) should be performed at least annually in sexually active patients. The CDC, Health Resources and Services Administration, National Institutes of Health, and Infectious Diseases Society of America have also published joint recommendations for incorporating HIV prevention into the HIV medical care setting. These guidelines reflect four basic priorities: (1) screening for risky behavior and STDs, (2) providing general and tailored risk reduction messages to patients, (3) when indicated, referring patients for additional risk reduction services and other services that may affect risk reduction (e.g., substance abuse treatment), and (4) ensuring that patients are provided with partner counseling and referral services.

VACCINE DEVELOPMENT

Education and modification of behavior are the only means of preventing transmission of HIV currently available. During the past years, significant effort has been directed toward the development of an effective vaccine against HIV. Although substantial progress has been achieved, several obstacles remain. Despite enormous advances in understanding the immunopathogenesis of HIV infection, the precise mechanism of protective immunity remains unknown. Without such knowledge, it is difficult to develop vaccines that ensure targeting the appropriate arm of the immune system that confers long-term protective immunity. Another obstacle is the lack of correlation of data from animal models to the potential protective effects of vaccines in humans. Although vaccine research has been continuing for many years, the results from phase IIB and phase III clinical trials have thus far been disappointing, and it was only recently that the results of a phase III efficacy trial showed a modest 30% protection. Over the next few years new trials with novel candidate HIV vaccines will be taking place around the world.

TREATMENT OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME

HENRY MASUR, LETHA HEALEY, AND COLLEEN HADIGAN

When the first cases of acquired immunodeficiency syndrome (AIDS) were recognized in the United States in the late 1970s, strategies for management of the patient focused on prompt diagnosis and treatment of opportunistic infections. Clinicians recognized that this strategy improved survival only modestly, but until the causative virus was discovered and antiretroviral drugs were developed, this was the best that could be accomplished. In that era, the median time to death after the first AIDS-defining opportunistic process was about 9 months, and very few patients survived more than 2 years after their initial opportunistic disease.

By the mid-1980s, clinicians began to recognize that chemoprophylaxis against the most common and severe opportunistic infections could be beneficial. Trimethoprim-sulfamethoxazole (TMP-SMX) to prevent *Pneumocystis jirovecii* pneumonia (PCP) and toxoplasmosis and rifabutin or clarithromycin or azithromycin to prevent *Mycobacterium avium* complex disease became the standard of care and provided a modest benefit in terms of prolonged AIDS-free survival.

With the licensing of zidovudine in 1987, treatment of the underlying retroviral cause of immunosuppression became possible for the first time. Monotherapy with nucleosides (zidovudine, didanosine, zalcitabine, stavudine, and lamivudine) in that era slowed the immunologic decline caused by human immunodeficiency virus (HIV), reduced the number of HIV-related opportunistic infections, and prolonged survival by months or a few years. The development of more potent antiretroviral agents in the mid-1990s and the opportunity to use drug combinations of agents with different mechanisms of action led to regimens that provided more potent and durable virologic and immunologic effects and better clinical benefit. These regimens were a major advance in the management of patients infected with HIV who had access to medical care and who were capable of taking and willing to take these drugs.

The development of multiple categories of antiretroviral drugs is one of the most gratifying testaments to the ability of biomedical science to recognize a new syndrome, to identify the novel causative agent, to develop active antiretroviral drugs, and to carry out rapidly clinical trials that demonstrated the benefits and toxicities of these new drug regimens. The evolution of this

therapy also demonstrated how difficult it is to operationalize therapy in the developed or the developing world and underlined the importance of collaboration among basic science, clinical medicine, and social science if benefit is to be delivered to the full range of infected persons.

Whereas some current combination antiretroviral therapies are available as single pills or as convenient once-daily or twice-daily regimens, taking these drugs has been no small challenge for patients in every social and economic stratum. For many patients who can tolerate and adhere to these regimens, the quality and duration of survival have improved dramatically. However, both patients and clinicians must recognize that all regimens have some adverse effects. As these drugs are evaluated in larger and larger populations, in diverse groups of patients, and during increasing periods, those toxicities are becoming better defined. Although some of these toxicities can be mitigated by screening for predisposing viral or host phenotypes or genotypes, toxicities can still be treatment limiting and occasionally fatal.

As patients who have access to care and who can adhere to treatment regimens have survived longer with potent, combination antiretroviral regimens, causes of morbidity and mortality have evolved. Liver, kidney, cardiovascular, and metabolic diseases have become more prominent causes of morbidity and mortality compared with AIDS-defining opportunistic infections and malignant neoplasms. Current evidence suggests that chronic inflammation, induced by persistent HIV replication, plays an important role in producing this end-organ damage, suggesting that the concept of "HIV-associated" processes needs to be reconsidered.

Guidelines from various professional societies around the world review current data and make recommendations.[1,2] When prospective, randomized, adequately powered clinical trials have been performed, recommendations can be made with more certainty than when data are derived from nonrandomized cohort studies or from other observational databases. Recommendations have evolved during the past 20 years as more drugs have been developed and as more studies have been published. For some populations, such as those with CD4 counts below 200 cells/mm^3, there is consensus that treatment is indicated because all clinical trials have supported such intervention. For patients with CD4 counts above 200 cells/mm^3, there is more debate because prospective randomized trials either have not been done or are not as convincing.[3]

A plausible argument can be made for starting antiretroviral therapy when HIV infection is first recognized, regardless of how high CD4$^+$ T-lymphocyte cell counts are, and continuing therapy for life,[3,4] even in developing countries.[5] Such an approach has the potential to provide clinical benefit to the individual patient, to reduce sexual transmission to HIV-uninfected partners, and to have long-term economic benefit. Proponents of this approach consider the benefits of early intervention to outweigh the known and as yet unknown toxicities of long-term antiretroviral therapy. A plausible argument can also be made that given this lack of knowledge of the long-term consequences of chronic antiretroviral therapy and uncertainty about the benefits at CD4$^+$ T-lymphocyte counts above 350 cells/mm^3, drug regimens should not be started until patients reach a CD4$^+$ T-lymphocyte cell threshold at which therapeutic intervention is documented by randomized prospective studies to be associated with improved survival and tolerable toxicity.

Until there are randomized, prospective trials assessing the long-term benefits of early versus late therapy for patients with CD4$^+$ T-lymphocyte cell counts above 350 cells/mm^3 and for patients with CD4$^+$ T-lymphocyte counts above 500 cells/mm^3, uncertainty about the best strategies will continue because published observational cohort studies are not as scientifically convincing as randomized prospective trials.

In 2011, there are more than two dozen licensed antiretroviral agents in six mechanistic categories. The challenge for clinicians and public health authorities in the developed and developing world is to define the best strategies to optimize clinical outcome in each geographic area and to determine how best to operationalize those strategies given the resources that are available.

Treatment of HIV and AIDS can be organized into four major areas: antiretroviral therapy, prophylaxis for opportunistic infections, treatment of HIV-related infections, and management of noninfectious complications related to HIV infection or antiretroviral therapy. These treatments need to be used with the goal of minimizing or preventing HIV-related complications and producing as little disruption as possible in the patient's lifestyle. With currently available therapies, patients with access to care who can adhere to recommended regimens can live for longer and longer times with very low risk for HIV-related complications.

ANTIRETROVIRAL THERAPY

Clinicians and patients must be clear about the goals of antiretroviral therapy. Current therapies cannot eradicate the virus because pools of latently infected CD4$^+$ T-lymphocyte cells are established soon after acute infection and have a long half-life. When HIV-infected patients have stopped antiretroviral therapy, even after many years of combination regimens and viral loads below 50 copies/mL, their viremia invariably rebounds to pretherapy levels within days or weeks of drug termination. Thus, a measured undetectable plasma viral RNA level does not indicate that the virus has been eliminated from the body. Virus may be present in plasma at levels below the detection capability of the laboratory assay and in body compartments other than blood, such as lymphoid tissue or the central nervous system (CNS). Provirus may be present in a variety of cells that can act as reservoirs for HIV, such as memory T cells. Thus, once therapy is initiated, treatment should be continued without interruption, except for serious toxicities or concurrent conditions that preclude oral therapy.

The realistic goal of antiretroviral therapy is to reduce HIV-associated morbidity and to prolong survival. The success of regimens is currently monitored by surrogate markers; reduction in the viral load in plasma to levels below 50 copies/mL and increase in CD4$^+$ T-lymphocyte cell counts to levels in the normal range are considered likely to correlate with long-term disease-free survival.

For most patients, antiretroviral therapy can reliably reduce viral loads to levels below 50 copies/mL when the circulating virus is susceptible to available drugs. When viral loads are reduced to low levels, further immune decline is usually prevented, and immune function is usually improved substantially both in the period immediately after initiation of therapy and then more slowly during subsequent months and years. Whereas most patients with effective virologic suppression will demonstrate improvement in CD4 count, a few patients will not show such benefit, for reasons that are usually not clear.

Patients may be identified during acute infection (within a few days to 6 months after acquisition of infection); or they may be identified when CD4 counts are relatively high, before they are highly susceptible to AIDS-defining complications (>200 cells/mm^3); or they may be identified when they meet the definition of AIDS (CD4 count < 200 cells/mm^3), when they are highly susceptible to AIDS-defining conditions. A case can be made for treating each of these groups of patients with antiretroviral therapy, although there is universal, long-standing agreement based on solid data only for the groups who have CD4 counts below 200/mm^3 or who have had an AIDS-defining condition.

As public health efforts expand testing for patients who engage in high-risk activities and offer "opt out" testing at medical and nonmedical venues, more and more patients are being identified early in the course of HIV infection, when they are asymptomatic and their CD4$^+$ T-lymphocyte cell counts are relatively high. Consensus about the benefits of treating such patients with antiretroviral therapy will develop as more prospective data are accumulated about patients' outcomes with such an approach.

A substantial number of patients still come to medical attention only when they develop opportunistic infections such as PCP, toxoplasmosis, cryptococcal meningitis, or cytomegalovirus (CMV) retinitis, times when their CD4$^+$ T-lymphocyte cell counts are characteristically low. These patients either have ignored the possibility of HIV infection due to high-risk activities or have not accessed early voluntary testing. There is virtually universal agreement that these patients should receive antiretroviral therapy, although there is debate as to the precise timing of such therapy in relation to treatment of their opportunistic process.

As antiretroviral regimens have become less toxic and more convenient, there is enhanced enthusiasm for initiation of antiretroviral therapy early as soon as HIV infection is recognized. However, antiretroviral therapy is not likely to be effective unless the patient is committed and able to adhere to the antiretroviral regimen and the clinician is skilled at managing the regimen. Studies have shown, as is intuitively obvious, that the likelihood of achieving a durable virologic response (i.e., plasma viral load below the limit of detection of the assay system used) depends on adherence. There is a direct relationship between missing doses of the antiretroviral therapy regimen and the development of HIV drug resistance. If a patient is not fully invested in taking the drugs regularly or is unable to adhere because of psychiatric, social, economic, or medical issues, initiation of antiretroviral therapy may not be indicated. Active drug and alcohol abuse, mental illness including depression, concomitant medical problems, poor clinician-patient relationship, history of

drug toxicity, and fear of drug toxicity can be strong predictors of poor adherence. Directly observed therapy can be a successful strategy to improve adherence, but this approach is not practical in most settings.

Successful management of HIV therapy also requires an experienced clinician. In the 1980s, there was considerable emphasis on "mainstreaming" HIV-infected patients (i.e., encouraging general internists, family practitioners, and a variety of other primary care providers to care for patients with HIV infection). Since that era, management has become dramatically more complex. Studies show that clinicians with experience (regardless of their formal training or certification) are more likely to follow current standards and guidelines than are clinicians with less experience. When it is feasible, patients should be managed by clinicians who have considerable experience and the capacity to keep abreast of the rapidly evolving field.

HIV has an extremely high mutation rate. Resistance to therapeutic agents can emerge rapidly, especially when viral loads are high, adherence is suboptimal, or resistance exists at baseline to one or more agents being used for therapy. Resistance to reverse transcriptase inhibitors is associated with amino acid substitutions in the reverse transcriptase enzyme. Resistance to protease inhibitors is associated with amino acid substitutions in the protease enzyme. Clinically important resistance can occasionally occur in untreated patients as a result of spontaneous mutations. For some drugs, a single mutation can produce clinically important resistance. For other drugs, significant resistance occurs only if several mutations take place. Most clinically important resistance, however, is a result of selective pressure from antiretroviral therapy. This resistance can be assessed by genotypic and phenotypic assays.

Resistance can emerge rapidly; for example, with nevirapine monotherapy, resistance can emerge within the first few days of treatment. Resistance can even emerge after a single dose of nevirapine because of the long half-life of this compound, which essentially exposes the patient to many days of monotherapy. Early experience with zidovudine showed that zidovudine resistance emerged during the initial 6 to 12 months of therapy. Current recommendations for therapy emphasize the use of combination regimens that include at least two and ideally three potent agents so that viral replication is maximally inhibited and mutation rates conferring resistance occur infrequently. This is best measured by consistent plasma HIV RNA (viral load) values below the level of detection with use of commercially available assays.

Thus, the goal of antiretroviral therapy is reduction of HIV infection–associated morbidity and mortality, best accomplished by maximal inhibition of HIV replication. Inhibition of viral replication should prevent HIV-related immunologic decline and promote immune reconstitution as well as bring about reduction in HIV infection–associated inflammation and its complications. Effective therapy should also reduce HIV transmission from the patient to sexual partners. Development of an effective program for individual patients requires considerable knowledge and commitment for both the health care provider and the patient.

When to Initiate Antiretroviral Therapy

All patients being considered for antiretroviral therapy need a careful evaluation by history, physical examination, and laboratory assessment including virologic and immunologic status (HIV viral load and $CD4^+$ T-lymphocyte cell count), clinical status (presence of AIDS-related opportunistic infections or tumors), and presence of comorbidities. The resistance pattern of the virus should be measured because drug resistance is increasingly prevalent in most communities. More assays are being developed to help predict the efficacy and safety of particular drugs, for instance, the presence of HLA B*5701 allele in the patient if abacavir therapy is being considered, and CCR5 coreceptor status of the virus if maraviroc is being considered.

Current guidelines for initiation of therapy are summarized in Tables 396-1 to 396-3. Patients with acute HIV infection (i.e., those in the process of seroconverting) and patients who have seroconverted in the previous 6 months should be considered for early therapy. About 40 to 90% of acutely infected patients experience symptomatic illnesses, and if the patient or health care provider considers the possibility that the symptoms might have been related to high-risk behavior, HIV infection can potentially be identified by serologic and virologic assays. In theory, early therapy should reduce the viral load in lymphoid tissue during the period before an effective host immune response is initiated and subsequently lead to lower viral loads and higher $CD4^+$ T-lymphocyte cell counts. The long-term clinical benefit of treating acute or early HIV infection has not been shown conclusively, however, and the potential benefits of treating acute HIV infection must be weighed against the disadvantages of toxicity, cost, and inconvenience. Many clinicians would offer at least 2 to 6 months of this therapy in an effort to reduce viral replication in lymphoid tissue and to produce a lower plasma HIV viral load. It is often difficult to stop such therapy when both the patient and the clinician witness the rapid fall in plasma viral load and the rebound in $CD4^+$ T-lymphocyte cell count. There is no consensus about the benefits of continuing such therapy lifelong.

TABLE 396-1 CONDITIONS FAVORING MORE RAPID INITIATION OF ANTIRETROVIRAL THERAPY

Pregnancy
AIDS-defining conditions
Acute opportunistic infections
Lower CD4 counts (e.g., <200 cells/mm^3)
Rapidly declining CD4 counts (e.g., >100 cells/mm^3 decrease per year)
Higher viral loads (e.g., >100,000 copies/mL)
HIV-associated nephropathy
Hepatitis B virus (HBV) coinfection when treatment for HBV is indicated

Modified from Panel on Antiretroviral Guidelines for Adults and Adolescents. Guidelines for the use of antiretroviral agents in HIV-1–infected adults and adolescents. Department of Health and Human Services. Jan. 10, 2011. http://www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf.

TABLE 396-2 WHEN TO INITIATE ANTIRETROVIRAL THERAPY IN TREATMENT-NAIVE PATIENTS

ART should be initiated in all patients with a history of an AIDS-defining illness or with a CD4 count of <350 cells/mm^3.
ART is also recommended for patients with CD4 counts between 350 and 500 cells/mm^3.
ART should also be initiated, regardless of CD4 count, in patients with the following conditions: HIVAN and HBV coinfection when treatment of HBV is indicated.
A combination ARV drug regimen is also recommended for pregnant women who do not meet criteria for treatment, with the goal to prevent perinatal transmission.
For patients with CD4 counts >500 cells/mm^3, 50% of the panel members favor starting ART; the other 50% of members view treatment as optional in this setting.
Patients initiating ART should be willing and able to commit to lifelong treatment and should understand the benefits and risks of therapy and the importance of adherence.
Patients may choose to postpone therapy, and providers, on a case-by-case basis, may elect to defer therapy based on clinical and/or psychosocial factors.

HIVAN = HIV-associated nephropathy.
Modified from Panel on Antiretroviral Guidelines for Adults and Adolescents. Guidelines for the use of antiretroviral agents in HIV-1–infected adults and adolescents. Department of Health and Human Services. Jan. 10, 2011. http://www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf.

For patients with chronic HIV infection, the decision to initiate therapy is influenced by data that demonstrate clinical benefits for patients with comparable clinical and laboratory findings. Observational studies provide some important clues about the risk for progression of patients to AIDS-defining complications. Figure 396-1 demonstrates the natural history of the interaction of HIV infection and $CD4^+$ T-lymphocyte cell count and their effect on the patient's outcome during a 3-year follow-up of untreated patients in the Multicenter AIDS Cohort Study. This figure indicates that the $CD4^+$ T-lymphocyte cell count and plasma HIV viral load influence the 3-year risk for progression to AIDS.

These data by themselves do not prove which patients would respond to therapy or which patients would respond best. These data do provide information about the magnitude of potential benefit in terms of AIDS-defining events. Contemporary understanding of the pathogenesis of HIV infection emphasizes the importance of non–AIDS-defining events that were not measured in this study and does not take into account potential benefits, such as reduced HIV transmission.

In terms of assessing patients in specific $CD4^+$ T-lymphocyte cell strata, chronically infected patients with $CD4^+$ T-lymphocyte cell counts of less than 200 cells/mm^3 are at high risk for development of opportunistic diseases, non–AIDS-defining morbidity, and death. These patients have been shown by clinical end point studies to benefit from antiretroviral therapy in terms of longer survival and delayed disease progression. For patients with $CD4^+$ T-lymphocyte cell counts of more than 200 cells/mm^3, there have been few prospective clinical end point studies to show conclusively when therapy should be initiated. A randomized trial in Haiti evaluated patients randomized to receive therapy when their $CD4^+$ T-lymphocyte cell counts were 200

TABLE 396-3 WHAT ANTIRETROVIRAL REGIMEN TO CHOOSE FOR INITIAL THERAPY

PREFERRED REGIMENS	COMMENTS
NNRTI-based regimen EFV/TDF/FTC	EFV should not be used during the first trimester of pregnancy or in women trying to conceive or not using effective and consistent contraception.
PI-based regimens (in alphabetical order) ATV/r + TDF/FTC DRV/r (once daily) + TDF/FTC	ATV/r should not be used in patients who require >20 mg omeprazole equivalent per day.
INSTI-based regimen RAL + TDF/FTC	
Preferred regimen for pregnant women LPV/r (twice daily) + ZDV/3TC	
ALTERNATIVE REGIMENS	**COMMENTS**
NNRTI-based regimens (in alphabetical order) EFV + (ABC or ZDV)/3TC NVP + ZDV/3TC	NVP Should not be used in patients with moderate to severe hepatic impairment (Child-Pugh B or C) Should not be used in women with pre-ARV CD4 >250 cells/mm^3 or men with pre-ARV CD4 >400 cells/mm^3
PI-based regimens (in alphabetical order) ATV/r + (ABC or ZDV)/3TC FPV/r (once or twice daily) + either [(ABC or ZDV)/3TC] or TDF/FTC LPV/r (once or twice daily) + either [(ABC or ZDV)/3TC] or TDF/FTC	ABC Should not be used in patients who test positive for HLA-B*5701 Use with caution in patients with high risk of cardiovascular disease or with pretreatment HIV RNA >100,000 copies/mL Once-daily LPV/r is not recommended in pregnant women.
ACCEPTABLE REGIMENS	
SQV/r + TDF/FTC NVP	

ABC = abacavir; ATV = atazanavir; 3TC = lamivudine; ddI = didanosine; DRV = darunavir; EFV = efavirenz; FPV = fosamprenavir; FTC = emtricitabine; LPV = lopinavir; NVP = nevirapine; RAL = raltegravir; r = low dose ritonavir; SQV = saquinavir; TDF = tenofovir; ZDV = zidovudine. The following combinations in the recommended list are available as fixed-dose combination formulations: ABC/3TC, EFV/TDF/FTC, LPV/r, TDF/FTC, and ZDV/3TC.
INSTI = integrase strand transfer inhibitor; NNRTI = non-nucleoside reverse transcriptase inhibitor; NRTI = nucleos(t)ide reverse transcriptase inhibitor; PI = protease inhibitor.
Modified from Panel on Antiretroviral Guidelines for Adults and Adolescents. Guidelines for the use of antiretroviral agents in HIV-1–infected adults and adolescents. Department of Health and Human Services. Jan. 10, 2011;1-161. http://www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf.

to 350 cells/mm^3 rather than less than 200 cells/mm^3; patients deferring therapy had a higher mortality and a higher rate of tuberculosis. Other observational studies support the benefit of treating these patients with antiretroviral therapy. Given the cumulative data, most clinicians are convinced that all patients with CD4$^+$ T-lymphocyte cell counts below 350 cells/mm^3 should be treated.

For patients with CD4$^+$ T-lymphocyte cell counts between 350 and 500 cells/mm^3, there are no randomized trials using current regimens to provide guidance about when to start therapy. Data from two cohort studies suggest that there is a declining risk of AIDS or death for subjects who start antiretroviral therapy at CD4$^+$ T-lymphocyte cell counts above 350 cells/mm^3 compared with those who start therapy later. Whereas these studies have relatively few end point events and cohort studies can be confounded by unrecognized biases, the weight of these trials plus the concern about end-organ damage from sustained HIV viral replication has led to recommendations in current guidelines that patients with CD4$^+$ T-lymphocyte cell counts of 350 to 500 cells/mm^3 should be treated.

For patients with CD4$^+$ T-lymphocyte cell counts above 500 cells/mm^3, there are also no prospective randomized trials. Data from one cohort study suggest that deferring therapy until patients' CD4$^+$ T-lymphocyte cell counts fall below 500 cells/mm^3 is associated with increased mortality. These data were not confirmed in another cohort study. Given the fact that no harm could be identified with earlier intervention, at least to date, some experts endorse treatment of all HIV-infected patients, regardless of CD4$^+$ T-lymphocyte cell count. Other experts, however, would not endorse treatment of patients with CD4$^+$ T-lymphocyte cell counts above 500 cells/mm^3.

In addition to CD4$^+$ T-lymphocyte cell count, there are a number of conditions that should favor rapid initiation of therapy. These include acute opportunistic infection, rapid decline in CD4$^+$ T-lymphocyte cell count (>100 cells/year), and high viral load (>100,000 copies/mL) (see Table 396-1).

Current guidelines also recommend that therapy be started regardless of CD4$^+$ T-lymphocyte cell counts in patients who have AIDS-defining diseases, HIV-associated nephropathy, pregnancy, or hepatitis B that will be treated (see Tables 396-1 and 396-2). Some experts would favor starting therapy in all patients with hepatitis C virus coinfection to slow progression of liver disease or cardiovascular disease. Whereas some antiretroviral agents may enhance the likelihood of cardiovascular disease, often by producing a more atherogenic lipid profile, some clinicians would favor initiation of therapy with drugs that are least likely to have cardiovascular effects. Uncontrolled HIV replication has also been associated with neurocognitive decline. Some studies have, additionally, shown neurocognitive improvement when antiretroviral therapy is initiated. Thus, there may be some neurocognitive advantage to initiation of antiretroviral therapy as either prevention of or therapy for the CNS process. There are also data indicating that age is related to treatment-related immune reconstitution. Therefore, initiation of therapy at an "early" age may be associated with more favorable immune response

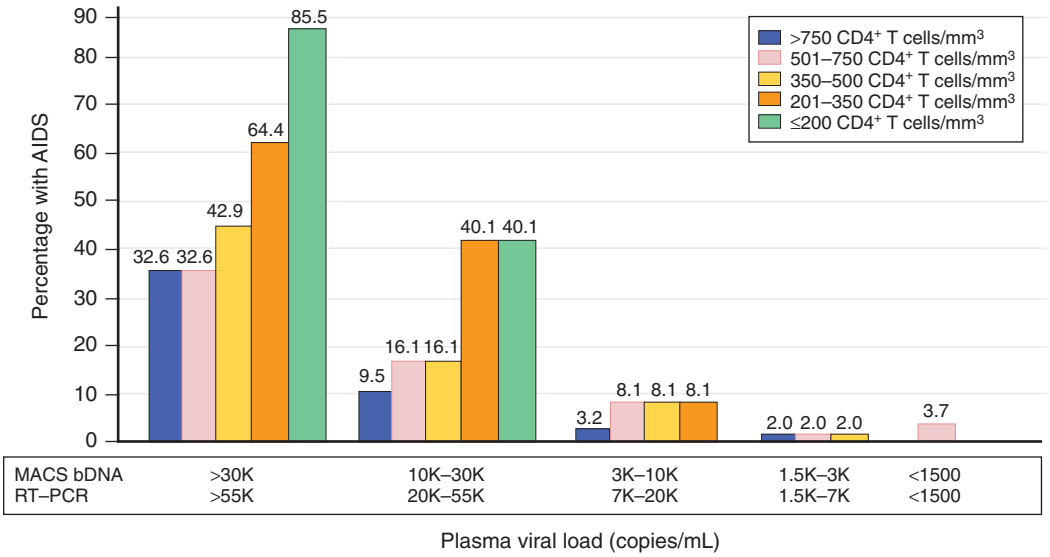

FIGURE 396-1. Likelihood for development of AIDS within 3 years. MACS = Multicenter AIDS Cohort Study; RT-PCR = reverse transcription–polymerase chain reaction.

than initiation of therapy "later," and age would thus be a factor in deciding when to initiate therapy.

HIV-infected patients with acute opportunistic infections deserve special focus in terms of when to start antiretroviral therapy. When antiretroviral therapy–naive patients develop an opportunistic infection, there has been considerable debate about the optimal time to initiate antiretroviral therapy. The advantages of immediate initiation of antiretroviral therapy include augmentation of immune response and reduction in likelihood that other HIV infection–associated complications will occur. There have been well-publicized cases, however, in which the augmented immune response has caused life-threatening exacerbations of the primary opportunistic process or of a previously unrecognized process (immune reconstitution syndrome [Chapter 402]), although the frequency of such cases has been unclear. A major argument against starting therapy has been that patients may not be dedicated to adherence when they leave the hospital. There are also concerns that toxicities of the antiretroviral agents may be confused with toxicities due to the drugs used to treat the acute infection and that drug interactions might interfere with the efficacy or safety of the drugs used to treat the opportunistic infection or the drugs used for antiretroviral therapy. Although it is difficult to generalize because not all opportunistic infections behave uniformly during immune reconstitution, retrospective and prospective studies do support the benefits of early versus deferred initiation of antiretroviral therapy. What the optimal time frame for initiation is (i.e., after how many days of opportunistic infection therapy or after how much clinical improvement) and what specific exceptions should be made for specific opportunistic infections and specific geographic areas remain to be determined.

What Antiretroviral Regimen to Initiate

More than 20 unique antiretroviral drugs in six mechanistic classes are currently approved by the U.S. Food and Drug Administration for sale in the United States. Some of these drugs are available in combination formulations of two or three agents in the United States (e.g., zidovudine plus lamivudine, lamivudine plus abacavir, zidovudine plus lamivudine plus abacavir, emtricitabine plus tenofovir, emtricitabine plus tenofovir plus efavirenz, and lopinavir plus ritonavir). Some of the drugs are also available in liquid formulations.

The regimen that is initiated should be potent enough to suppress the viral load below the level of assay detection for a prolonged period. This goal currently requires a combination regimen that optimally includes two nucleoside reverse transcriptase inhibitors plus either efavirenz or a ritonavir-boosted protease inhibitor.

Table 396-3 shows regimens recommended by the U.S. Department of Health and Human Services guidelines. Such recommendations are updated regularly as new data become available.

It is notable that the list of preferred regimens has changed during the past few years as more drugs have been developed and as trials have been published that demonstrated enhanced efficacy or improved safety with new regimens. Drugs that were popular a decade ago, such as nelfinavir, indinavir, didanosine, and stavudine, are seldom used currently, and zalcitabine and delavirdine are no longer marketed in the United States. Even drugs such as zidovudine, lamivudine, and lopinavir, which have benefited many patients, are no longer preferred agents, although they continue to have a role in certain patients. The field continues to evolve rapidly as trials are completed and analyzed.

Which regimen a health care provider should choose for an individual patient depends on a variety of factors. The regimen should be compatible with a patient's lifestyle. Adherence is more likely with regimens that can be taken once or twice per day than with those that are taken more often. Comorbid conditions such as cardiovascular disease, chemical dependency, liver disease, psychiatric disease, renal disease, and tuberculosis are relevant, as is pregnancy or the potential for the patient to become pregnant. For instance, ritonavir-based regimens that enhance atherogenic lipid profiles might be less desirable in patients with cardiovascular disease, and tenofovir might be less desirable in patients with renal or metabolic bone disease. Drug interactions are major considerations that should be carefully considered; ritonavir has multiple interactions that make it a poor choice in patients receiving rifampin for tuberculosis, for instance, or certain antiseizure regimens. Pregnancy would preclude the use of efavirenz during at least the first trimester because of evidence of this drug's teratogenicity. HLA B*5701 and coreceptor tropism results would influence the safety or efficacy of abacavir and maraviroc, respectively.

Drugs must be acceptable to the patient; if the patient cannot swallow certain sized pills, if the taste is unacceptable, or if the patient is convinced that the drugs will produce unacceptable toxicity, the patient is not likely to be adherent and to achieve the virologic results that would produce long disease-free survival.

Planned interruptions (structured or strategic treatment interruptions) of antiretroviral therapy have been considered by some patients and health care providers to reduce the lifestyle burden of taking medications, to reduce medication-related toxicity, to decrease cost, or to improve immune control of HIV infection. These approaches are no longer recommended because of adverse immunologic and clinical events after interruption of treatment.

Immune-based therapies have been investigated in an attempt to augment immunity against HIV-associated infections and tumors. Interleukin-2, given subcutaneously 5 days every 2 months for several cycles, has been shown to increase $CD4^+$ T-lymphocyte cell counts in a substantial fraction of patients. However, in long-term controlled, randomized studies, these increases in $CD4^+$ T-lymphocyte cell counts did not correlate with improved prognosis in conjunction with standard antiretroviral therapy.

Changing an Unsuccessful Antiretroviral Regimen

The initial antiretroviral therapy regimen may need to be changed because of toxicity, drug availability, cost, preference of the patient, lack of efficacy, or comorbid conditions. The initial decision to start therapy and considerations to change a regimen are important because of the limited number of antiretroviral agents that can be used in subsequent regimens. A long-term strategy needs to be developed for each patient, with a focus on what approach might be available if the current regimen fails. If the patient is unlikely to be adherent to the new regimen, the best long-term strategy may be a drug holiday, with deferral of a new regimen until the patient is ready to be adherent. Similarly, if a patient's viral load were detectable but less than 5000 copies/mL and the $CD4^+$ T-lymphocyte cell count were stable and greater than 200 to 350 cells/mm^3, it might be reasonable to consider maintaining the current regimen rather than switching to a more complex regimen that would expose the patient to other previously untried classes of drugs, although many experts would be reluctant to allow even that degree of viral replication to persist.

Lack of efficacy can be defined in a variety of ways: failure to meet the virologic milestones (in a treatment-naive patient, the HIV RNA level should be below 400 copies/mL by 24 weeks and below 50 copies/mL by 48 weeks after starting of therapy); $CD4^+$ T-lymphocyte cell counts that either fail to increase or decline; and clinical deterioration. Not all of these outcomes will benefit from a change in treatment. Changing the regimen may not alter the outcome of patients who have deteriorated clinically or failed to increase their $CD4^+$ T-lymphocyte cell count despite virologic suppression. Moreover, virologic suppression must be carefully defined. Small and intermittent virologic breakthroughs of 50 to 200 copies/mL are not necessarily indications to change the regimen, that is, they are not necessarily a harbinger of poor immunologic or clinical response.

In terms of their implications for therapy, each of these aspects of failure must be interpreted in context. A patient with a high initial viral load (e.g., >1 million copies/mL) whose viral loads are declining might be recommended to remain on a regimen if the viral load is still declining at 6 months. Similarly, a patient who started a regimen when the $CD4^+$ T-lymphocyte cell count was low and in whom an opportunistic infection developed at a time when the HIV viral load was below the level of assay detection might be unlikely to benefit from a different antiretroviral therapy regimen. Decisions about changing therapies must also consider what treatment options are feasible in view of previous drug exposure, viral resistance, drug tolerability, and drug availability.

There are many reasons for treatment to fail. Poor adherence of the patient is probably the most common cause, and clinicians may find it especially difficult to identify this factor. Altered drug pharmacokinetics resulting from abnormal absorption or metabolism of the drug may also be a factor. Drug interactions with licensed drugs or "alternative" medicines may be relevant. The patient may have acquired a drug-resistant virus on initial infection, or the patient's virus may have become resistant during therapy. These causes of regimen failure must be investigated carefully to maximize the likelihood that the next regimen will succeed.

After a regimen has failed, the new regimen should include at least two and ideally three agents proven to be currently active by the results of resistance testing obtained while the patient was taking the failing regimen. Both phenotypic and genotypic resistance assays can provide useful information if the assay is performed while the patient is receiving the failing regimen. There is no definitive guideline regarding which assay is more useful. Some agents (i.e., the nucleoside inhibitors lamivudine and emtricitabine) may confer

partial antiviral activity for other drugs (e.g., zidovudine) despite predicted drug resistance on genotypic and phenotypic testing. In general, adding a single new agent to a failing regimen is not recommended because of the risk for development of rapid resistance. Newer agents have demonstrated potent activity against virus shown to be resistant to multiple agents and can be considered for inclusion in a new regimen for a patient determined to have failed prior regimens. Tipranavir, darunavir, maraviroc, etravirine, enfuvirtide, and raltegravir are examples of newer agents that show promise in combination regimens for patients with highly resistant virus.

Potential Complications of Antiretroviral Regimens

Like any medication, each antiretroviral agent is associated with toxicities. Some are class specific, such as mitochondrial toxicities with nucleoside analogues or rash and CNS dysfunction with non-nucleoside reverse transcriptase inhibitors. Others are drug specific, such as urolithiasis and interstitial nephritis with indinavir, diarrhea with nelfinavir, or a characteristic hypersensitivity reaction with abacavir.

Certain toxicities deserve special mention. Chronic compensated hyperlactatemia occurs during treatment with nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs). As fewer patients are receiving ddI, d4T, or ddC, this complication is likely to become less common. In rare cases, decompensated lactic acidosis (Chapter 120) accompanied by hepatic steatosis and hepatomegaly can occur and is associated with high mortality. Risk factors for this potentially fatal syndrome include female gender, obesity, late-stage pregnancy or the postpartum period, and use of didanosine and stavudine. The lactic acidosis syndrome often presents as nonspecific gastrointestinal symptoms, including nausea, abdominal pain, vomiting, diarrhea, weakness, myalgias, paresthesias, and hepatomegaly. Hepatic enzymes may be normal or only slightly elevated. Elevated lactate levels may be associated with an anion gap, elevated creatine kinase and lactate dehydrogenase, and an enlarged fatty liver on computed tomography. Therapy consists of supportive measures and discontinuation of all nucleoside analogue drugs. Bicarbonate infusions and hemodialysis may be helpful. There is growing evidence that most patients can be successfully restarted on a new antiretroviral therapy regimen.

Mitochondrial dysfunction in association with NRTIs may be accompanied by several complications, including peripheral neuropathy, cardiomyopathy, myopathy, pancreatitis, and lipoatrophy. Although antiretroviral drug toxicity can contribute to these conditions, it is possible that HIV itself or opportunistic infections, or both, may also play an etiologic role. As tenofovir and emtricitabine are replacing nucleosides that have had greater risk of mitochondrial toxicity, it is expected that mitochondrial complications will become less frequent.

HIV infection and antiretroviral therapies have been associated with body fat abnormalities or lipodystrophy. Loss of peripheral fat or lipoatrophy, most notable in the face and extremities, as well as abnormal accumulation of abdominal and dorsocervical fat may be seen, each alone or in combination. Lipoatrophy has been most closely linked to NRTIs in association with mitochondrial toxicity. Although causality has not been established, lipid accumulation may be a consequence of protease inhibitors, more so than of NRTIs. It remains unknown whether fat distribution abnormalities represent various manifestations of a single pathologic process, but increasingly they seem to represent distinct entities or toxicities of antiretroviral therapy. When fat maldistribution occurs, it can be disfiguring and distressing. There is growing evidence that switching antiretroviral therapy to regimens with less mitochondrial toxicity (e.g., switching from stavudine-, didanosine-, or zidovudine-containing regimens to tenofovir or nucleoside-sparing regimens) can result in improvements in lipoatrophy during a period of many months or years. Strategies to restore physiologic growth hormone levels can reduce abdominal visceral fat and improve lipid profile, but these benefits do not appear to persist after withdrawal of growth hormone therapies.

Before the advent of antiretroviral therapy, HIV infection was associated with reduced high-density lipoprotein cholesterol and elevated triglyceride levels. Antiretroviral therapy, in particular most protease inhibitors, is associated with elevated total serum cholesterol and fasting triglyceride levels (Chapter 213). Evidence is mounting that these atherogenic lipid profiles are important factors contributing to the accelerated atherosclerosis manifested as increased risk for cardiovascular and cerebrovascular disease independent of other recognized risk factors, such as age, tobacco use, and family history. Most clinicians monitor and treat these lipid abnormalities as they would manage abnormalities in an HIV-uninfected patient. When lipid management programs (Chapter 213) are implemented, however, careful consideration must be given to drug interactions, especially interactions between protease inhibitors and β-hydroxy-β-methylglutaryl–coenzyme A reductase inhibitors (statins). Replacement of the offending agent with an alternative antiretroviral (using atazanavir or atazanavir-ritonavir in place of alternative protease inhibitors, or nevirapine instead of efavirenz) may be effective in reducing the lipid elevations.

Elevations in lipids alone do not appear to account for all the excess risk for cardiovascular disease observed in HIV-infected patients. Other factors, possibly related to drug toxicity or chronic inflammation, are probably implicated. For example, insulin resistance and diabetes are increasingly identified in HIV-infected patients, in particular in patients treated with antiretroviral therapy. As with hyperlipidemia, the use of certain protease inhibitors is linked to impaired insulin sensitivity. However, the risk of diabetes has been associated with some NRTIs. The combination of insulin resistance, hyperlipidemia, and abnormal fat distribution represents many of the components of metabolic syndrome (Chapter 237), a condition known to be associated with increased risk for diabetes and cardiovascular disease. Therefore, accelerated atherosclerosis may be due in part to this combination of factors as well as to traditional risk factors as indicated earlier.

Hepatotoxicity is an important complication of antiretroviral therapy. Serum transaminase elevations have been reported with all licensed protease inhibitors and non-NRTIs and have been associated with nucleoside agents as well. In some patients, the transaminase elevations are mild and unassociated with symptoms. In other cases, symptomatic hepatitis or associated hepatic steatosis with or without lactic acidosis requires cessation of the drug. Among the non-NRTIs, nevirapine has the greatest potential for causing symptomatic hepatitis. Manifestations often include fever, rash, and eosinophilia and usually occur within 12 weeks of initiation of therapy. Protease inhibitor–associated liver enzyme abnormalities can occur at any juncture during therapy. Ritonavir-containing regimens are particularly likely to be associated with hepatic toxicity. Hepatitis C, hepatitis B, alcohol, elevated baseline liver function test results, and other hepatotoxic drugs are risk factors for the development of protease inhibitor–associated liver toxicity. Preliminary results from the use of integrase inhibitors and CCR5 antagonists suggest that hepatotoxicity is relatively uncommon with these agents.

Decreased bone mineral density and avascular necrosis are complications of HIV infection that appear to be associated with HIV and antiretroviral therapy. Evidence indicates that fractures may be increased in patients with HIV infection. Avascular necrosis of the hips and other joints appears to be a separate and distinct syndrome, possibly associated with previous steroid use. There are few data to guide the development of preventive or therapeutic strategies for these bone disorders.

Nephrotoxicity is an emerging concern for patients receiving long-term tenofovir therapy.

PREVENTION OF HIV-ASSOCIATED OPPORTUNISTIC INFECTIONS

Patients with HIV infection and severe immunodeficiency develop characteristic and predictable opportunistic infections. Because the period of susceptibility to opportunistic infections in patients with HIV infection can be measured by $CD4^+$ T-lymphocyte cell counts, a strategy of chemoprophylaxis is particularly attractive for patients whose immunity has not been restored with antiretroviral therapy or immunomodulating therapies.

Chemoprophylaxis regimens are available for most treatable HIV-associated opportunistic infections. Table 396-4 and E-Table 396-1 summarize regimens that are recommended for primary and secondary chemoprophylaxis. Table 396-4 and E-Table 396-1 summarize the $CD4^+$ T-lymphocyte cell counts at which chemoprophylaxis should be implemented. Chemoprophylaxis for various pathogens should be started when the $CD4^+$ T-lymphocyte cell count declines to specific levels (depending on the pathogen) to prevent an initial episode of disease (primary prophylaxis). This prophylaxis can be stopped if immunity is augmented by antiretroviral therapy (Table 396-5) but must be restarted if immunity again declines below designated thresholds. Similarly, if an opportunistic infection develops, suppressive therapy (secondary prophylaxis) is indicated for life for most opportunistic infections unless immunity is restored by antiretroviral therapy.

The regimens recommended in Table 396-4 and E-Table 396-1 have been shown to prevent primary and subsequent occurrence of disease. The use of these regimens improves survival of the patient in several instances (PCP, *M. avium* complex disease, and *M. tuberculosis* infection) and decreases the patient's morbidity.

TABLE 396-4 PROPHYLAXIS TO PREVENT FIRST EPISODE OF HIV-RELATED OPPORTUNISTIC DISEASE

PATHOGEN	INDICATION	FIRST CHOICE	ALTERNATIVE
Pneumocystis pneumonia (PCP)	$CD4^+$ count <200 cells/mm^3 or oropharyngeal candidiasis $CD4^+$ <14% or history of AIDS-defining illness $CD4^+$ count >200 but <250 cells/mm^3 if monitoring $CD4^+$ count every 1-3 months is not possible	Trimethoprim-sulfamethoxazole (TMP-SMX) 1 double-strength PO daily; *or* 1 single-strength daily	TMP-SMX 1 double-strength PO 3 times weekly; *or* Dapsone 100 mg PO daily or 50 mg PO bid; *or* Dapsone 50 mg PO daily + pyrimethamine 50 mg PO weekly + leucovorin 25 mg PO weekly; *or* Aerosolized pentamidine 300 mg via Respirgard II nebulizer every month; *or* Atovaquone 1500 mg PO daily; *or* Atovaquone 1500 mg + pyrimethamine 25 mg + leucovorin 10 mg PO daily
Toxoplasma gondii encephalitis	*Toxoplasma* IgG–positive patients with $CD4^+$ count <100 cells/mm^3 Seronegative patients receiving PCP prophylaxis not active against toxoplasmosis should have *Toxoplasma* serology retested if $CD4^+$ count declines to <100 cells/mm^3. Prophylaxis should be initiated if seroconversion occurred.	TMP-SMX, 1 double-strength PO daily	TMP-SMX 1 double-strength PO 3 times weekly; *or* TMP-SMX 1 single-strength PO daily; Dapsone 50 mg PO daily + pyrimethamine 50 mg PO weekly + leucovorin 25 mg PO weekly; *or* (Dapsone 200 mg + pyrimethamine 75 mg + leucovorin 25 mg) PO weekly; (Atovaquone 1500 mg ± pyrimethamine 25 mg + leucovorin 10 mg) PO daily
Mycobacterium tuberculosis infection (TB) (treatment of latent TB infection or LTBI)	(+) diagnostic test for LTBI, no evidence of active TB, and no prior history of treatment for active or latent TB (–) diagnostic test for LTBI, but close contact with a person with infectious pulmonary TB and no evidence of active TB A history of untreated or inadequately treated healed TB (i.e., old fibrotic lesions) regardless of diagnostic tests for LTBI and no evidence of active TB	Isoniazid (INH) 300 mg PO daily or 900 mg PO twice weekly for 9 months—both plus pyridoxine 50 mg PO daily; *or* For persons exposed to drug-resistant TB, selection of drugs after consultation with public health authorities	Rifampin (RIF) 600 mg PO daily × 4 months; *or* Rifabutin (RFB) (dose adjusted based on concomitant antiretroviral therapy) × 4 months
Disseminated *Mycobacterium avium* complex (MAC) disease	$CD4^+$ count <50 cells/mm^3—after ruling out active MAC infection	Azithromycin 1200 mg PO once weekly; *or* Clarithromycin 500 mg PO bid; *or* Azithromycin 600 mg PO twice weekly	RFB 300 mg PO daily (dosage adjustment based on drug-drug interactions with antiretroviral therapy); rule out active TB before starting RFB
Streptococcus pneumoniae infection	$CD4^+$ count >200 cells/mm^3 and no receipt of pneumococcal vaccine in the past 5 years $CD4^+$ count <200 cells/mm^3—vaccination can be offered In patients who received polysaccharide pneumococcal vaccination (PPV) when $CD4^+$ count <200 cells/mm^3 but has increased to >200 cells/mm^3 in response to antiretroviral therapy	23-valent PPV 0.5 mL IM × 1 Revaccination every 5 years may be considered	
Influenza A and B virus infection	All HIV-infected patients	Inactivated influenza vaccine 0.5 mL IM annually	
Histoplasma capsulatum infection	$CD4^+$ count ≤150 cells/mm^3 and at high risk because of occupational exposure or live in a community with a hyperendemic rate of histoplasmosis (>10 cases/100 patient-years)	Itraconazole 200 mg PO daily	
Coccidioidomycosis	Positive IgM or IgG serologic test result in a patient from a disease-endemic area; and $CD4^+$ count <250 cells/mm^3	Fluconazole 400 mg PO daily Itraconazole 200 mg PO bid	
Varicella-zoster virus (VZV) infection	*Pre-exposure prevention:* Patients with $CD4^+$ count ≥200 cells/mm^3 who have not been vaccinated, have no history of varicella or herpes zoster, or who are seronegative for VZV Note: Routine VZV serologic testing in HIV-infected adults is not recommended. *Postexposure—close contact with a person who has active varicella or herpes zoster:* For susceptible patients (those who have no history of vaccination or of either condition, or are known to be VZV seronegative)	*Pre-exposure prevention:* Primary varicella vaccination (Varivax), 2 doses (0.5 mL SC) administered 3 months apart If vaccination results in disease because of vaccine virus, treatment with acyclovir is recommended. *Postexposure therapy:* Varicella-zoster immune globulin (VariZIG) 125 IU per 10 kg (maximum of 625 IU) IM, administered within 96 hours after exposure to a person with active varicella or herpes zoster Note: As of June 2007, VariZIG can be obtained only under a treatment IND (1-800-843-7477, FFF Enterprises).	VZV-susceptible household contacts of susceptible HIV-infected persons should be vaccinated to prevent potential transmission of VZV to their HIV-infected contacts. *Alternative postexposure therapy:* Postexposure varicella vaccine (Varivax) 0.5 mL SC × 2 doses, 3 months apart if $CD4^+$ count >200 cells/mm^3; *or* Preemptive acyclovir 800 mg PO 5×/day for 5 days These two alternatives have not been studied in the HIV population.

TABLE 396-4 PROPHYLAXIS TO PREVENT FIRST EPISODE OF HIV-RELATED OPPORTUNISTIC DISEASE—cont'd

PATHOGEN	INDICATION	FIRST CHOICE	ALTERNATIVE
Human papillomavirus (HPV) infection	Women aged 15-26 yr	HPV quadrivalent vaccine 0.5 mL IM months 0, 2, and 6	
Hepatitis A virus (HAV) infection	HAV-susceptible patients with chronic liver disease, or who are injection-drug users, or men who have sex with men. Certain specialists might delay vaccination until $CD4^+$ count >200 cells/mm^3.	Hepatitis A vaccine 1 mL IM × 2 doses—at 0 and 6-12 months IgG antibody response should be assessed 1 month after vaccination; nonresponders should be revaccinated	
Hepatitis B virus (HBV) infection	All HIV patients without evidence of prior exposure to HBV should be vaccinated with HBV vaccine, including patients with $CD4^+$ count <200 cells/mm^3. *Patients with isolated anti-HBc:* (consider screening for HBV DNA before vaccination to rule out occult chronic HBV infection)	Hepatitis B vaccine IM (Engerix-B 20 µg/mL or Recombivax HB 10 µg/mL) at 0, 1, and 6 months Anti-HBs should be obtained 1 month after completion of the vaccine series.	Some experts recommend vaccinating with 40-µg doses of either vaccine.
	Vaccine nonresponders: Defined as anti-HBs <10 IU/mL 1 month after a vaccination series For patients with low $CD4^+$ count at the time of first vaccination series, certain specialists might delay revaccination until after a sustained increase in $CD4^+$ count with antiretroviral therapy.	Revaccinate with a second vaccine series.	Some experts recommend revaccinating with 40-µg doses of either vaccine.

Modified From Centers for Disease Control and Prevention. Guidelines for Prevention and treatment of opportunistic infections in HIV-infected adults and adolescents. Recommendations from CDC, the National Institutes of Health, and the HIV Medicine Association of the Infectious Disease Society of America. *MMWR Morb Mortal Wkly Rep.* 2009;58(RR-4).

TABLE 396-5 CRITERIA FOR DISCONTINUING AND RESTARTING OPPORTUNISTIC INFECTION PROPHYLAXIS FOR ADULTS AND ADOLESCENTS WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION

OPPORTUNISTIC INFECTION	CRITERIA FOR DISCONTINUING PRIMARY PROPHYLAXIS	CRITERIA FOR RESTARTING PRIMARY PROPHYLAXIS	CRITERIA FOR DISCONTINUING SECONDARY PROPHYLAXIS/ CHRONIC MAINTENANCE THERAPY	CRITERIA FOR RESTARTING SECONDARY PROPHYLAXIS/ CHRONIC MAINTENANCE
Pneumocystis pneumonia (PCP)	$CD4^+$ count >200 cells/mm^3 for >3 months in response to antiretroviral therapy (ART)	$CD4^+$ count <200 cells/mm^3	$CD4^+$ count increased from <200 cells/mm^3 to >200 cells/mm^3 for ≥3 months in response to ART If PCP is diagnosed when $CD4^+$ count >200 cells/mm^3, prophylaxis should probably be continued for life regardless of $CD4^+$ count rise in response to ART.	$CD4^+$ count <200 cells/mm^3, or if PCP recurred at a $CD4^+$ count >200 cells/mm^3
Toxoplasma gondii encephalitis (TE)	$CD4^+$ count >200 cells/mm^3 for >3 months in response to ART	$CD4^+$ count <100-200 cells/mm^3	Successfully completed initial therapy, remain asymptomatic of signs and symptoms of TE, and $CD4^+$ count >200 cells/mm^3 for >6 months in response to ART	$CD4^+$ count <200 cells/mm^3
Microsporidiosis	Not applicable	Not applicable	No signs and symptoms of non-ocular microsporidiosis and $CD4^+$ count >200 cells/mm^3 for >6 months in response to ART Patients with ocular microsporidiosis should be on therapy indefinitely regardless of $CD4^+$ count.	No recommendation
Disseminated *Mycobacterium avium* complex (MAC) disease	$CD4^+$ count >100 cells/mm^3 for ≥3 months in response to ART	$CD4^+$ count <50 cells/mm^3	If fulfill the following criteria Completed ≥12 months therapy, and No signs and symptoms of MAC, and Have sustained (≥6 months) $CD4^+$ count >100 cells/mm^3 in response to ART	$CD4^+$ count <100 cells/mm^3
Bartonellosis	Not applicable	Not applicable	If fulfill the following criteria Received 3-4 months of treatment $CD4^+$ count >200 cells/mm^3 for ≥6 months Certain specialists would discontinue therapy only if *Bartonella* titers have also decreased by four-fold.	No recommendation
Mucosal candidiasis	Not applicable	Not applicable	If used, reasonable to discontinue when $CD4^+$ count >200 cells/mm^3	No recommendation

TABLE 396-5 CRITERIA FOR DISCONTINUING AND RESTARTING OPPORTUNISTIC INFECTION PROPHYLAXIS FOR ADULTS AND ADOLESCENTS WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION—cont'd

OPPORTUNISTIC INFECTION	CRITERIA FOR DISCONTINUING PRIMARY PROPHYLAXIS	CRITERIA FOR RESTARTING PRIMARY PROPHYLAXIS	CRITERIA FOR DISCONTINUING SECONDARY PROPHYLAXIS/ CHRONIC MAINTENANCE THERAPY	CRITERIA FOR RESTARTING SECONDARY PROPHYLAXIS/ CHRONIC MAINTENANCE
Cryptococcal meningitis	Not applicable	Not applicable	If fulfill the following criteria Completed course of initial therapy Remain asymptomatic of cryptococcosis $CD4^+$ count ≥200 cells/mm^3 for >6 months in response to ART Certain specialists would perform a lumbar puncture to determine if cerebrospinal fluid is culture and antigen negative before stopping therapy.	$CD4^+$ count <200 cells/mm^3
Histoplasma capsulatum infection	If used, $CD4^+$ count >150 cells/mm^3 for 6 months on ART	For patients at high risk for acquiring histoplasmosis, restart at $CD4^+$ count ≤150 cells/mm^3.	If fulfill the following criteria Received itraconazole for ≥1 year Negative blood cultures $CD4^+$ count >150 cells/mm^3 for ≥6 months in response to ART Serum *Histoplasma* antigen <2 units	$CD4^+$ count ≤150 cells/mm^3
Coccidioidomycosis	If used, $CD4^+$ count ≥250 cells/mm^3 for ≥6 months	If used, restart at $CD4^+$ count <250 cells/mm^3	**Only for patients with focal coccidioidal pneumonia**: Clinically responded to ≥12 months of antifungal therapy $CD4^+$ count >250 cells/mm^3 Receiving ART Suppressive therapy should be continued indefinitely, even with increase in $CD4^+$ count on ART for patients with diffuse pulmonary, disseminated, or meningeal diseases.	No recommendation
Cytomegalovirus retinitis	Not applicable	Not applicable	$CD4^+$ count >100 cells/mm^3 for >3-6 months in response to ART. Therapy should be discontinued only after consultation with an ophthalmologist, taking into account magnitude and duration of $CD4^+$ count increase, anatomic location of the lesions, vision in the contralateral eye, and the feasibility of regular ophthalmologic monitoring. Routine (every 3 months) ophthalmologic follow-up is recommended for early detection of relapse or immune restoration uveitis.	$CD4^+$ count <100 cells/mm^3
Isospora belli infection	Not applicable	Not applicable	Sustained increase in $CD4^+$ count to >200 cells/mm^3 for >6 months in response to ART and without evidence of *I. belli* infection	No recommendation

Modified From Centers for Disease Control and Prevention. Guidelines for Prevention and treatment of opportunistic infections in HIV-infected adults and adolescents. Recommendations from CDC, the National Institutes of Health, and the HIV Medicine Association of the Infectious Disease Society of America. *MMWR Morb Mortal Wkly Rep.* 2009;58(RR-4).

Several caveats about the use of chemoprophylaxis are worth noting, however. First, some opportunistic infections occur at $CD4^+$ T-lymphocyte cell counts above the recommended thresholds for starting chemoprophylaxis. Of PCP cases, 5 to 10% occur at $CD4^+$ T-lymphocyte cell counts above 200 cells/mm^3. In some instances, clinical information, such as the development of oral candidiasis or substantial weight loss, may provide additional clues that the patient is clinically more immunosuppressed than the laboratory parameters would predict. A high viral load (e.g., >100,000 copies/mL) may also suggest that earlier institution of chemoprophylaxis is warranted.

Second, patients may be unable to tolerate certain chemoprophylactic agents. TMP-SMX is often associated with intractable pruritus or rash and cannot be used by many patients with HIV infection.

Third, no chemoprophylactic regimen is completely effective. Some regimens fail because of poor adherence, but some fail because of poor host immune response or pathogen resistance. Prescribing a chemoprophylactic regimen does not guarantee that the targeted disease will never develop.

Finally, a decision to use a chemoprophylactic agent depends on the balance between its benefit in terms of efficacy and its disadvantages in terms of toxicity, inconvenience, drug interactions, ecologic effects (e.g., effects on producing resistance in targeted and bystander organisms), and cost. Some effective drugs, such as fluconazole for *Candida* and *Cryptococcus* and valganciclovir for CMV, are generally not recommended because their disadvantages were judged to outweigh their benefits.

TMP-SMX is the agent of choice for prevention of PCP. This drug should be started when the $CD4^+$ T-lymphocyte cell count decreases to 200 cells/mm^3, when oral candidiasis develops (regardless of the $CD4^+$ T-lymphocyte cell count), or when the patient has had a previous episode of PCP. Prophylaxis should be continued until the $CD4^+$ T-lymphocyte cell count increases to more than 200 cells/mm^3 for a period of at least 3 months as a result of antiretroviral therapy. Several regimens of TMP-SMX are effective; one double-strength tablet per day, one single-strength tablet per day, and one double-strength tablet three times weekly are all recommended. The daily regimens have proven to be moderately more effective than the three-times-per-week regimen. TMP-SMX can be associated with a variety of toxicities, including rash, fever, pruritus, nausea, vomiting, nephritis, hyperkalemia, and aseptic meningitis. For reasons that have not been well delineated, rash occurs at an unusually high frequency in HIV-infected patients who take TMP-SMX. Lower-dose regimens (e.g., a single-strength rather than a

double-strength tablet or three times weekly rather than daily) seem to be better tolerated. Gradual dose escalation may also improve the tolerability of TMP-SMX prophylaxis. Evidence of enzyme mutations in *Pneumocystis,* which probably confers sulfonamide resistance, raises the ominous possibility that this useful prophylactic and therapeutic agent may lose the impressive efficacy that it has enjoyed to date. The clinical relevance of this mutation is not certain.

Alternatives to TMP-SMX for the chemoprophylaxis of PCP include dapsone, dapsone-pyrimethamine, sulfadiazine-pyrimethamine, atovaquone, and aerosolized pentamidine. These regimens are not as effective as TMP-SMX in preventing PCP. In addition, TMP-SMX provides protection against toxoplasmosis, bacterial pneumonia, and enteric infections. None of the alternative regimens provides protection against all these pathogens, and all have associated toxicities.

Chemoprophylaxis against toxoplasmosis should be offered to patients with $CD4^+$ T-lymphocyte cell counts below 100 cells/mm^3 with positive *Toxoplasma* serology (IgG) and should be continued until the $CD4^+$ T-lymphocyte cell count increases to more than 200 cells/mm^3 for at least 3 months after treatment with antiretroviral therapy. The preferred treatment is TMP-SMX (one double-strength tablet daily), but alternative regimens are dapsone plus pyrimethamine (with or without folinic acid) daily or atovaquone administered daily. For patients intolerant of TMP-SMX therapy, recommended alternatives for both PCP and toxoplasmosis prophylaxis include dapsone plus pyrimethamine plus leucovorin or atovaquone with or without leucovorin plus pyrimethamine.

Clarithromycin or azithromycin is the chemoprophylactic agent of choice for *M. avium* complex disease in HIV-infected patients with $CD4^+$ T-lymphocyte cell counts below 50 cells/mm^3. Each of these agents is more effective than placebo, and each is preferred to rifabutin because rifabutin is less effective and associated with multiple complex drug interactions. Clarithromycin and azithromycin provide additional protection against bacterial pneumonia. These drugs are relatively well tolerated; however, the weekly regimen of azithromycin can be associated with considerable nausea. Azithromycin causes fewer drug interactions than clarithromycin does and is preferred by some clinicians when multiple other drugs metabolized by the cytochrome P-450 system are being used.

Prophylaxis for *M. tuberculosis* infection is an important aspect of the management of HIV-infected patients, especially in communities in which tuberculosis is common. Purified protein derivative (PPD) or interferon-γ release assay screening for all patients with newly diagnosed HIV infection and regular screening thereafter are important for identification of subclinically infected patients because HIV-infected individuals have such a high likelihood for reactivation of latent tuberculosis. Latently infected patients (defined as a PPD reaction ≥5 mm for this population of patients) or patients recently exposed to active tuberculosis should be treated with one of the recommended regimens, with careful attention to the toxicities and interactions of the regimen chosen.

Immunization is an important component of preventive therapy for HIV-infected patients. Vaccination with pneumococcal vaccine is generally recommended for all HIV-infected patients with $CD4^+$ T-lymphocyte cell count above 200 cells/mm^3 unless they have received a prior dose within the past 5 years, as clinical trials have demonstrated a lower risk of pneumococcal bacteremia after vaccination. Revaccination can be considered in patients who received initial immunization when their $CD4^+$ T-lymphocyte cell count was below 200 cells/mm^3 but have subsequently experienced a rise in $CD4^+$ T-lymphocyte cells to above 200 as a result of antiretroviral therapy. HIV-infected patients who do not have evidence of prior exposure to hepatitis A or B or have high risk of acquiring these infections or concomitant hepatitis C should be vaccinated with the appropriate hepatitis A or B vaccine. It is generally recommended that hepatitis B surface antibody testing be conducted 1 month after the third and final dose of the vaccine is administered to document an appropriate response. Some experts would recommend either repeating the entire hepatitis B vaccination series (single or double doses) or administering a single booster dose in patients who fail to develop hepatitis B surface antibody after completion of the usual three-dose series.

Primary chemoprophylaxis for fungal or herpesvirus diseases is not currently recommended in the United States. Primary prophylaxis may be effective, but the benefits are currently thought to be outweighed in the United States and western Europe by the effects of prophylaxis on pathogen resistance and by the toxicity and cost of drugs that target diseases that are usually readily treatable.

MANAGEMENT OF HIV-ASSOCIATED OPPORTUNISTIC INFECTIONS

Minimizing the effect of acute opportunistic infections on the lifestyle and survival of patients depends on prompt recognition of such diseases and expeditious institution of appropriate therapy. Patients and health care providers need to be familiar with the signs and symptoms of HIV-associated opportunistic infections and neoplasms so that diseases can be treated early, before manifestations are severe.

The manifestations of HIV-related opportunistic infections often differ from manifestations in other populations of patients. PCP, for instance, is usually much less acute in patients with HIV infection than in those receiving high-dose corticosteroids or antineoplastic chemotherapy. CMV disease is associated with retinitis or colitis most often in patients with HIV disease and only rarely with pneumonitis; in contrast, organ transplant recipients almost always manifest pneumonitis, and retinitis rarely develops. *M. avium* complex disease is common in patients with HIV infection but rare in patients with most other causes of immunosuppression. Similarly, therapy for various opportunistic infections may also differ. Certain drugs may not be tolerated as well by HIV-infected patients as by other immunosuppressed patients; the unusually high incidence of rash associated with TMP-SMX is a good example of this phenomenon. Drug regimens need to be continued for longer periods; unless the immune competence can be augmented substantially by antiretroviral therapy, the likelihood of recurrence for most HIV-associated infections is so high that lifelong suppressive or maintenance therapy (e.g., secondary prophylaxis) must be maintained. Drug-drug interactions are often important considerations, especially if patients are receiving antiretroviral therapy; rifampin, rifabutin, and fluconazole are examples of drugs that may have clinically important drug interactions with antiretroviral agents that could require dose modifications of either the antiretroviral agent or the drug used to treat the opportunistic infection. HIV-infected patients frequently have multiple concurrent opportunistic infections. Patients are often being treated or receiving prophylaxis for multiple infections simultaneously, thereby leading to potential additive toxicities or drug interactions. Finally, HIV-infected patients are administered multiple courses of antimicrobial agents, often for prolonged periods. These patients have the potential for the development of drug-resistant pathogens themselves, and they are exposed to drug-resistant pathogens in clinics, hospitals, and other group settings. They are at high risk for disease caused by drug-resistant pathogens, such as *M. tuberculosis, P. jirovecii, Streptococcus pneumoniae,* and *Candida.* All of these issues support the concept that optimal management should emphasize identification of the specific organism causing a specific syndrome because the range of possible etiologic agents is broad and the adverse consequences of unnecessary drugs are magnified in patients with HIV infection compared with many other populations.

The manifestations and treatment of specific opportunistic and nonopportunistic pathogens are discussed in other chapters. Additional chapters detail pulmonary disease (Chapter 398), skin disorders (Chapter 399), hematologic problems (Chapter 400), gastrointestinal disease (Chapter 397), and neurologic disorders (Chapter 401). Several additional syndromes deserve particular mention.

Fever is a common finding in patients with HIV infection. As noted earlier, patients with HIV infection are susceptible to a wide range of processes that can cause fever, including opportunistic and nonopportunistic infections, neoplasms, and drug toxicities. The $CD4^+$ T-lymphocyte cell count is a valuable indicator of the likelihood for opportunistic pathogens. At high $CD4^+$ T-lymphocyte cell counts (e.g., >300 cells/mm^3), the evaluation should probably be similar to that for HIV-uninfected healthy individuals, although patients do have enhanced predisposition to certain processes, notably pneumococcal disease, tuberculosis, and specific neoplasms such as lymphoma and Kaposi's sarcoma.

Fever and Wasting

Early in the HIV epidemic, patients often sought care for fever of several weeks' or months' duration, associated with considerable weight loss. This is less common in the era of effective antiretroviral therapy, but it still occurs in the United States and western Europe and is especially common in emerging countries. Many of the opportunistic infections associated with HIV infection can cause this syndrome. In some patients, chronic cough, chronic diarrhea, abnormal liver function test results, and other focal findings can lead to a directed evaluation. Some patients have no focal or localizing findings. In such patients, methodical evaluation is required with specific attention to the

possibility of pulmonary or disseminated tuberculosis, disseminated *M. avium* complex or fungal disease, lymphoma, and endocrine abnormalities such as adrenal insufficiency. Diagnostic evaluations that merit special consideration include mycobacterial blood cultures and serum cryptococcal and *Histoplasma* antigen testing. Extensive imaging procedures should be considered before empirical therapy is initiated.

Retinitis

Ocular manifestations are one of the most common complications of HIV infection. When patients have visual complaints, it is important to determine the anatomic location of the lesion (e.g., cornea, choroid, retina, cranial nerve, or occipital lobe) to establish the appropriate diagnostic and therapeutic approach.

CMV retinitis is the most common vision-threatening lesion. Patients almost universally have positive serum anti-CMV IgG levels and $CD4^+$ T-lymphocyte cell counts below 50 cells/mm^3. CMV causes irreversible necrosis of the retina, although treatment can restore some vision as edema of the retina subsides. Untreated, CMV retinitis causes progressive loss of vision in both eyes.

The diagnosis of CMV retinitis can be made during routine retinal examination (dilated indirect ophthalmoscopy) performed by an experienced ophthalmologist. Examination with a direct ophthalmoscope evaluates just 10% of the total retinal area; disease can be excluded only by a full funduscopic evaluation. Polymerase chain reaction (PCR) of the aqueous or vitreous can be used to document CMV, as can retinal biopsy, but such procedures are almost never used given the characteristic clinical findings. In patients with CMV retinitis, CMV disease may also be present or eventually develop in other anatomic locations, such as the colon or CNS.

The goal of therapy for CMV retinitis is to arrest progression of the disease, to prevent further spread of infection, and to preserve visual function. Therapy with one of the recommended modalities (e.g., oral valganciclovir, intravenous ganciclovir or foscarnet, or an ocular implant plus oral valganciclovir) is usually effective; maintenance therapy is necessary lifelong unless antiretroviral therapy leads to substantial immunologic reconstitution. If such reconstitution occurs, immune reconstitution syndrome (Chapter 402) can cause substantial ocular disease.

Other pathogens can also cause retinitis. Varicella-zoster virus (VZV) can cause acute retinal necrosis ($CD4^+$ T-lymphocyte cell count >50 cells/mm^3) or progressive outer retinal necrosis ($CD4^+$ T-lymphocyte cell count <50 cells/mm^3). The former often responds to acyclovir; the latter usually does not. Toxoplasmosis can likewise cause retinitis. Experienced ophthalmologists can generally distinguish *Toxoplasma* retinochoroiditis from CMV or VZV disease or from disease caused by herpes simplex virus, mycobacteria, or fungi. However, such diagnoses can be difficult to establish solely on the basis of funduscopic examination.

Central Nervous System Mass Lesions

In the era before antiretroviral therapy, focal brain lesions developed in 10% of patients, and the majority of such patients came to attention when their $CD4^+$ T-lymphocyte cell counts were less than 100 cells/mm^3. Initial signs and symptoms range from focal deficits (hemiparesis, aphasia, diplopia, seizures) to generalized weakness or altered mental status. Neuroimaging is important to confirm the clinical diagnosis of a mass lesion and to distinguish among general diagnostic categories (e.g., bacterial brain abscess, tumor, opportunistic infection, or progressive multifocal leukoencephalopathy). Neuroimaging does not, however, provide a microbiologic diagnosis. Positron emission tomography with radiolabeled glucose to measure tissue metabolism or single-photon emission computed tomography to measure metabolically linked cerebral blood flow appears to be useful to distinguish tumors (e.g., lymphoma) from infections (e.g., toxoplasmosis).

The majority of focal contrast-enhancing brain lesions in HIV-infected patients are caused by cerebral toxoplasmosis or primary CNS lymphoma. On magnetic resonance imaging or computed tomography, these lesions are often associated with surrounding edema. Although primary CNS lymphoma typically involves solitary brain lesions and cerebral toxoplasmosis is more commonly associated with multiple lesions, these diagnoses cannot be distinguished solely by neuroradiographic parameters.

Toxoplasmosis almost always is a result of reactivation of previously acquired disease in patients with $CD4^+$ T-lymphocyte cell counts below 50 cells/mm^3. Almost all patients have positive serum IgG antibodies against *Toxoplasma* if serology is performed by a reference laboratory. The diagnosis of toxoplasmosis is usually established by either response to empirical therapy or brain biopsy. Cerebrospinal fluid (CSF) examination is rarely helpful in establishing toxoplasmosis as the diagnosis.

The majority of patients with cerebral toxoplasmosis (65 to 90%) respond rapidly to standard two-drug anti-*Toxoplasma* therapy with pyrimethamine (200 mg orally once, followed by 50 to 75 mg daily) plus either sulfadiazine (1 to 1.5 g orally every 6 hours) or clindamycin (600 mg orally or intravenously every 6 hours). Clinical improvement is generally seen within several days, and neuroradiographic improvement occurs within 2 to 3 weeks. Failure to reach these milestones should suggest other diagnoses, such as lymphoma. Patients who respond should be treated for a minimum of 6 weeks after resolution or stabilization of the clinical and radiologic abnormalities. Lifelong suppressive therapy is necessary to prevent recurrences (80% recurred in the pre–antiretroviral therapy era without secondary prophylaxis), unless the patient responds immunologically to antiretroviral therapy.

Primary CNS lymphoma and generalized lymphoma both occur in patients who are usually naive to antiretroviral therapy and commonly have less than 100 cells/mm^3. Both diseases progress rapidly, with high morbidity and mortality. HIV-associated primary CNS lymphoma occurs most often in patients with $CD4^+$ T-lymphocyte cell counts of 100 cells/mm^3 or lower. Epstein-Barr viral DNA can be detected by PCR in the CSF of most but not all patients.

Most authorities recommend treatment of primary CNS lymphoma with combination chemotherapy. Lesions are highly responsive to irradiation, but radiation therapy is associated with considerable morbidity and a dismal long-term prognosis.

Progressive multifocal leukoencephalopathy involves white matter lesions and is generally clinically distinct from the manifestations of toxoplasmosis or lymphoma. Patients usually have subacute limb weakness, sensory loss, gait difficulties, cognitive impairment, or any combination of these findings. Magnetic resonance imaging shows predominantly white matter lesions with no contrast enhancement or mass effect. JC viral DNA can be demonstrated by PCR examination of CSF.

The prognosis for progressive multifocal leukoencephalopathy is dismal; most patients die within 4 months unless they have a robust immunologic response to antiretroviral therapy. No specific therapy has been shown to be effective for progressive multifocal leukoencephalopathy.

Diarrhea

Chronic diarrhea is a common problem for patients with HIV infection and $CD4^+$ T-lymphocyte cell counts below 100 to 200 cells/mm^3. Bacteria, viruses, and protozoa are often identified, as is *Clostridium difficile* colitis. See Chapter 397 for detailed information.

Parasitic and Fungal Infections Acquired Outside the United States

In patients who live in emerging countries or those who have traveled to such areas, latent infections may reactivate once they return to the United States or emigrate there. Leishmaniasis, Chagas' disease, and malaria are examples of parasitic diseases that can be more frequent and more severe in patients with HIV infection than in those without HIV infection. *Leishmania,* for example, can reactivate years after residence in an endemic area such as the Mediterranean basin or Brazil and be associated with fever, cytopenia, and hepatosplenomegaly. Therapy with liposomal amphotericin B or pentavalent antimony is effective, although treatment may have to be lifelong unless immunity is reconstituted with highly active antiretroviral therapy. Similarly, *Trypanosoma cruzi* can be manifested as a focal cerebral mass lesion or lesions years after residence in an endemic area; therapy with benznidazole or nifurtimox has been used successfully.

IMMUNE RECONSTITUTION SYNDROMES

When patients with HIV infection initiate antiretroviral therapy, their augmented immune response may produce clinical syndromes that seem to represent immunologic or inflammatory reactions rather than disease progression from proliferating organisms. Within days, weeks, or months after antiretroviral therapy is started and sometimes before the $CD4^+$ T-lymphocyte cell count has risen, patients may manifest such a syndrome. Immune reconstitution inflammatory syndrome in HIV/AIDS is discussed in detail in Chapter 402.

MANAGEMENT OF HIV-ASSOCIATED NEOPLASMS

Therapy for HIV-associated lymphoma, Kaposi's sarcoma, human papillomavirus (HPV)–associated neoplasms, and other malignant processes such

as primary effusion cell lymphoma and multicentric Castleman's disease is detailed in Chapter 400. Early in the HIV epidemic, there was little optimism that these neoplastic processes could be treated successfully. More recent studies, however, suggest that even for HIV-associated lymphoma, rates of remission and long-term survival are improving. In treatment of HIV-associated neoplasms, particular attention to antiretroviral regimens, drug toxicities, drug interactions, and chemoprophylaxis for HIV-associated opportunistic infections is required if the prognosis is to be optimized.

For patients treated successfully with long-term antiretroviral therapy, there is growing evidence that other tumors (i.e., tumors that are not AIDS defining) are becoming increasingly frequent. Lung cancer, hepatoma, Hodgkin's disease, and rectal carcinoma are examples of tumors that are occurring with increased frequency; the frequency may well be related both to HIV-related immunosuppression and to cofactors such as tobacco, alcohol, and HPV.

PREGNANCY AND HIV INFECTION

All pregnant women should be offered antiretroviral therapy after the first trimester to minimize transmission of virus to the fetus. The choice of drugs and the timing of initiation of therapy should be influenced by the pregnancy.

Most antiretroviral drugs are safe in pregnant women, to the extent they have been studied. Many of the toxicities caused by antiretroviral agents may contribute to parallel complications of pregnancy, however (e.g., the hyperglycemia associated with protease inhibitors may exacerbate pregnancy-associated diabetes). There are specific concerns about the use of nucleosides during pregnancy, especially stavudine and didanosine, in view of their association with hepatic steatosis and lactic acidosis in several pregnant women. There is also particular concern about the use of efavirenz because of teratogenicity studies in animals and anecdotal human reports. Antiretroviral regimens must be chosen carefully and monitored.

GASTROINTESTINAL MANIFESTATIONS OF HIV AND AIDS

TAMSIN A. KNOX AND CHRISTINE WANKE

INTRODUCTION

Gastrointestinal (GI) diseases were among the leading causes of morbidity and mortality in persons infected with human immunodeficiency virus (HIV) before the advent of highly active antiretroviral therapy (HAART) in 1996. Profound wasting and chronic diarrhea are still manifestations of end-stage acquired immunodeficiency syndrome (AIDS) in persons not receiving or resistant to antiretroviral therapy (ART). However, the common GI problems found today in persons receiving effective ART have shifted away from the enteric and hepatobiliary infections associated with low $CD4^+$ counts. Current GI issues are mainly due to side effects of antiretroviral medications, to nutritional and metabolic disorders associated with chronic HIV disease and therapy, and to liver disease from coinfection with hepatitis B virus (HBV) and hepatitis C virus (HCV).

The degree of immunosuppression, measured by the $CD4^+$ count, is the most important determinant of the likelihood of a GI illness, the type of disease, and its severity. The more profound the $CD4^+$ count suppression, the more likely a GI disease will be present.

The route of transmission of HIV may affect GI function; men who have sex with men (MSM) have higher rates of diarrhea and Kaposi's sarcoma than do those who acquired HIV from intravenous drug use (IVDU). Alcohol abuse or IVDU predisposes to liver disease. Regional exposures may increase the risk for disease. In resource-limited settings, lack of ART, increased exposure to pathogens, lack of clean water, poverty, and hunger are associated with increased prevalence and severity of GI disease. In contrast, nutritional and metabolic diseases such as obesity, metabolic syndrome, and fatty liver are seen in HIV populations with high caloric and fat intake and lack of exercise. All treatment recommendations are summarized in Table 397-1.

GASTROINTESTINAL DISEASES FOUND WITH $CD4^+$ COUNTS GREATER THAN 200 TO 500 CELLS/μL

The GI diseases discussed in this section may also be seen with more advanced HIV infection.

Side Effects of Medications

Adverse effects of medications are frequently seen in the course of HIV treatment and may be due to ART or to the medications required for treatment or prevention of opportunistic infections. Gastric effects, including nausea, vomiting, loss of appetite, and dyspepsia, may occur as a symptom of the HIV infection itself or in response to ART regimens, particularly those with zidovudine, didanosine, ritonavir, amprenavir, or indinavir. Hypersensitivity reactions to ART, such as occurs in persons with the HLA-B5701 haplotype who take abacavir, may also be manifested as fever, abdominal pain, and rash. Didanosine, stavudine, and pentamidine may cause acute pancreatitis.

Lactic acidosis is a life-threatening condition caused by mitochondrial toxicity from nucleoside reverse transcriptase inhibitors (NRTIs), particularly stavudine, didanosine, and zidovudine. Early discontinuation of NRTIs and supportive care are key to recovery, but the syndrome may be difficult to diagnose because of nonspecific findings such as fatigue, nausea, muscle aches, weight loss, or abdominal pain. Blood lactate levels are usually greater than 5 mmol/mL. Nevirapine has been associated with liver toxicity when used in individuals with $CD4^+$ counts higher than 400 cells/μL. One of the most common adverse effects of atazanavir has been asymptomatic elevation in indirect bilirubin. Some ART agents have also been associated with the development of significant elevations in triglycerides, to levels above 1000 mg/dL, and the development of pancreatitis.

Although all antiretrovirals have been associated with diarrhea, nelfinavir is particularly known to cause a secretory form of diarrhea. Intestinal

TABLE 397-1 RELATIONSHIP OF GASTROINTESTINAL DISEASES TO CD4⁺ COUNTS IN HIV-INFECTED PATIENTS

CD4⁺ COUNT	SYSTEM	SYMPTOMS AND DISEASES	TREATMENT
>200-500 cells/μL	Gastrointestinal and pancreas	**Nausea, vomiting, abdominal pain**	
		Side effects of medications	Changes in antiretroviral regimen
		Pancreatitis	Lipid-lowering agents, low-fat diet, no alcohol
		Diarrhea	Treat specific pathogens, if present
			Antimotility agents and fiber
	Nutritional and metabolic	**Lactic acidosis**	Stop nucleoside reverse transcriptase inhibitors
		Stavudine, didanosine, zidovudine	
		Changes in body shape	
		Obesity	Diet, exercise
		Metabolic syndrome	Diet, exercise, lipid-lowering agents, insulin-sensitizing agents
		Visceral obesity	hGH/GHRH in clinical trials
	Liver	**Liver function abnormalities, cirrhosis**	
		Chronic hepatitis with HCV	Pegylated interferon and ribavirin
		Chronic HBV infection	Nucleosides/tides for HBV infection
		Hepatotoxicity	Stop implicated antiretrovirals
	Oral lesions (≈400-500 cells/μL)	**Plaques, pain**	
		Oral thrush	Clotrimazole troche, nystatin, oral azoles
		Hairy leukoplakia	Acyclovir
		Herpes simplex-1	Acyclovir, famciclovir, valacyclovir
		Idiopathic ulcers	Corticosteroids, thalidomide (men)
		Gingivitis	Topical chlorhexidine, oral metronidazole
		Kaposi's sarcoma	Radiation, intralesional injection, systemic chemotherapy
	Anorectal lesions	**Anorectal pain, mass, discharge, tenesmus**	
		Anal fissure, fistula, or perirectal abscess	Local care, surgery
		Foreign body in rectum	Endoscopic or surgical removal
		Sexually transmitted disease	
		Gonorrhea, *Chlamydia trachomatis*, syphilis	Specific antibiotic therapy
		Herpes simplex infection	Acyclovir, famciclovir, valacyclovir
		Condyloma	Podophyllin, surgical excision, or ablation
		Anal cancer	Surgery, chemoradiation therapy
<200 cells/μL	Esophagus	**Dysphagia, odynophagia**	
	<200 cells/μL	*Candida*	Fluconazole, itraconazole, (voriconazole)
	<50 cells/μL	CMV	Ganciclovir
		Idiopathic ulcers	Oral corticosteroids, thalidomide (men)
		HSV	Acyclovir, famciclovir, valaciclovir
<100 cells/μL	Intestine	**Diarrhea**	
		Bacterial, viral, or protozoal infection	Treat specific pathogens
		AIDS enteropathy	Antimotility agents, nutritional support, ART
		Abdominal pain, fever	
		CMV	Treat specific pathogens
		Mycobacterium tuberculosis, MAC, *Histoplasma Cryptosporidium*	Surgery if perforation or dead bowel
	Malignancy	**GI bleeding, weight loss, or abdominal pain**	
		Kaposi's sarcoma	As above
		Lymphoma	Systemic chemotherapy
<50 cells/μL	Wasting	**Weight loss**	
		Increased metabolic demands (infection, HIV)	Treat HIV and underlying infections
		Decreased oral intake	Appetite stimulants
		Malabsorption	Anabolic steroids, hGH
	Hepatobiliary	**Hepatomegaly, elevated liver function test results**	
		Opportunistic infections—MAC, fungal	Consider liver biopsy
		Lymphoma	
		Jaundice, RUQ pain, elevated liver function test results	
		AIDS cholangiopathy	ERCP and sphincterotomy
		Acalculous cholecystitis	Laparoscopic cholecystectomy

AIDS = acquired immunodeficiency syndrome; ART = antiretroviral therapy; CMV = cytomegalovirus; ERCP = endoscopic retrograde cholangiopancreatography; GHRH = growth hormone–releasing hormone; GI = gastrointestinal; HBV = hepatitis B virus; HCV = hepatitis C virus; hGH = human growth hormone; HIV = human immunodeficiency syndrome; HSV = herpes simplex virus; MAC = *Mycobacterium avium* complex; RUQ = right upper quadrant.

pathogens should be sought in stool examinations despite a normal CD4⁺ count or low HIV load.

Nutritional and Metabolic Disorders

With the advent of effective ART and the conversion of HIV to a chronic, manageable disease, overnutrition and obesity have become frequent complications of HIV infection. Lifestyle factors and poor dietary choices may help promote the development of overweight/obesity, but some weight gain and increases in visceral fat may be related to the use of specific ART agents. HIV-associated lipodystrophy syndrome, which was recognized after the introduction of effective triple ART regimens, is a complex of four distinct components: visceral fat accumulation, subcutaneous fat atrophy, atherogenic lipid profiles, and glucose intolerance. The pathogenesis remains unclear, but nutritional intake probably contributes to all components except fat atrophy. Chronic inflammation caused by long-term HIV infection and selected antiretrovirals has been implicated as well, particularly the protease inhibitors. Host factors (genetics) also probably play a role in producing these syndromes. The co-occurrence of visceral fat accumulation, atherogenic lipid profiles, and glucose intolerance defines metabolic syndrome, diagnosis of which requires three of the following factors: high triglyceride levels, low high-density lipoprotein levels, hypertension, elevated waist circumference, and glucose intolerance. The prevalence of metabolic syndrome has increased dramatically in HIV-infected individuals, and there is concern that it may contribute to the increased risk for cardiovascular disease in persons infected with HIV.

Liver Disease

Liver disease is now the second leading cause of death in those with HIV infection because of the prevalence of coinfection with chronic viral hepatitis (Chapter 151). Coinfection with HCV is present in approximately 25%, depending on the HIV transmission category: 50 to 90% of IVDUs and hemophiliacs, 10 to 20% of heterosexuals, and 5 to 10% of MSM. Chronic HBV infection, defined by the presence of hepatitis B surface antigen (HBsAg), is found in approximately 10% of persons with HIV, and some have more than one viral coinfection. Hepatic fibrosis progresses more rapidly in HIV-infected individuals and leads to cirrhosis, decompensated liver disease, or hepatic failure (Chapter 157). This may be further accelerated by alcohol use, steatosis, or fatty liver disease and by hepatotoxicity from ART. Coinfection with HCV or HBV increases the risk for death by four- to six-fold over HIV infection alone. Mortality from liver disease increases as $CD4^+$ cells decline, more markedly with $CD4^+$ counts lower than 100 cells/μL. Early diagnosis and treatment of HCV and HBV may arrest or slow the progression of hepatic fibrosis and reduce the hepatotoxicity associated with antiretroviral treatment.

All persons with HIV infection should be screened for coinfection with HBV and HCV. A positive serologic test for HBsAg indicates chronic HBV infection and should be followed by tests for HBV DNA and hepatitis B e antigen. Those without chronic HBV infection and with no protective antibody to HBV surface antigen (negative anti-HBs) should be vaccinated against HBV. If treatment of hepatitis B is to be initiated in the absence of ART, a dual regimen of telbivudine and adefovir is appropriate because these agents will not select for HIV resistance. A positive test for HCV antibody should prompt testing for HCV RNA, which determines whether chronic HCV infection is present. Noninvasive markers of hepatic fibrosis, serum biomarkers, and hepatic elastography (to measure hepatic stiffness) are being developed to replace liver biopsy. The prevalence of hepatocellular carcinoma (HCC) (Chapter 202) is increased in those with HIV coinfection; it is found at a younger age and is more aggressive in HIV-infected patients. Regular 6-month screening for HCC by serum α-fetoprotein levels and ultrasound imaging of the liver in persons with cirrhosis may help identify lesions earlier.

Randomized clinical trials have shown that anti-HCV therapy can induce a sustained virologic response (SVR), that is, undetectable levels of HCV RNA measured 6 months after the end of treatment. However, SVR rates are approximately 60 to 80% of those achieved in persons with HCV monoinfection. Pegylated interferon alfa given for 48 weeks with ribavirin is associated with significant side effects, including anemia, bone marrow suppression, weight loss, flulike symptoms, and depression. To avoid drug interactions, neither didanosine (lactic acidosis) nor zidovudine (anemia) should be given with ribavirin.

Hepatotoxicity from ART occurs in up to 12% of patients started on a new ART regimen. Risk factors for hepatotoxicity include chronic HCV or HBV infection, female sex, and the use of ritonavir or nevirapine in the regimen. Effective ART has been associated with reduced hepatic inflammation, less progression of hepatic fibrosis, and decreased mortality from liver disease.

Oral Lesions

New oral lesions should raise suspicion for HIV disease. The lesions may be unsightly but asymptomatic or cause discomfort and difficulty eating. Thrush appears as white plaques, usually on the buccal mucosa. Oral hairy leukoplakia, which is associated with Epstein-Barr virus, consists of raised shaggy, dirty white patches on the sides of the tongue but is not premalignant.

Oral ulcers are caused by infection with herpes simplex virus type 1 (HSV-1) and tend to be more severe and persistent than ulcers in immunocompetent hosts. Idiopathic ulcers, similar to those found in the esophagus, are found in patients with advanced HIV disease. These deep, necrotic ulcers are most commonly found on the buccal and pharyngeal mucosa. They respond to systemic corticosteroids or thalidomide. Gingivitis and periodontal disease appear as linear or diffuse erythema of the gums. With declining $CD4^+$ counts, it may progress to necrotizing gingivitis with pain and hemorrhage. There is increasing concern that these bacterial diseases may contribute to systemic inflammation and more rapid progression of HIV disease.

Kaposi's sarcoma (Chapter 400), a multicentric malignancy of endothelial cells caused by human herpesvirus 8 infection, is more common in MSM with HIV infection in the United States but is also prevalent in Africa. Oral lesions are found in half of persons with other sites of Kaposi's sarcoma and appear on the palate or gums as raised reddish or bluish nodules.

Anorectal Diseases

Anorectal disorders in HIV-infected individuals are more prevalent in MSM. Anal fissures, fistulas, abscesses, and foreign objects may be found on anal examination as a consequence of receptive anal intercourse or manipulation. Proctitis caused by gonorrhea *(Neisseria gonorrhoeae)* (Chapter 307) is characterized by mucopurulent discharge from the anus, tenesmus, and bleeding. *Chlamydia trachomatis* infection (Chapter 326) also causes proctitis and inguinal lymphadenopathy. Cultures and swabs of the discharge are diagnostic.

Primary syphilis (Chapter 327) is manifested as an anal chancre or ulcer that may be tender because of its location. Secondary syphilis appears 2 to 6 months later as condylomata lata, or warty masses around the anus. Perianal, shallow painful ulcers caused by HSV (Chapter 382) evolve as the initial vesicles rupture. These ulcerations may be cultured for HSV, or scrapings will show viral inclusions. Patients may have concurrent herpes proctitis.

Anal condylomata or warts are caused by infection with human papillomavirus (HPV) (Chapter 381) and appear as white, pink, or gray painless lesions around the anus and in the anal canal. HPV types 16 and 18 are associated with the development of dysplasia and squamous cell cancer of the anus, which is manifested as bleeding or a mass. The prevalence of anal dysplasia may be as high as 50% in HIV-positive MSM, and the incidence of anal cancer has increased more than six-fold in the past 2 decades. Screening via anal cytology is being pioneered for high-risk individuals.

GASTROINTESTINAL DISEASES MORE COMMONLY SEEN WITH $CD4^+$ COUNTS LESS THAN 200 CELLS/μL

GI illness increases in prevalence and severity as the $CD4^+$ count declines. With marked immunosuppression, there may be multiple concurrent infections. Although specific antimicrobial therapy may control the infection, HAART is the most effective therapy.

Esophageal Diseases

Candidal esophagitis (Chapter 346) is the most common esophageal infection in HIV-infected individuals. The combination of oral thrush and dysphagia has a positive predictive value of 90% for esophageal candidiasis. If the symptoms do not resolve with treatment in 7 days, endoscopy is indicated. Cytomegalovirus (CMV) (Chapter 384) and idiopathic esophageal ulcerations may appear when the $CD4^+$ count falls below 50 cells/μL. Odynophagia, or severe pain on swallowing, is the initial symptom. Endoscopy shows large ulcerations with elevated margins, and CMV inclusions are seen in biopsy samples. HSV infections are much less common and appear as confluent shallow ulcerations in the esophagus. Idiopathic ulceration is diagnosed by the absence of viral inclusions on biopsy specimens.

Diarrhea

Diarrhea remains a common illness in HIV-infected individuals, even in the era of effective ART. Infections of the small intestine are accompanied by large-volume watery diarrhea. Colonic disease may be manifested as bloody, inflammatory, or small-volume diarrhea and tenesmus. Routine bacterial pathogens, including *Salmonella*, *Campylobacter*, and *Shigella*, have all been documented to cause diarrhea in HIV-infected patients. Enteroaggregative *Escherichia coli* has been identified as a cause of persistent diarrhea in HIV-infected individuals. The use of multiple antibiotics in HIV-infected patients has led to the frequent occurrence of *Clostridium difficile* colitis. Mycobacterial infections with either *Mycobacterium tuberculosis* or atypical mycobacteria, most commonly *Mycobacterium avium* complex (MAC), may infiltrate the small bowel in HIV-infected patients. Although *M. tuberculosis* infection occurs with exposure in individuals with moderate $CD4^+$ cell depletion, disseminated MAC disease occurs only in individuals with $CD4^+$ counts lower than 50 cells/μL.

Most often, viral diarrheas are similar in manifestation to those in the general population, pathogens are not routinely identified in the clinical setting, and disease is self-limited. However, CMV may cause disease throughout the length of the GI tract in HIV-infected patients with $CD4^+$ counts lower than 50 cells/μL. In the small bowel, CMV may cause a watery diarrhea and, in the colon, a colitis with blood and signs of inflammation on endoscopy. Biopsy with identification of virus in tissue is required to make the diagnosis of CMV enteric disease.

Parasitic causes of diarrhea are common in HIV-infected individuals. Opportunistic parasitic pathogens include *Cryptosporidium parvum*, the microsporidial organisms *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*, and *Cyclospora cayetanensis*. Persistent diarrhea caused by cryptosporidiosis (Chapter 358) occurs when the $CD4^+$ count is less than 200 cells/μL, and the most effective control of this pathogen is treatment of HIV.

Pathogens are not found in up to half of cases of diarrhea in HIV-infected patients, even after a full diagnostic evaluation. This condition has been called *AIDS enteropathy* and is associated with chronic diarrhea, malnutrition, and wasting. It is possible that some of the chronic diarrhea is caused by pathogens that are not yet recognized or by noninfectious causes such as lymphoma. It is also likely that some of these pathogen-negative diarrheas are caused by HIV itself, which may infect the enterocyte, as well as lymphoid tissue within the gut.

Malignancy

Kaposi's sarcoma (Chapter 400) may develop at any location in the GI tract. Kaposi's lesions appear endoscopically as raised reddish nodules that may bleed spontaneously. Non-Hodgkin's lymphomas may involve any portion of the GI tract, as well as the liver, and are manifested as bleeding, obstruction, weight loss, or abdominal pain.

Wasting

Wasting in HIV-infected individuals is defined by the World Health Organization as a body mass index of less than 18.5 kg/m^2. Weight loss and wasting are still seen in patients with treated HIV infection, and even modest weight loss of 3% or greater increases mortality.

In uncontrolled HIV infection, multiple factors contribute to wasting. Caloric requirements are increased by the metabolic demands of HIV replication, concurrent opportunistic infections, and fever. Oral intake may be poor because of nausea, anorexia, dysphagia, odynophagia, or chronic diarrhea or as a result of food insecurity, depression, or dementia. Weight loss is exacerbated by malabsorption of nutrients from small intestinal or pancreatic disease. HIV-infected persons may not be able to increase caloric intake to overcome the loss of nutrients in stool and meet the metabolic demands of their illness. Targeted approaches to wasting and weight loss include treatment of HIV or opportunistic infections, frequent small meals, and use of appetite stimulants (megestrol acetate, dronabinol), anabolic steroids (testosterone, oxandrolone, nandrolone), or recombinant human growth hormone, as indicated. With control of HIV replication, nutritional status and weight generally improve, although they may not return to premorbid levels if the wasting was severe.

Hepatobiliary Disease

Hepatobiliary disease is associated with very low $CD4^+$ counts, often less than 20 cells/μL. Evaluation of abnormalities in liver function should initially exclude HBV and HCV infection and drug-induced hepatotoxicity, particularly that involving antiretroviral or sulfa-containing medications. The presence of hepatomegaly suggests an infiltrative process such as MAC or fungal infection or lymphoma. Alkaline phosphatase is disproportionately elevated. Liver imaging often does not show a localized lesion but determines whether biliary dilation is present, a finding suggestive of extrahepatic disease. Liver biopsy with special stains and cultures may be definitive.

In contrast, the presence of right upper quadrant pain with or without jaundice indicates biliary tract disease (Chapter 158). AIDS cholangiopathy includes a sclerosing cholangitis–like process with diffuse biliary strictures and dilations and papillary stenosis with narrowing of the distal common bile duct at the entrance to the duodenum. In papillary stenosis, the common bile duct is dilated proximal to the stenosis. Acalculous cholecystitis may also be seen. These changes are caused by infection of the biliary tree with *Cryptosporidium*, microsporidia, *Isospora belli*, or CMV in the setting of profound immunosuppression. Endoscopic retrograde cholangiopancreatography can be performed to establish the diagnosis, obtain brushings for examination, and treat papillary stenosis by sphincterotomy. Treatment of the specific organism seldom eradicates infection because of the degree of immunosuppression. However, treatment with ART can result in marked improvements in biliary findings.

APPROACH TO GASTROINTESTINAL DISEASES

The GI tract is host to a myriad of infectious and infiltrative diseases in HIV-infected persons. Even so, routine GI diseases such as diverticulitis, choledocholithiasis, or peptic ulcer disease must be considered, particularly in those treated with ART. The clinician is guided by the symptom complex, as laid out in Table 397-1, to identify the probable organisms or tumors by clinical findings. The $CD4^+$ count influences the likelihood of the type of GI infection. It is important to remember that multiple illnesses may occur simultaneously with HIV infection and that finding one cause of a symptom or complaint may not be sufficient.

With diarrhea, careful stool evaluations should include cultures for *Salmonella*, *Shigella*, and *Campylobacter*; assay for *Clostridium difficile* toxin; and at least three examinations for parasites, including acid-fast stains for MAC and *Cryptosporidium*. If these measures are unrevealing, upper GI endoscopy with biopsy of the small intestine is indicated to diagnose protozoal infections with *Cryptosporidium*, *Isospora belli*, or microsporidia. Signs of colitis are best evaluated by flexible sigmoidoscopy or colonoscopy with biopsy and cultures. Examination and biopsy of the terminal ileum with acid-fast stain is necessary to confirm the diagnosis of pathogens such as *M. tuberculosis* or MAC.

All persons with HIV should be screened for coinfection with HBV and HCV and vaccinated against hepatitis A and B if not immune. Finally, close attention to serial measurement of weight and calculation of the body mass index is crucial to identify those who may have poor outcomes as a result of weight loss or excessive weight gain.

PULMONARY MANIFESTATIONS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME

LAURENCE HUANG

DEFINITION

Respiratory symptoms are common in individuals infected with human immunodeficiency virus (HIV), and HIV-infected patients are subject to a wide spectrum of pulmonary diseases, both those associated with HIV (Table 398-1) and those not associated with HIV. The spectrum of HIV-associated pulmonary diseases encompasses opportunistic infections, neoplasms, and other pulmonary disorders. Table 398-1 lists the most frequent pulmonary diseases seen in HIV-infected patients in the United States. In other parts of the world, these frequencies may be strikingly different. Although each pulmonary disease has characteristic clinical and radiographic findings, they can vary and often overlap.

TABLE 398-1 HIV-ASSOCIATED PULMONARY DISEASES

Opportunistic Infections

BACTERIAL	MYCOBACTERIAL	FUNGAL	VIRAL/ PARASITIC
Streptococcus pneumoniae	*Mycobacterium tuberculosis*	*Pneumocystis jirovecii**	Cytomegalovirus
Haemophilus species	*Mycobacterium kansasii*	*Cryptococcus neoformans*	Influenza
Pseudomonas aeruginosa	*Mycobacterium avium* complex	*Histoplasma capsulatum*	*Toxoplasma gondii*
Staphylococcus aureus		*Coccidioides immitis*	
Klebsiella pneumoniae		*Aspergillus* species (esp. *fumigatus*)	

Neoplasms and Selected Noninfectious Diseases

NEOPLASM	LYMPHOPROLIFERATIVE DISORDERS	MISCELLANEOUS DISORDERS
Kaposi's sarcoma	Nonspecific interstitial pneumonitis	Pulmonary arterial hypertension
Non-Hodgkin's lymphoma	Lymphocytic interstitial pneumonitis	Chronic obstructive pulmonary disease
Lung cancer		Sarcoidosis
		Immune reconstitution syndromes

*The form of *Pneumocystis* that infects humans is *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*).

TABLE 398-2 DIAGNOSTIC APPROACH TO PULMONARY DISEASE IN HIV-INFECTED PERSONS: CLUES

CLINICAL SETTING
Ambulatory: URI > acute bronchitis > bacterial pneumonia > *Pneumocystis* pneumonia
Hospital: bacterial pneumonia > *Pneumocystis* pneumonia > TB > pulmonary KS
Intensive care unit: *Pneumocystis* pneumonia > bacterial pneumonia; non–AIDS associated > AIDS associated conditions
CD4$^+$ CELL COUNT (see Table 398-3)
PATIENT BACKGROUND
HIV transmission category: MSM—increased incidence of KS; IDU—increased incidence of bacterial pneumonia, TB
Habits: cigarettes—increased incidence of bacterial bronchitis, bacterial pneumonia, COPD, RB-ILD, bronchogenic carcinoma
Travel and residence: assess risk for endemic fungal diseases, TB
MEDICAL BACKGROUND AND USE OF PROPHYLAXIS
Previous disease: increased incidence of recurrence of bacterial pneumonia, *Pneumocystis* pneumonia, fungal pneumonias
Prophylaxis/maintenance: decreased incidence of disease—*Pneumocystis* pneumonia, fungal pneumonias, TB (if PPD positive or positive interferon-γ release assay)
SYMPTOMS AND SIGNS
Respiratory symptoms: especially cough (productive or nonproductive) and symptom duration
Symptoms suggesting extrapulmonary or disseminated disease
Physical examination of the chest: focal or nonfocal findings
Signs suggesting extrapulmonary or disseminated disease
LABORATORY TESTS
WBC count: elevated or, if normal, elevated relative to baseline—bacterial pneumonia
Serum LDH: elevated—nonspecific but classically seen in *Pneumocystis* pneumonia
Arterial blood gas: nonspecific but useful for prognosis, management decisions (e.g., admission and whether corticosteroids are indicated for *Pneumocystis* pneumonia)
CHEST RADIOGRAPH (see Figs. 398-9 and 398-10)

AIDS = acquired immunodeficiency syndrome; COPD = chronic obstructive pulmonary disease; HIV, human immunodeficiency virus; IDU = injection drug user; KS = Kaposi's sarcoma; LDH = lactate dehydrogenase; MSM = men who have sex with men; PPD = purified protein derivative (in an HIV-infected person, PPD is considered positive if ≥5-mm induration); RB-ILD = respiratory bronchiolitis–interstitial lung disease; TB = tuberculosis; URI = upper respiratory tract infection; WBC = white blood cell.

DIAGNOSIS

Initial Diagnostic Approach

The frequency of HIV-associated opportunistic pneumonias and the need for prompt treatment of these infections often focus the initial diagnostic approach and management on identifying and treating possible infectious causes. However, HIV-infected persons may have HIV-associated neoplasms or other disorders, and the prevalence of these noninfectious conditions may be increasing. In addition, risk factors for HIV infection, such as injection drug use, may also contribute to pulmonary disease (e.g., endocarditis with septic pulmonary emboli). Finally, HIV-infected individuals may have preexisting pulmonary disease (e.g., asthma), or pulmonary disease unrelated to their HIV infection (e.g., pulmonary embolism) may develop and be the cause of their respiratory symptoms. Therefore, in the proper clinical context, clinicians must also consider noninfectious HIV-associated pulmonary diseases and non–HIV-associated disorders before embarking on an exhaustive search for HIV-associated opportunistic infections. This is especially important inasmuch as HIV-infected patients receiving combination antiretroviral therapy are living longer and new associations with traditionally non–HIV-related disorders are increasingly being found.

Clinical Setting

The clinical setting in which the patient is encountered and evaluated has an impact on the relative frequency of the pulmonary diseases seen (Table 398-2). The Pulmonary Complications of HIV Infection Study found that patients seen as outpatients more often had upper respiratory tract infections and acute bronchitis than pneumonia secondary to bacteria or *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*). However, neither of the former conditions typically necessitates hospitalization, whereas a significant number of patients with the latter diseases require hospitalization. The most common pulmonary diseases in hospitalized HIV-infected patients are bacterial pneumonia, followed by *Pneumocystis* pneumonia, both of which are significantly more frequent than the next most common diagnoses: tuberculosis, pulmonary Kaposi's sarcoma (KS), and *Cryptococcus neoformans* pneumonia. The Pulmonary Complications of HIV Infection Study found that the most common pulmonary disease in patients requiring critical care was *Pneumocystis* pneumonia, followed by bacterial pneumonia. Currently, non–acquired immunodeficiency syndrome (AIDS)-associated conditions are often more frequent indications for critical care than are AIDS-associated conditions in HIV-infected persons.

The geographic location may also influence the frequency of different diagnoses. In specific populations or particular geographic regions, mycobacterial and endemic fungal pneumonias become important considerations. Worldwide, tuberculosis is the dominant disease. In endemic areas, diseases caused by *Histoplasma capsulatum* or *Coccidioides immitis* are among the most frequent infections seen.

Laboratory Findings

CD4$^+$ Lymphocyte Count

The CD4$^+$ cell count is an excellent indicator of an HIV-infected patient's risk for the development of a specific opportunistic infection or a particular neoplasm. Many of the HIV-associated pulmonary diseases become manifested once a patient's CD4$^+$ cell count has declined to a certain level, and these diseases only occasionally occur in a patient whose CD4$^+$ cell count is above that level (Table 398-3). The exceptions are diseases that can develop in persons without underlying immunodeficiency, such as bacterial pneumonia, tuberculosis, and non-Hodgkin's lymphoma. These diseases can occur at any CD4$^+$ cell count in HIV-infected patients. However, their incidence increases as the CD4$^+$ cell count declines. One study found that the risk for bacterial pneumonia in HIV-infected subjects with a CD4$^+$ cell count of less than 200 cells/μL was more than 5.5 times greater than that in subjects whose CD4$^+$ cell count was higher than 500 cells/μL. In addition, as the CD4$^+$ cell count declines, the incidence of bacterial pneumonia accompanied by bacteremia (especially *Streptococcus pneumoniae*) and the incidence of *Mycobacterium tuberculosis* infection accompanied by extrapulmonary or disseminated disease increase, features that have important implications for diagnosis.

At CD4$^+$ cell counts lower than 200 cells/μL, *Pneumocystis* and *C. neoformans* pneumonias become significant diagnoses to consider. A review from

TABLE 398-3 $CD4^+$ CELL COUNT RANGES FOR HIV-ASSOCIATED PULMONARY DISEASES

ANY $CD4^+$ CELL COUNT
Bacterial pneumonia (most often *S. pneumoniae, Haemophilus* species)
M. tuberculosis pneumonia
Influenza
Non-Hodgkin's lymphoma
Lung cancer
Nonspecific interstitial pneumonitis
Lymphocytic interstitial pneumonitis
Pulmonary arterial hypertension
Chronic obstructive lung disease
$CD4^+$ CELL COUNT <200 CELLS/μL
Pneumocystis pneumonia
Cryptococcus neoformans pneumonia
$CD4^+$ CELL COUNT <100 CELLS/μL
Bacterial pneumonia caused by *Pseudomonas aeruginosa*
Toxoplasma gondii pneumonia
Pulmonary Kaposi's sarcoma
$CD4^+$ CELL COUNT <50 CELLS/μL
Mycobacterium avium complex—usually associated with disseminated disease
Histoplasma capsulatum—usually associated with disseminated disease
Coccidioides immitis—usually associated with disseminated disease
Aspergillus species (most often *Aspergillus fumigatus*) pneumonia
Cytomegalovirus pneumonia—usually associated with disseminated disease

the Clinical Center of the National Institutes of Health found that 46 of 49 patients (94%) in whom *Pneumocystis* pneumonia was diagnosed had a $CD4^+$ cell count of less than 200 cells/μL. The Multicenter AIDS Cohort Study demonstrated that HIV-infected subjects with a $CD4^+$ cell count lower than 200 cells/μL at study entry had nearly a five-fold greater risk for *Pneumocystis* pneumonia than did subjects who had a $CD4^+$ cell count higher than 200 cells/μL at entry. Finally, the Pulmonary Complications of HIV Infection Study reported that 95% of 145 cases of *Pneumocystis* pneumonia occurred in subjects whose $CD4^+$ cell count was less than 200 cells/μL (median $CD4^+$ count, 29 cells/μL).

At $CD4^+$ cell counts lower than 100 cells/μL, pneumonias secondary to *Pseudomonas aeruginosa* and *Toxoplasma gondii* and lung involvement by KS are increasingly diagnosed. One study of 64 HIV-infected patients with pulmonary toxoplasmosis diagnosed by bronchoalveolar lavage (BAL) reported a mean $CD4^+$ cell count of 40 cells/μL; 82% had a $CD4^+$ count of less than 50 cells/μL, and only 4% had a count higher than 200 cells/μL. A series of 168 consecutive HIV-infected patients with pulmonary KS diagnosed by bronchoscopy reported a median $CD4^+$ cell count of 19 cells/μL; 68% had a $CD4^+$ count lower than 50 cells/μL, and only 4% had a count higher than 200 cells/μL.

Finally, at $CD4^+$ cell counts lower than 50 cells/μL, nontuberculous mycobacteria (*Mycobacterium avium* complex), endemic (*H. capsulatum, C. immitis*) and nonendemic (*Aspergillus* species) fungi, and cytomegalovirus increasingly become important causes to consider. These diseases are usually accompanied by extrapulmonary or disseminated disease, which can dominate the clinical findings. In many of these cases, the patient may have minimal or no respiratory complaints, and findings on chest radiography are often normal. One review noted respiratory complaints in 53% of HIV-infected patients with disseminated histoplasmosis and normal findings on chest radiography in 43%.

History

Patient Background

A number of important diagnostic clues can be gleaned from a patient's personal and medical background that may help suggest specific diagnoses (see Table 398-2).

Health Habits and Mode of HIV Transmission

A patient's health-related habits and mode of acquiring HIV influence the relative frequency of various HIV-related and non–HIV-related pulmonary diseases. In the United States, HIV-associated KS is seen almost exclusively in men who report having sexual relationships with other men. Bacterial pneumonia and tuberculosis are more common in HIV-infected patients who are injection drug users than in HIV-infected patients without a history of injection drug use. Furthermore, injection or other illicit drug use can cause a variety of non–HIV-related pulmonary diseases such as endocarditis-associated septic pulmonary emboli, pulmonary talcosis/interstitial lung disease, aspiration pneumonia secondary to respiratory depression, and drug-induced pulmonary edema.

HIV-infected patients who smoke tobacco are at increased risk for a variety of smoking-related respiratory illnesses and diseases. Both bacterial bronchitis and bacterial pneumonia are more common in HIV-infected cigarette smokers than in HIV-infected nonsmokers or former smokers. This is especially the case in persons with a $CD4^+$ cell count lower than 200 cells/μL. In addition, HIV-infected patients who report a long history of cigarette use may have manifestations of chronic obstructive pulmonary disease (COPD) or respiratory bronchiolitis/interstitial lung disease as the cause of their symptoms. Emerging evidence suggests that HIV infection itself is associated with an increased risk for lung carcinoma.

Travel and Residence

Travel to or residence in a geographic region that is endemic for fungi such as *C. immitis, H. capsulatum*, or *Penicillium marneffei* is a strong determinant of the risk for exposure, infection, and ultimately disease. HIV-infected patients without such a history are unlikely to have been exposed and infected and are therefore unlikely to contract these diseases. Clinicians caring for patients in nonendemic areas would be wise to query their patients for details on their residence and travel history if the findings are suggestive of an endemic fungal infection.

Tuberculosis is more common in certain geographic areas and in certain populations. HIV-infected patients who were born in or have traveled to a country with a high prevalence of tuberculosis and patients who are homeless or previously incarcerated are at higher risk for exposure to *M. tuberculosis*. Patients with a positive purified protein derivative (PPD) tuberculin skin test result (defined as ≥5-mm induration in HIV-infected persons), especially if recent converters, and those with a positive result on an interferon-γ release assay are at increased risk for the development of tuberculosis.

Medical Background and Use of Prophylaxis

Many HIV-related opportunistic infections recur, and the current manifestation may be due to recurrence or relapse of a previous pulmonary disease (see Table 398-2). Bacterial infections are often recurrent, and patients with recurrent episodes of bacterial pneumonia are subject to the development of airway damage or bronchiectasis, which in turn predisposes them to further bacterial infections. Patients with previous *Pneumocystis* pneumonia are at high risk for recurrence, especially if their $CD4^+$ cell count remains lower than 200 cells/μL. If the $CD4^+$ cell count rises to higher than 200 cells/μL with antiretroviral therapy, prophylaxis against *Pneumocystis* can be safely discontinued in the majority of patients. Similarly, patients with previous cryptococcosis, coccidioidomycosis, or histoplasmosis are at high risk for relapse. Patients with a positive PPD reaction, a positive interferon-γ release assay result, or a chest radiograph with fibrotic lesions consistent with tuberculosis and no evidence of active tuberculosis and no previous history of treatment of latent tuberculosis infection (LTBI) should receive therapy for LTBI; failure to do so places the patient at a high risk for tuberculosis. In HIV-infected patients, adherence to the prescribed prophylaxis regimen lessens the probability of disease, whereas failure to adhere to the regimen frequently results in recurrent or relapsed disease.

Diagnostic Evaluation (see Table 398-2)

Symptoms

All of the HIV-associated pulmonary diseases may be accompanied by cough, dyspnea, or less commonly, pleuritic chest pain, or any combination of these symptoms. However, each pulmonary disease has a characteristic manifestation, and particular aspects of these symptoms may be useful in suggesting a specific diagnosis. For example, most patients with bacterial pneumonia have a cough productive of purulent sputum, whereas most patients with *Pneumocystis* pneumonia have a nonproductive cough. Bacterial pneumonias caused by *S. pneumoniae* and *Haemophilus* species characteristically have an acute onset and symptom duration of 3 to 5 days. In contrast, *Pneumocystis* pneumonia usually has a subacute onset and symptom duration of 2 to 4 weeks. Thus, in an HIV-infected patient with a $CD4^+$ count lower than 200 cells/μL (and hence at risk for both pneumonias), the presence of cough productive of purulent sputum with a symptom duration of a few days favors the diagnosis of bacterial pneumonia. In contrast, the absence of purulent sputum

with a symptom duration of a few weeks strongly favors the diagnosis of *Pneumocystis* pneumonia.

Constitutional symptoms such as fever, night sweats, and weight loss may suggest the presence of a systemic or disseminated disease. Fever and weight loss may be the sole complaints associated with disseminated mycobacterial or fungal disease, or they may be "B" symptoms associated with non-Hodgkin's lymphoma.

Extrapulmonary symptoms, when present, are often useful in suggesting a specific diagnosis. Although HIV-infected patients can have multiple concurrent illnesses, many of the HIV-associated pulmonary diseases have important extrapulmonary manifestations that account for their nonpulmonary findings. For example, respiratory symptoms and headache in a patient with a $CD4^+$ cell count lower than 200 cells/μL should suggest the possibility of *C. neoformans* pneumonia and meningitis. In fact, although the lungs are the portal of entry for *Cryptococcus*, many patients have no respiratory complaints or have minimally symptomatic pulmonary disease and the diagnosis is suggested only by the presence of extrapulmonary symptoms.

Signs

HIV-infected patients with pneumonia may be febrile, tachycardic, and tachypneic. The presence of systemic hypotension often suggests a fulminant disease process (e.g., bacterial septicemia). Pulse oximetry frequently reveals a decrease in oxygen saturation and also provides an estimate of the severity of the disease. The presence of exercise-induced oxygen desaturation is reported to be a sensitive indicator of *Pneumocystis* pneumonia.

Examination of the lungs may suggest a cause of the respiratory symptoms. Patients with bacterial pneumonia often have focal lung findings suggestive of consolidation or pleural effusion, or both. In contrast, patients with *Pneumocystis* pneumonia most often have normal findings on lung examination and only a minority have inspiratory crackles (usually bilateral). Abnormal findings on lung examination may be the result of a nonpulmonary disease. For example, rales in association with an S_3 cardiac gallop and elevated jugular venous pressure suggest a cardiac etiology.

The remainder of the physical examination may also suggest a cause of the respiratory symptoms. Altered mental status in a patient with pulmonary disease whose $CD4^+$ cell count is lower than 200 cells/μL suggests *C. neoformans* with neurologic involvement. A patient with focal neurologic findings and pulmonary disease may have concurrent *T. gondii* encephalitis and pneumonitis. The presence of mucocutaneous KS lesions may point to pulmonary KS. However, the absence of KS lesions on the skin and mucous membranes does not preclude the possibility of significant visceral disease, including the lung. An abdominal examination revealing hepatosplenomegaly suggests either disseminated mycobacterial or fungal disease or non-Hodgkin's lymphoma.

Laboratory Tests

Laboratory tests may provide important clues to the diagnosis of pulmonary disease (see Table 398-2). In general, however, HIV-infected patients typically have a host of laboratory abnormalities that are nonspecific or caused by conditions unrelated to the pulmonary disease. Laboratory tests that may be useful include a complete blood count with a white blood cell count and differential, serum lactate dehydrogenase (LDH), and arterial blood gas (ABG) analysis. These tests also serve as prognostic markers and as baseline values for subsequent measurements. Serial measurements are useful in any patient who fails to exhibit a clinical response or who worsens despite appropriate therapy.

Serum LDH is often elevated in patients with *Pneumocystis* pneumonia. However, it may be elevated with other pulmonary (including bacterial pneumonia and tuberculosis) and nonpulmonary conditions. Despite its diagnostic limitations, the degree of LDH elevation has been shown to correlate with prognosis and response to therapy. Patients with *Pneumocystis* pneumonia and an initially markedly elevated or increasing serum LDH level despite treatment of *Pneumocystis* pneumonia have a poor prognosis. ABG analysis is useful for prognosis, as well as for clinical decisions regarding whether to admit the patient and whether corticosteroids are indicated in those with *Pneumocystis* pneumonia.

Imaging

Chest Radiograph

The chest radiograph is the cornerstone for evaluation of pulmonary diseases in HIV-infected patients. Because each of these diseases has a characteristic radiographic appearance, the radiograph can narrow the diagnostic possibilities and suggest a diagnostic approach.

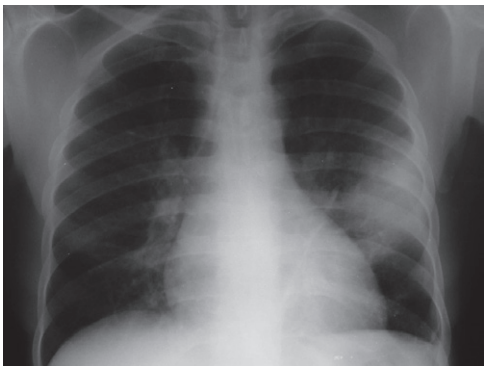

FIGURE 398-1. Chest radiograph of an HIV-infected person, $CD4^+$ cell count higher than 200 cells/μL, revealing left lingular consolidation. Sputum and blood cultures were positive for *Streptococcus pneumoniae*. (Courtesy Laurence Huang, MD, and Chin Tang Huang, MD.)

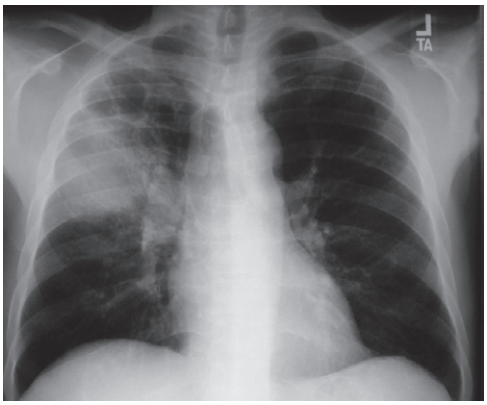

FIGURE 398-2. Chest radiograph of an HIV-infected person, $CD4^+$ cell count higher than 200 cells/μL, demonstrating a right upper lobe infiltrate with areas of cavitation. Sputum acid-fast bacillus stain was positive, and multiple sputum cultures grew *Mycobacterium tuberculosis*.

Bacterial pneumonia is currently the most common pulmonary disease seen in HIV-infected persons at many institutions in the United States. The most frequently identified pathogens are *S. pneumoniae*, *Haemophilus* species, *Staphylococcus aureus*, and *P. aeruginosa*. Classically, chest radiographs of HIV-infected patients with bacterial pneumonia demonstrate focal, segmental, or lobar consolidation, similar to that observed in non–HIV-infected persons (Fig. 398-1). However, this finding may be more frequent in pneumonias caused by *S. pneumoniae* and to a lesser extent *Haemophilus* species than in community-acquired *P. aeruginosa*. The presence of cavitary pneumonia may be more suggestive of *Staphylococcus* or *Pseudomonas* than either *Streptococcus* or *Haemophilus*.

Tuberculosis can be associated with a variety of chest radiographic findings, including upper lung zone infiltrates, often with cavitation (Fig. 398-2), middle or lower lung zone consolidation (or both) mimicking bacterial pneumonia (Fig. 398-3), miliary or nodular disease, and pleural effusions or intrathoracic adenopathy (or both). The frequency with which each of these specific findings is seen is influenced in part by the patient's $CD4^+$ cell count. HIV-infected patients with a $CD4^+$ cell count well higher than 200 cells/μL are more likely to have a radiograph showing upper lung zone infiltrates and cavitation than are patients with a $CD4^+$ count lower than 200 cells/μL. In this latter group, patients are as likely or more likely to have a radiograph demonstrating mid or lower lung zone involvement (or both) or diffuse involvement and are more likely to have associated intrathoracic adenopathy. One study of radiographic findings in HIV-infected patients with tuberculosis found that the proportion of patients with cavitary infiltrates declined significantly as the $CD4^+$ cell count decreased from 400 cells/μL or higher to less than 200 cells/μL whereas the proportion with noncavitary infiltrates and with intrathoracic adenopathy increased significantly as the $CD4^+$ count declined. Thus, the radiographic key to diagnosis of tuberculosis is

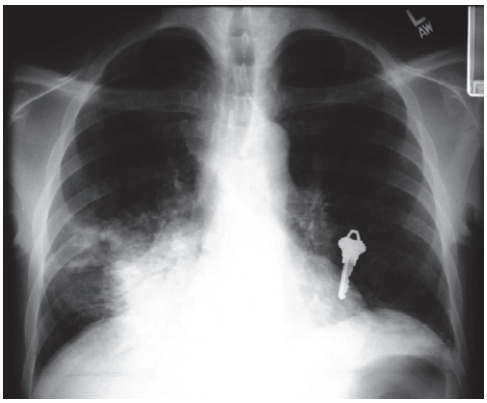

FIGURE 398-3. Chest radiograph of an HIV-infected person, CD4⁺ cell count less than 200 cells/μL, revealing right lower lung zone consolidation with air bronchograms. Sputum culture grew *Mycobacterium tuberculosis* that was resistant to rifampin treatment. In this case, the key to the diagnosis of tuberculosis was knowledge of the patient's CD4⁺ cell count and an understanding that tuberculosis can be manifested in this manner in such an individual.

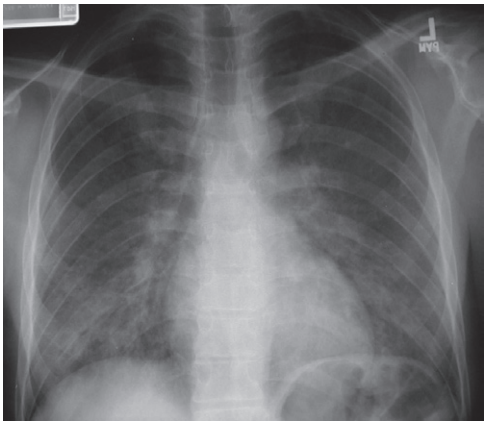

FIGURE 398-4. Chest radiograph of an HIV-infected person, CD4⁺ cell count less than 200 cells/μL, demonstrating the characteristic bilateral, reticular-granular opacities of *Pneumocystis* pneumonia. Bronchoscopy with examination of bronchoalveolar lavage fluid revealed *Pneumocystis jirovecii*.

knowledge of the patient's CD4⁺ cell count and the patterns common at that CD4⁺ count.

Classically, *Pneumocystis* pneumonia is characterized by bilateral interstitial-reticular or granular opacities (Fig. 398-4). Frequently, the opacities are symmetrical, and they are diffuse when the disease is severe. One large study revealed that 7% of HIV-infected patients with *Pneumocystis* pneumonia had thin-walled cysts (pneumatoceles) (Fig. 398-5) and 4% had honeycomb lesions. Infiltrates were bilateral in 95% and involved the entire lung in 48%. Several reports have described the radiographic findings in patients receiving aerosolized pentamidine prophylaxis; these radiographs characteristically revealed an upper lung zone predominance mimicking mycobacterial disease. However, upper lung zone predominance can also be seen in patients who never received aerosolized pentamidine, and the pattern present (reticular, granular) is more important than the distribution in suggesting the diagnosis of *Pneumocystis* pneumonia.

Although bilateral interstitial-reticular infiltrates are the most common radiographic manifestation (mimicking *Pneumocystis* pneumonia), pulmonary involvement by *Cryptococcus* can also result in an alveolar or nodular pattern, thin-walled cysts or cavities, nodules, masses (Fig. 398-6A and B), intrathoracic adenopathy, and pleural effusions.

Pulmonary KS is characteristically accompanied by bilateral opacities in a central or perihilar distribution (Fig. 398-7). One large study of HIV-infected patients with pulmonary KS diagnosed by bronchoscopy (in which BAL studies were negative for infectious organisms) found that 95% of chest radiographs demonstrated peribronchial cuffing and tram track opacities with (45%) or without (50%) more extensive perihilar coalescent opacities. Small nodules (50%) or nodular opacities (28%) were seen on 78%, Kerley's B lines on 71%, and pleural effusions on 53% of the radiographs.

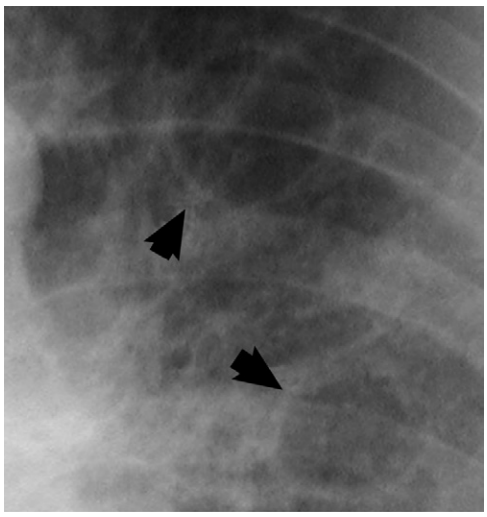

FIGURE 398-5. Close-up of the left lung from a chest radiograph of an HIV-infected person, CD4⁺ cell count less than 200 cells/μL. Two thin-walled cysts *(arrows)* are present as a result of *Pneumocystis* pneumonia.

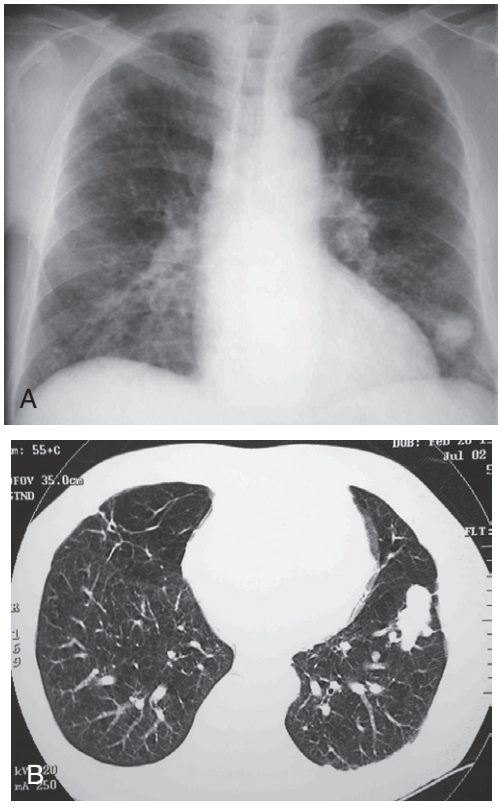

FIGURES 398-6. A and B, Chest radiograph and chest computed tomography (CT) scan of an HIV-infected person, CD4⁺ cell count less than 200 cells/μL. A multilobulated noncalcified mass measuring 4.6 × 2.4 cm is present in the left lower lobe with multiple adjacent satellite nodules. Culture from CT-guided transthoracic needle aspiration revealed *Cryptococcus neoformans*.

Chest Computed Tomography

Chest computed tomography (CT) is more sensitive than chest radiography for detecting the presence and defining the characteristics and extent of pulmonary disease. However, CT is unnecessary in most evaluations because the clinical and chest radiographic findings often suggest a single or a few diagnoses to consider primarily. There are a number of specific clinical scenarios in which chest CT may be of particular use in HIV-infected patients. High-resolution CT (HRCT) is extremely useful in patients with clinically suspected *Pneumocystis* pneumonia and normal or unchanged findings on chest radiography. Patients with *Pneumocystis* pneumonia and normal chest radiographic findings have patchy areas of ground-glass opacity on HRCT (Fig. 398-8). Although the presence of ground-glass opacity is nonspecific and

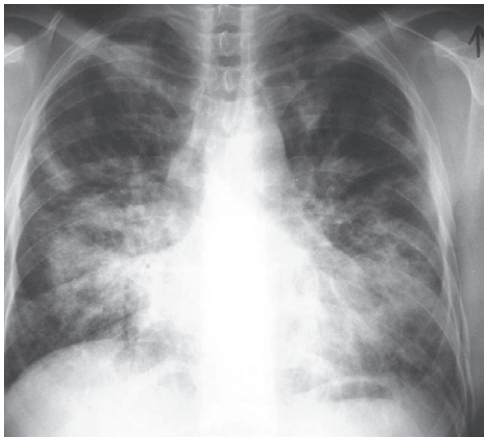

FIGURE 398-7. Chest radiograph of an HIV-infected person, $CD4^+$ cell count less than 100 cells/μL, with the characteristic bilateral, middle, and lower lung zone, predominantly central distribution of abnormalities of pulmonary Kaposi's sarcoma. The patient had no evidence of mucocutaneous Kaposi's sarcoma, and the diagnosis of pulmonary disease was made by bronchoscopy with visualization of characteristic erythematous-violaceous Kaposi's sarcoma lesions throughout the visible airway (see Fig. 398-11).

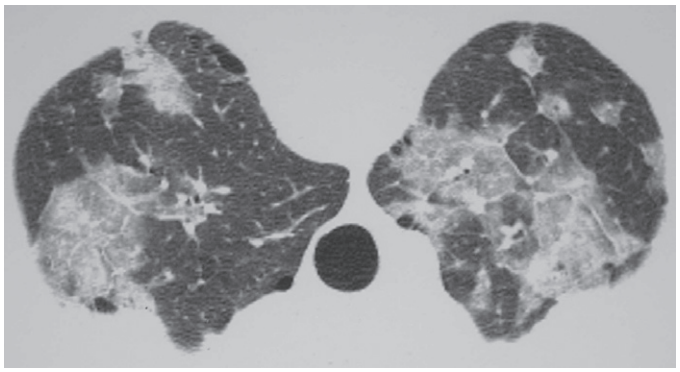

FIGURE 398-8. Chest high-resolution computed tomography (HRCT) in an HIV-infected person, $CD4^+$ cell count less than 200 cells/μL, whose chest radiograph showed normal findings. Because of clinical suspicion of *Pneumocystis* pneumonia (PCP), the patient underwent HRCT, which demonstrates the characteristic patchy ground-glass opacities of PCP. Induced sputum examination revealed *Pneumocystis jirovecii*.

may be seen with a number of pulmonary disorders, its absence strongly argues against the presence of *Pneumocystis* pneumonia.

Chest CT can also be useful in suggesting a diagnosis in cases in which the chest radiograph reveals multiple pulmonary nodules. A predominance of nodules less than 1 cm in diameter in a centrilobular distribution strongly suggests the presence of an opportunistic infection, whereas a predominance of nodules larger than 1 cm in diameter is suggestive of neoplasm. When the nodules are mostly less than 1 cm in diameter, the presence of intrathoracic adenopathy, especially if low attenuation (another use for CT), indicates that mycobacterial (or fungal) disease is probable. When the nodules are mostly greater than 1 cm in diameter, the finding of associated peribronchovascular thickening inevitably results in a diagnosis of pulmonary KS.

In patients suspected of having disseminated mycobacterial or fungal disease, the chest radiograph may reveal little or no parenchymal lung involvement. However, chest CT may reveal intrathoracic adenopathy, which if low attenuation, strongly suggests these infections. Finally, chest CT is useful in guiding diagnostic procedures such as bronchoscopy, transthoracic needle aspiration (see Fig. 398-6B), and occasionally, surgical procedures.

Pulmonary Function Tests

Pulmonary function testing can be useful in evaluating respiratory complaints in HIV-infected patients. In patients complaining of dry cough or dyspnea (or both) whose findings on chest radiography are normal, spirometry may diagnose airflow obstruction that is often responsive to bronchodilators. It may also reveal a pattern suggestive of COPD, which is increasingly being recognized as a noninfectious complication of HIV infection. Pulmonary function testing in patients with *Pneumocystis* pneumonia frequently reveals a restrictive ventilatory defect with decreased lung volumes and increased airflow. In addition, the diffusing capacity for carbon monoxide (DLCO) is a sensitive, but nonspecific indicator of *Pneumocystis* pneumonia, and a normal DLCO makes the diagnosis of *Pneumocystis* pneumonia extremely unlikely.

Selected Diagnostic Tests

The approach to the evaluation of HIV-infected patients with suspected pulmonary disease begins with consideration of the spectrum of pulmonary diseases outlined in Table 398-1. After a careful history and physical examination supplemented by selected laboratory tests and a chest radiograph, the goal is to arrive at a probable diagnosis (or at most a few diagnoses) for which specific diagnostic tests can be ordered and appropriate treatment can be initiated (Figs. 398-9 and 398-10). The next sections provide a discussion of selected diagnostic tests (E-Table 398-1).

Blood Cultures

Blood can be obtained for bacterial, fungal, and mycobacterial culture. Because *S. pneumoniae* is the most frequent cause of bacterial pneumonia and because pneumococcal pneumonia is often accompanied by bacteremia in HIV-infected patients (especially those with a $CD4^+$ cell count <200 cells/μL), blood cultures should usually be performed in patients with suspected bacterial pneumonia. When positive, blood cultures are specific for the diagnosis, and in an era of increasing antibiotic resistance, the utility of drug susceptibility testing cannot be overemphasized. Tuberculosis and many of the fungal pneumonias may be manifested as extrapulmonary or disseminated disease with minimal or absent respiratory complaints and normal findings on chest radiography. For this reason, mycobacterial and fungal blood cultures should usually be performed for suspected tuberculous or fungal infection, especially if the $CD4^+$ cell count is lower than 200 cells/μL.

Serology

Serum cryptococcal antigen (sCRAG) is an extremely sensitive test for the presence of cryptococcemia and cryptococcal meningitis, and a negative sCRAG test result virtually rules out the diagnosis of cryptococcal meningitis. However, sCRAG may occasionally be negative in HIV-infected patients who have isolated cryptococcal pneumonia. sCRAG is extremely specific for cryptococcal infection; false-positive test results are rare. Therefore, sCRAG should be determined in all patients with suspected cryptococcal disease, and patients positive for sCRAG should undergo evaluation to determine the extent of disease (i.e., lumbar puncture for possible meningitis), whereas those negative for sCRAG but with respiratory complaints or chest radiographic findings should undergo further pulmonary evaluation (i.e., bronchoscopy with BAL). There appears to be little to no utility in measuring serial sCRAG titers in patients with cryptococcal disease.

Similar to sCRAG, *H. capsulatum* polysaccharide antigen (HPA) is a sensitive test for the presence of disseminated histoplasmosis. However, the HPA test may be negative in patients with mild or localized disease. The antigen, which can be measured in blood and other fluids (including BAL fluid) but is most commonly assayed from urine, should be determined in patients with suspected histoplasmosis. In the proper clinical context, a positive result indicates *H. capsulatum* infection. However, patients with a positive HPA test result should have appropriate material (i.e., blood) sent for fungal culture because fungal pathogens such as *P. marneffei*, *Blastomyces dermatitidis*, and *Paracoccidioides braziliensis* may cause a false-positive result. One important benefit of serial HPA testing is its use in diagnosing relapsed disease; a 2-unit increase is associated with relapsed disease.

Most cases of *T. gondii* encephalitis result from reactivation of latent infection. In studies of central nervous system toxoplasmosis, up to 97% of HIV-infected patients were positive for *Toxoplasma* IgG, with a smaller percentage being positive for *Toxoplasma* IgM. Although a positive *Toxoplasma* IgG finding merely indicates previous infection and cannot itself be taken as proof of acute toxoplasmosis, a negative *Toxoplasma* IgG finding, especially if accompanied by a negative IgM finding, makes the diagnosis of toxoplasmosis unlikely.

Sputum

Most patients with bacterial pneumonia have a productive cough. Current U.S. guidelines recommend that sputum Gram stain and culture be performed in hospitalized patients with suspected bacterial pneumonia and whenever the presence of identified pathogens would alter empirical therapy.

Sputum acid-fast bacillus (AFB) smear and culture are the foundations for the diagnosis of pulmonary tuberculosis and other nontuberculous

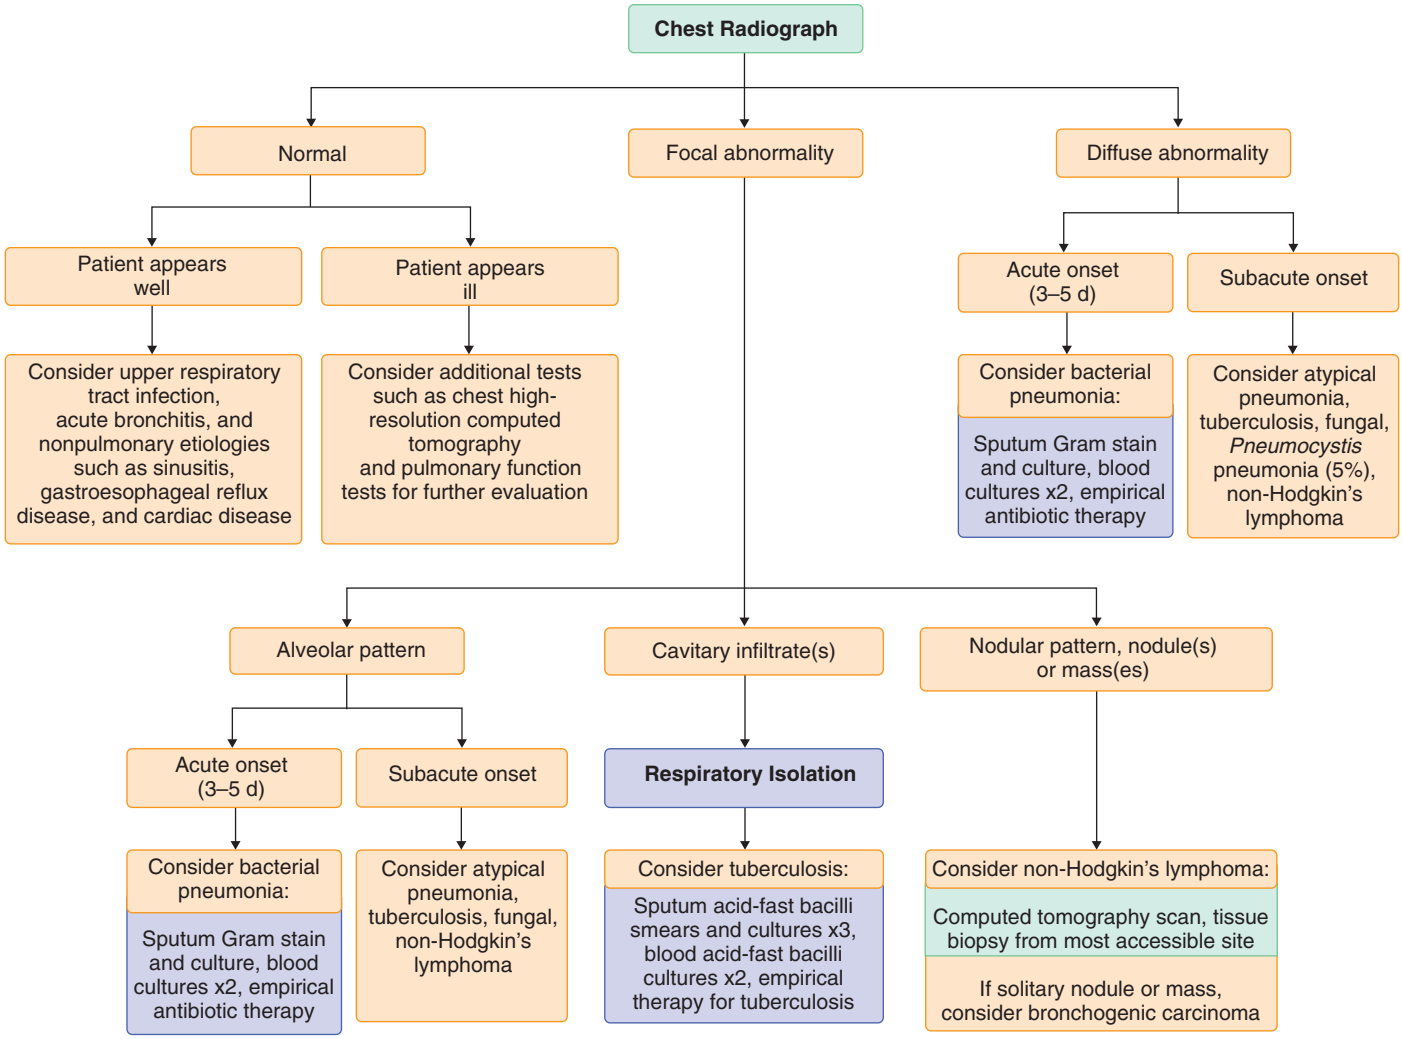

FIGURE 398-9. Diagnostic approach to an HIV-infected patient with suspected pulmonary disease, $CD4^+$ cell count greater than 200 cells/μL, according to the predominant chest radiograph findings.

mycobacterial pneumonias. Sputum AFB specimens—either spontaneous or induced—should ideally be obtained on 2 to 3 consecutive days, preferably in the morning. Several studies report that the sensitivity of sputum AFB smear and culture for tuberculosis in HIV-infected patients is similar to that seen in the overall population; other studies report that its sensitivity is lower. The sensitivity of sputum AFB smear for *M. tuberculosis* ranged from 50% to 60% in two large series; in HIV-infected persons with disseminated disease, the sensitivity was significantly higher (90%). In one of these studies, the proportion of patients who were sputum AFB smear positive was no different in those with normal chest radiographic findings and those with abnormal findings. Thus, all patients with suspected tuberculosis, even if the findings on chest radiography are negative, should have two to three sputum specimens sent for AFB smear and culture. Patients with a positive AFB smear must be presumed to have tuberculosis, and appropriate measures must be instituted while awaiting either culture or nucleic acid amplification test results. Patients with negative sputum AFB smear results may still have tuberculosis detected on culture or determined by clinical and radiographic response but are at reasonably low likelihood for transmission, so respiratory isolation (if hospitalized) can be discontinued. A single positive sputum AFB culture result for *M. tuberculosis* is diagnostic of tuberculosis, but the same cannot be said for a sputum specimen positive for a nontuberculous mycobacterium (i.e., *Mycobacterium kansasii, M. avium* complex). In these patients a positive sputum culture can be due to colonization, and determination of when these mycobacteria are causing pulmonary disease relies on a constellation of clinical, radiographic, and microbiologic criteria.

Most patients with *Pneumocystis* pneumonia have a dry, nonproductive cough, and sputum must be induced. Sputum induction should be performed in a properly engineered room to minimize transmission of infectious microorganisms. Sputum induction is a sensitive diagnostic test for *Pneumocystis* pneumonia, with a reported sensitivity ranging from 55% in early studies to 95% with fluorescent antibody testing. At institutions where sputum induction is performed, the need for bronchoscopy is decreased significantly. In addition, induced sputum has led to the diagnosis of cases of certain bacterial, mycobacterial, fungal, and parasitic pneumonias and suggested the presence of bacterial bronchitis/bronchopneumonia. Polymerase chain reaction–based assays applied to noninvasive respiratory specimens (i.e., oropharyngeal washing or gargle) have been reported to have encouraging results but are typically available only in a research setting. Thus, sputum induction should be the initial diagnostic test for patients with suspected *Pneumocystis* pneumonia at institutions where it is available.

Although experience is limited when compared with that for tuberculosis and *Pneumocystis* pneumonia, sputum examination, culture, or both can occasionally diagnose fungal pneumonias, including *C. neoformans*, *H. capsulatum*, and *C. immitis*, but not invasive *Aspergillus* disease.

Bronchoscopy

Bronchoscopy is a mainstay in the diagnosis of HIV-associated pulmonary disease. It should be considered for any patient with pulmonary disease whose severity warrants prompt and accurate diagnosis, for patients with suspected pulmonary KS, for patients in whom the diagnosis is unclear despite less invasive diagnostic tests (e.g., sputum), and for those who are failing empirical therapy for a presumed pathogen.

Bronchoscopy with BAL is the "gold standard" diagnostic test for *Pneumocystis* pneumonia. The sensitivity of BAL alone for *Pneumocystis* pneumonia is reported to be 95% or greater. Bronchoscopy with BAL can be performed in patients with suspected *Pneumocystis* pneumonia whose induced sputum examination is negative. There are institutional differences in the sensitivity of BAL, and both BAL and transbronchial biopsy (TBBX) are warranted at institutions where the yield of these two procedures is complementary.

Bronchoscopy is an important modality for diagnosing cryptococcal pneumonia, especially if the disease is limited to the lungs. BAL fluid culture has

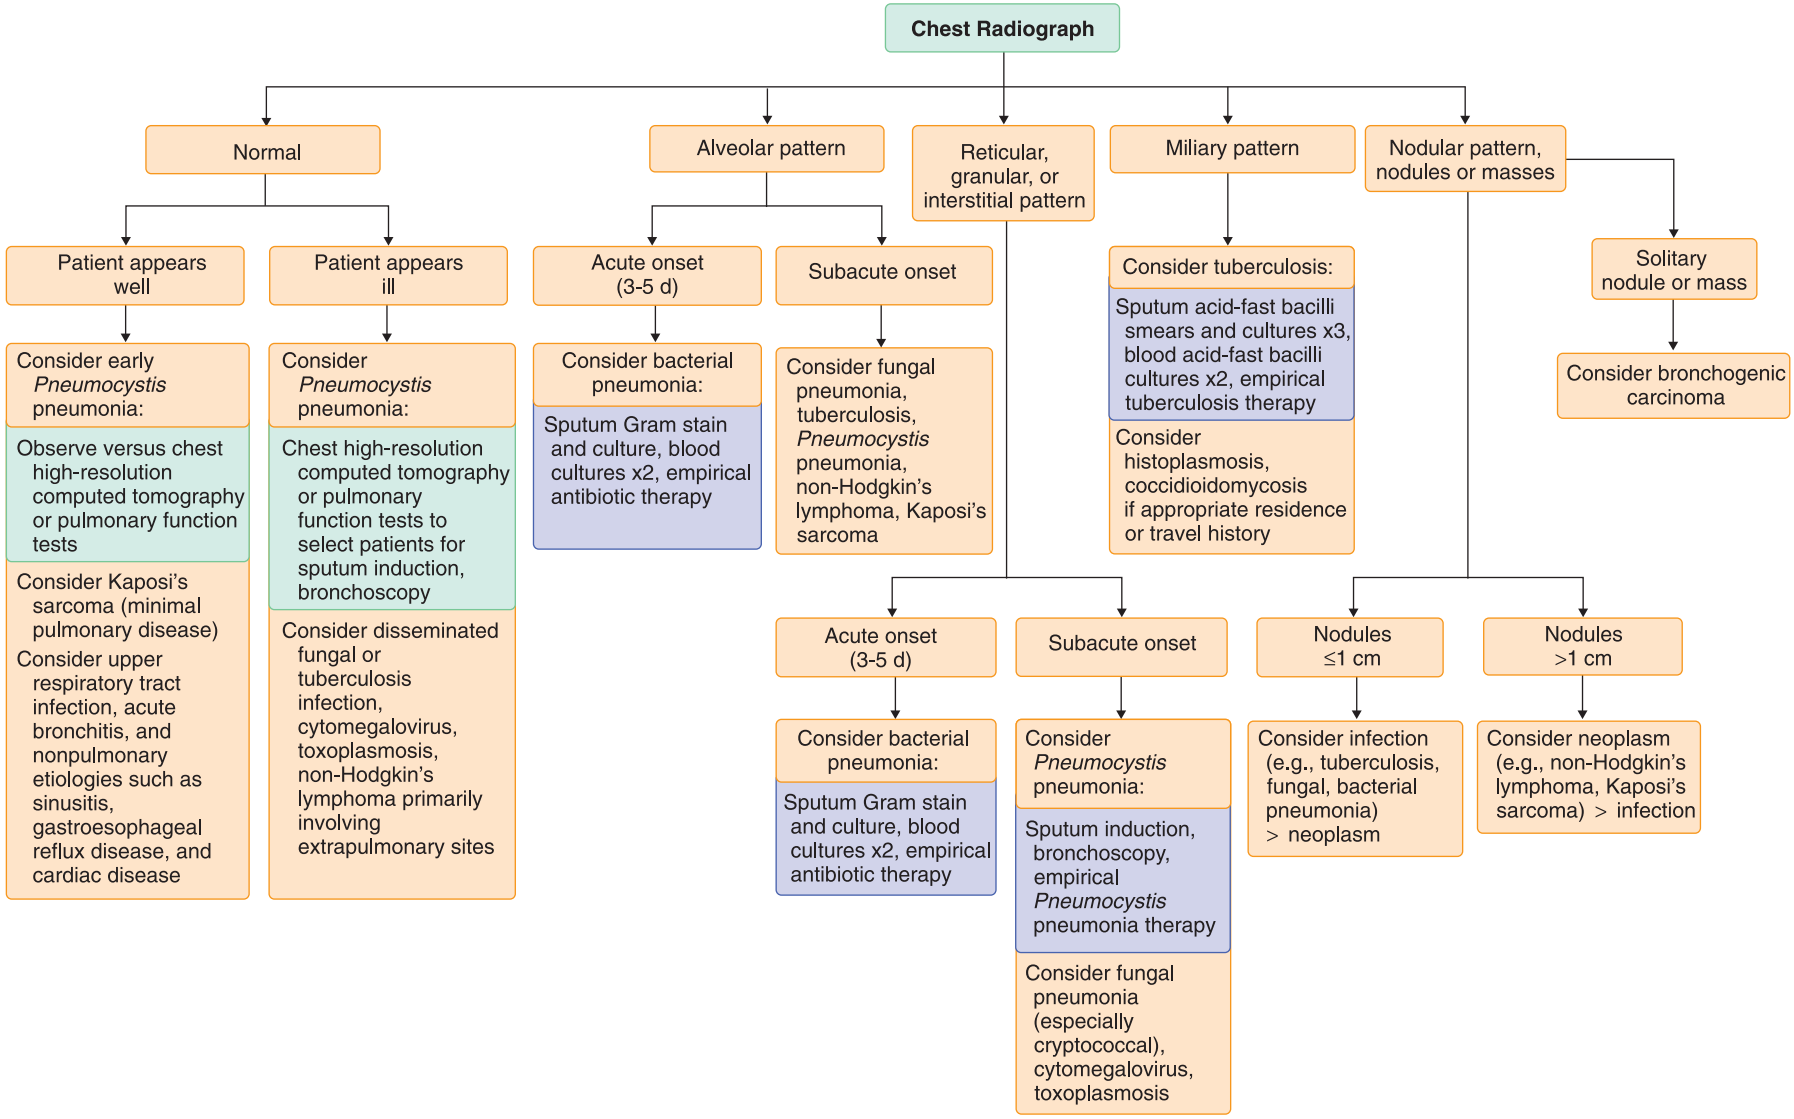

FIGURE 398-10. Diagnostic approach to an HIV-infected patient with suspected pulmonary disease, CD4⁺ cell count less than 200 cells/μL, according to the predominant chest radiograph findings. Some of the diagnoses listed usually occur when the CD4⁺ cell count is below 100 cells/μL or even below 50 cells/μL (see Table 398-3).

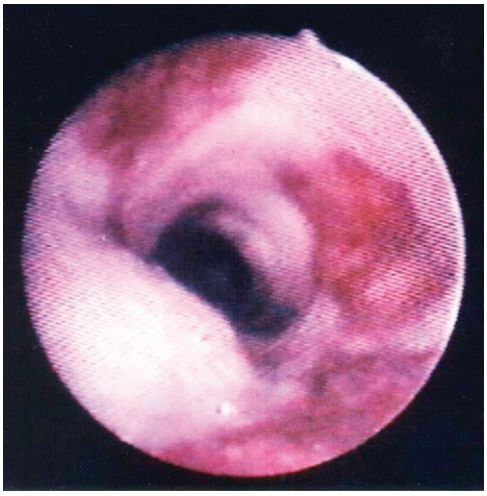

FIGURE 398-11. Characteristic Kaposi's sarcoma lesions located in the trachea in an HIV-infected person, CD4⁺ cell count less than 100 cells/μL. Concurrent bronchoalveolar lavage also revealed *Pneumocystis* pneumonia.

been reported to be positive in more than 80% of HIV-infected patients with cryptococcal pneumonia.

Bronchoscopy with a thorough visual inspection of the airways is the procedure of choice for the diagnosis of pulmonary KS. In these patients, neither TBBX nor endobronchial biopsy adds to the yield when the characteristic KS lesions are seen (Fig. 398-11). However, the absence of visible KS lesions does not preclude their presence in more distal airways, nor does it preclude the possibility of parenchymal KS involvement. In these select patients, TBBX can occasionally establish the diagnosis.

Bronchoscopy with BAL may diagnose *M. tuberculosis* (although the diagnostic yield improves with the addition of TBBX), *H. capsulatum*, *C. immitis*, and *T. gondii* pneumonia. Bronchoscopy with TBBX (or other tissue biopsy specimen) is required to establish a definitive diagnosis of *Aspergillus* and cytomegalovirus pneumonia. Similarly, biopsy is an important tool for the diagnosis of pulmonary disease caused by non-Hodgkin's lymphoma and lung cancer.

Other Procedures

Diagnostic thoracentesis should be considered for any HIV-infected patient with evidence of pleural effusion in whom other tests are nondiagnostic or empyema is a concern. In most situations, pleural fluid culture or cytology in the case of non-Hodgkin's lymphoma or lung cancer can establish the diagnosis. However, in patients with pleural effusion and suspected tuberculosis, the diagnostic yield is improved with the addition of pleural biopsy.

CT-guided transthoracic needle aspiration is an important and useful diagnostic procedure for selected patients. HIV-infected patients with focal parenchymal lesions, most often peripheral lung nodules or masses that may be beyond the reach of a bronchoscope, are ideal candidates for CT-guided aspiration. Mediastinoscopy should be considered for patients with a mediastinal mass or adenopathy, or both. Video-assisted thoracoscopic surgery can be an important procedure in selected patients.

Occasionally, despite all these efforts, HIV-infected patients with pulmonary disease may elude definitive diagnosis. In such patients, consideration should be given to open lung biopsy, although the results have been mixed. Even though open lung biopsy often provides important new information, patients who undergo this procedure are frequently already so ill that this new information fails to translate into improved survival.

Complications

Noninfectious Complications

The focus of the evaluation and management of respiratory symptoms in an HIV-infected patient is frequently placed on opportunistic infections and their prompt diagnosis and treatment. However, several noninfectious complications associated with HIV infection warrant discussion.

Kaposi's Sarcoma

The overwhelming majority of HIV-infected patients with KS in the United States are men who have sexual relationships with other men (Chapter 400). Clinically symptomatic pulmonary KS occurs at the lower range of CD4⁺ cell counts, but tracheobronchial lesions may be seen in patients with higher CD4⁺ counts who are undergoing bronchoscopy for other reasons. Most patients with pulmonary KS have mucocutaneous disease.

Pulmonary KS is characterized by nonproductive cough, dyspnea, and occasionally fever. Chest pain and hemoptysis are less frequently noted. Symptoms are usually present for weeks or months but may also progress rapidly in a manner indistinguishable from opportunistic infection. Pulmonary KS is characteristically accompanied by bilateral middle to lower lung zone opacities in a central or perihilar distribution; the presence of isolated upper lung zone opacities should raise suspicion for opportunistic pneumonia. Typical chest radiographic findings include linear densities (bronchial wall thickening), nodules or nodular opacities of varying size, Kerley's B lines, pleural effusions, and intrathoracic adenopathy. Chest CT often demonstrates the characteristic peribronchovascular distribution with associated nodules.

The diagnosis of pulmonary KS is usually established by bronchoscopy. The finding of characteristic endobronchial, reddish purple, flat or slightly raised lesions is sufficient to diagnose pulmonary disease in the proper clinical context (Fig. 398-11). Most patients with chest radiographic findings suggestive of pulmonary KS have endobronchial KS lesions seen below the level of the carina. However, the absence of lesions in the observable airway does not preclude more distal airway disease or parenchymal, pleural, or nodal involvement. When clinical suspicion for pulmonary KS is strong but no endobronchial KS lesions are seen, TBBX should be considered to establish the diagnosis. A significant proportion of patients with pulmonary KS have concurrent opportunistic infection, and patients undergoing evaluation for pulmonary KS should be concomitantly evaluated for opportunistic infection.

Non-Hodgkin's Lymphoma

Most HIV-infected patients with non-Hodgkin's lymphoma have widely disseminated disease and extranodal involvement (Chapter 400). Frequent extranodal sites include the liver, spleen, bone marrow, meninges, and gastrointestinal tract, whereas intrathoracic involvement is seen in a smaller proportion. Occasionally, the lung is the only site involved. Patients with non-Hodgkin's lymphoma can have a wide range of CD4⁺ counts.

When the lungs are involved, the most common symptoms are cough and dyspnea, with pleuritic chest pain and hemoptysis occurring less frequently. Classic "B" symptoms such as fever, sweats, and weight loss are also common features. The most frequent parenchymal lung findings on chest radiography are multiple nodular opacities or masses, lobar infiltrates, and diffuse interstitial infiltrates. Occasionally, a solitary nodule or mass is seen. Pleural effusions are the most common radiographic abnormality; they are detected in 40 to 70% of cases and may occur in the absence of parenchymal disease. Hilar and mediastinal adenopathy is found in up to 60% of patients.

The diagnosis of non-Hodgkin's lymphoma requires demonstration of malignant lymphocytes on cytology or biopsy specimens. Persons with isolated intrathoracic involvement should undergo bronchoscopy with biopsy or CT-guided transthoracic needle aspiration. Other options include mediastinoscopy, thoracoscopy, and open lung biopsy. For patients with effusions, pleural fluid cytology or biopsy (or both) is often diagnostic.

Lung Cancer

The incidence of lung cancer is higher in HIV-infected persons than in non–HIV-infected persons. Whether this increased incidence is due to HIV infection itself or to potential confounders such as greater rates of tobacco smoking in HIV-infected persons remains somewhat controversial. Most HIV-infected persons in whom lung cancer develops are tobacco smokers. Adenocarcinoma is the most frequently reported type. The clinical and chest radiographic findings, diagnosis, and management of lung cancer in HIV-infected patients are identical to those in immunocompetent patients (Chapter 197). Importantly, HIV infection should not be considered a contraindication to resection but instead be considered an important concurrent underlying medical problem, much the same as one would consider underlying cardiac or pulmonary disease. The median survival in HIV-infected patients with lung cancer is similar to that of age-matched, non–HIV-infected lung cancer patients.

Nonspecific Interstitial Pneumonitis

Nonspecific interstitial pneumonitis (NSIP) has been reported at various frequencies. Because it is a histologic diagnosis, its incidence depends partly on the frequency that biopsy is performed during the diagnostic evaluation.

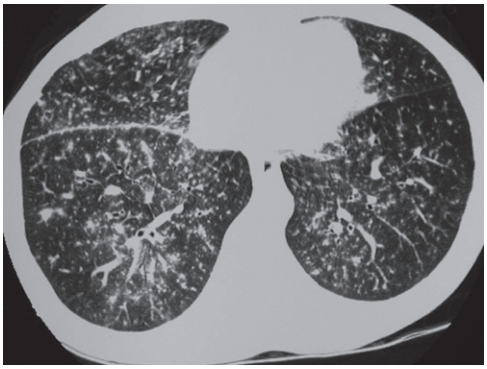

FIGURE 398-12. Chest high-resolution computed tomography in an HIV-infected person, CD4$^+$ cell count less than 200 cells/μL. Lymphocytic interstitial pneumonitis was diagnosed by transbronchial biopsy.

Symptoms of NSIP include dyspnea, nonproductive cough, and fever. These clinical features are indistinguishable from *Pneumocystis* pneumonia. However, NSIP may occur at CD4$^+$ cell counts higher than 200 cells/μL, whereas *Pneumocystis* pneumonia rarely does. Chest radiographic findings in patients with NSIP are nonspecific and usually indistinguishable from those of *Pneumocystis* pneumonia, and as with *Pneumocystis* pneumonia, patients with NSIP can have normal radiographic findings. The most common radiographic abnormality seen was a diffuse interstitial pattern. Other abnormalities include pleural effusions, alveolar infiltrates, and nodules. Pulmonary function tests often reveal a mildly decreased diffusing capacity. The diagnosis of NSIP requires histologic confirmation and exclusion of other causes.

Lymphocytic Interstitial Pneumonitis

The most striking feature of HIV-associated lymphocytic interstitial pneumonitis (LIP) is the effect of age on its incidence. LIP has been a frequent AIDS-defining diagnosis in children but is rare in adults. Symptoms of LIP include slowly progressive dyspnea, nonproductive cough, and fever indistinguishable from that caused by opportunistic infection. The chest radiograph is nonspecific in patients with LIP and characteristically shows bilateral reticulonodular "interstitial" infiltrates with lower lung zone predominance. Hilar or mediastinal adenopathy is occasionally seen and can potentially be used to distinguish LIP from *Pneumocystis* pneumonia. Pulmonary function tests often reveal a restrictive ventilatory defect and a decreased diffusing capacity. Chest CT demonstrates small (2 to 4 mm) nodules, frequently in a peribronchovascular distribution, or diffuse areas of ground-glass opacity (Fig. 398-12). The diagnosis of LIP requires histologic confirmation by biopsy.

Pulmonary Arterial Hypertension

Increasingly, pulmonary arterial hypertension (Chapter 68) is being recognized as an HIV-associated condition, although many HIV-infected persons with this condition have concurrent risk factors for pulmonary hypertension (e.g., cigarette smoking resulting in COPD and end-stage liver disease causing portal hypertension). The characteristic clinical manifestation is progressive dyspnea, with nonproductive cough, chest pain, and syncope or near-syncope seen in a minority. Chest radiographic findings include cardiomegaly and prominence of the pulmonary arteries. Most often, a chest radiograph or an electrocardiogram with evidence of right ventricular hypertrophy first suggests the diagnosis of pulmonary hypertension. Patients in whom pulmonary hypertension is diagnosed should undergo an evaluation for secondary causes, including underlying cardiac and pulmonary diseases (e.g., COPD, recurrent pulmonary emboli). In general, treatment of HIV-associated pulmonary arterial hypertension is similar to that in non–HIV-infected persons (Chapter 68), except that concurrent antiretroviral therapy has been used, with varying success.

Chronic Obstructive Pulmonary Disease

COPD (Chapter 88) is emerging as an HIV-associated condition. Early reports suggested that HIV-infected cigarette smokers were at greater risk for the development of emphysema than were HIV-infected nonsmokers or nonimmunocompromised cigarette smokers, and large cohort studies support this association. In addition to cigarette smoking, repeated opportunistic pulmonary infections may eventually result in the development of chronic bronchitis and bronchiectasis. The clinical and radiographic findings, diagnosis, and management of obstructive lung disease in HIV-infected patients are identical to that in immunocompetent patients (Chapter 88), including the use of inhaled corticosteroids, when indicated.

Sarcoidosis

Several cases of sarcoidosis in HIV-infected patients have been reported. In these cases the clinical and radiographic manifestations, diagnosis, and clinical course with corticosteroid therapy were similar to cases of sarcoidosis in non–HIV-infected persons (Chapter 95).

Pulmonary Manifestations of Immune Reconstitution Inflammatory Syndromes

The initiation of combinations of potent antiretroviral medications and the subsequent improvement in immune function have also resulted in several syndromes that have important clinical implications (Chapter 402). Interestingly, in some of the reports, the use of antiretroviral therapy transiently exacerbated the disease, whereas in others, its use was seemingly solely responsible for the reported improvements. Finally, in some cases, the use of antiretroviral therapy has been associated with the development of pulmonary disease that is host mediated.

The transient worsening of clinical symptoms and signs and chest radiographic findings of tuberculosis after the initiation of appropriate antituberculous therapy has been well recognized. These paradoxical reactions are thought to represent an enhanced antituberculous immune response, and they usually resolve with continued therapy alone. HIV-infected patients in whom tuberculosis develops and who receive concurrent antiretroviral and antituberculous therapy appear to have an increased incidence of paradoxical worsening and immune reconstitution inflammatory syndrome. The radiographic findings can consist of new or worsening parenchymal disease, new or worsening intrathoracic lymphadenopathy, and new or worsening pleural effusion. HIV-infected patients with tuberculosis and suspected paradoxical reactions must also be thoroughly evaluated for progressive tuberculosis resulting from drug resistance or patient nonadherence and for the presence of a concurrent, superimposed opportunistic infection.

Similar to tuberculosis, paradoxical reactions in HIV-infected patients have been reported in those receiving concurrent therapy for HIV and opportunistic infection, including important pulmonary pathogens such as *Pneumocystis* and *Cryptococcus*. In some of these cases the manifestations of immune reconstitution are severe and patients require mechanical ventilation for respiratory failure.

The use of antiretroviral therapy, even in the absence of specific chemotherapy, often results in clinical regression and, occasionally, complete resolution of KS lesions (including pulmonary KS). However, case reports also indicate that patients with pulmonary KS may likewise experience a paradoxical worsening as a result of immune reconstitution inflammatory syndrome.

Improved immune function may also play a role in the development of host-mediated pulmonary disease. There are several reports of sarcoidosis or a sarcoidosis-like disease that developed after the initiation of antiretroviral therapy. In addition, hypersensitivity pneumonitis to avian antigen that developed only after the patient's immune function improved with antiretroviral therapy has been described. Diseases in which the host's immune response plays an essential role in pathogenesis can be expected to become more prevalent as more HIV-infected patients receive potent antiretroviral therapy.

399 SKIN MANIFESTATIONS IN PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION

TOBY MAURER

From the beginning of the epidemic, skin disease has frequently been the initial feature of infection with human immunodeficiency virus (HIV). Cutaneous manifestations are often predictive of the stage of immunosuppression and long-term prognosis. Morbidity from skin diseases, particularly from opportunistic infections, has decreased with the advent of antiretroviral treatment (ART), although there are still significant dermatologic problems for patients in the post-ART era. Cutaneous manifestations seen in patients with HIV may be categorized as infectious, neoplastic, inflammatory, or related to ART.

INFECTIOUS MANIFESTATIONS

HIV Seroconversion Exanthem

Frequently observed in acute HIV infection is an infectious mononucleosis–like illness that precedes seroconversion by 2 to 6 weeks. The rash is characterized by erythematous macules and papules ranging from 2 mm to a few centimeters, particularly on the upper part of the trunk and face with relative sparing of peripheral regions. It is commonly accompanied by aphthous or penile ulceration, or both. There is evidence that very early after infection, HIV goes to dendritic cells in skin and causes an inflammatory response, which may explain the rash. At this stage the viral load may be very high and is suggestive of acute HIV seroconversion, although the HIV antibody test is likely to be negative.

Viruses

Herpes Zoster

Herpes zoster (Chapter 383) is often observed even at relatively normal $CD4^+$ counts and may therefore be the first feature of HIV infection. The mouth may also be affected. In any patient younger than 50 years with zoster, risk factors for HIV should be explored and consideration given to HIV testing. Zoster infection may be multidermatomal or disseminated even in patients with relatively high $CD4^+$ counts, and if it involves the eye, treatment with intravenous acyclovir should be considered. Antiviral treatment should be started at any time during the disease course (not only within the first 48 hours, as with zoster not associated with HIV). Less severe disease normally responds to standard treatment. There have been a few reports of a verrucous chronic form of zoster occurring in more severely immunosuppressed patients; this form of zoster is usually associated with acyclovir resistance. Zoster has been one of the more commonly reported diseases in patients with immune reconstitution inflammatory syndrome (IRIS) (Chapter 402) and has been noted to appear in the second phase of IRIS, that is, later than the initial 3 months of ART.

Herpes Simplex Virus

Infection with herpes simplex virus (HSV) (Chapter 382) should always be considered in patients with HIV who have mucocutaneous ulcerations (Fig. 399-1), particularly in the anogenital area. Patients with $CD4^+$ counts lower than 200 cells/μL may require higher doses of acyclovir to treat the infection. (See Table 399-1 for skin conditions occurring at $CD4^+$ counts lower than 200 cells/μL in patients not receiving ART.) Patients who fail to respond may have HSV with acyclovir resistance, and alternative agents such as foscarnet or cidofovir may be required. The presence of HSV clinically or subclinically increases the likelihood of transmission of HIV. There also appears to be synergy between HSV and HIV, which may mean faster progression of HIV disease. Daily acyclovir therapy to suppress coinfection with HSV-2 has recently been found not to reduce the risk for transmission of HIV.■

Human Papillomavirus

Human papillomavirus infection (Chapter 381) is very common in all stages of HIV infection. Common, flat, genital, and plantar warts are all seen with increased frequency. Patients with significant immunosuppression may have particularly extensive warts that are recalcitrant to standard treatment. Most patients commencing ART often notice considerable improvement or resolution of the warts. However, some patients receiving ART will not clear their warts despite improvement in the $CD4^+$ count, suppressed viral load, and resolution of all other opportunistic infections. The reasons for this observation remain obscure. Treatment modalities include cryotherapy, surgery, laser, topical salicylic acid preparations, podophyllin, intralesional bleomycin, and contact sensitization immunotherapy. Imiquimod has proved to be a useful modality for genital warts but appears to be less effective in the HIV setting. Anal carcinoma and anal intraepithelial neoplasia are frequent in HIV-infected patients (men and women), and screening anal Papanicolaou smears may be helpful in identifying anal dysplasia.

FIGURE 399-1. Chronic herpes simplex infection.

TABLE 399-1 SKIN CONDITIONS COMMON IN PATIENTS WITH $CD4^+$ COUNTS LESS THAN 200 CELLS/μL AND NOT RECEIVING ANTIRETROVIRAL THERAPY

Photodermatitis
Psoriasis, difficult to control or involving more than 50% of the body
Pruritic papular eruption associated with HIV infection
Prurigo nodularis
Oral hairy leukoplakia
Molluscum contagiosum
Eosinophilic folliculitis

TABLE 399-2 SKIN CONDITIONS THAT CAN OCCUR AT ANY $CD4^+$ COUNT

Eczema
Xerosis
Tinea/onychomycosis
Kaposi's sarcoma
Warts
Syphilis

Molluscum Contagiosum

Molluscum contagiosum is a poxvirus (Chapter 380) that causes a self-limited papular umbilicated eruption commonly seen in children. It is rarer in adults and, when present on the face, persistent, or severe, raises the possibility of HIV coinfection. It tends to occur when the $CD4^+$ count falls below 200 cells/μL. First-line treatment is ART because molluscum contagiosum is invariably cleared with rising $CD4^+$ counts. Ablative treatments such as cryotherapy or curettage will treat individual lesions more expeditiously but can leave scarring; however, without ART the lesions are likely to recur.

Epstein-Barr Virus (Oral Hairy Leukoplakia)

Oral hairy leukoplakia (OHL) is characterized by nonpainful white plaques with a feathered edge, particularly on the lateral border of the tongue. It is associated with Epstein-Barr virus (Chapter 385) and is very rare in immunocompetent hosts. OHL can occur at any $CD4^+$ count and may therefore be the initial feature of HIV infection. (See Table 399-2 for skin diseases not

FIGURE 399-2. Staphylococcal folliculitis.

affected by the $CD4^+$ count.) The appearance of OHL was a poor prognostic indicator before ART. There is no specific treatment of OHL, although it tends to resolve when patients are receiving ART. Superinfection with *Candida* spp should be considered if the lesions are painful.

Bacteria

Staphylococcus aureus

Infections with *Staphylococcus aureus* (Chapter 296) are commonly seen in HIV disease. Staphylococcal folliculitis (Fig. 399-2) tends to be more severe or refractory to treatment in HIV-infected patients than in those who are HIV negative. Other cutaneous manifestations of staphylococcal infection include cellulitis, ecthyma (necrotic plaques), or, rarely, botryomycosis. Treatment of folliculitis includes antiseptic washes such as chlorhexidine solution, eradication of nasal carriage with mupirocin ointment, and, occasionally, systemic antibiotics. More severe infections may require intravenous antibiotics. There has been concern that patients infected with HIV are at increased risk for the development of infections, particularly recurrent infections with methicillin-resistant *S. aureus* (MRSA). Rifampicin is often used to clear MRSA, but caution should be used in patients receiving ART because rifampicin is a potent inducer of cytochrome P-450 and will therefore interfere with protease inhibitors. Risk factors for infection, including colonization with *S. aureus*, are being explored.

Bartonella

Bacillary angiomatosis is caused by *Bartonella* species (most commonly *Bartonella henselae* and *Bartonella quintana*) (Chapter 323). Occult infection with *Bartonella* should be considered in any HIV-infected patient with fever of unknown origin. The cutaneous lesions appear as purple papules, nodules, or ulcers in HIV-positive individuals. Clinically, they may resemble lesions of Kaposi's sarcoma (KS) and may also be confused with pyogenic granuloma or cutaneous lymphoma. These lesions should always undergo biopsy with tissue sent for culture. Bacillary angiomatosis responds to antibiotics such as macrolides, which will be needed for at least a 2-month course of treatment. Bacillary angiomatosis can be associated with visceral disease; in particular, the liver and spleen may be affected.

Syphilis

Syphilis (Chapter 327) is frequently seen in patients with HIV infection. Its cutaneous manifestations are protean, and therefore syphilis should be considered in any patient infected with HIV who has a new cutaneous eruption. An example of a secondary syphilis exanthem is shown in Figure 399-3. Primary, secondary, and tertiary forms of syphilis may be manifested clinically as they are in HIV-negative individuals, although atypical findings are not uncommon. Serology is not as reliable in patients with HIV infection, and skin biopsy may be useful in establishing the diagnosis. First-line

FIGURE 399-3. Secondary syphilis.

treatment is still with penicillin. Azithromycin resistance has been reported. Follow-up titers of syphilis serology should be documented to ensure adequate treatment and central nervous system (CNS) clearance.

Fungi

Candida

Oral candidiasis (Chapter 346) is commonly seen in patients with immunodeficiency, including HIV infection. It is characterized by white, cheesy plaques and papules loosely adherent to the tongue and oropharynx. Topical therapies include clotrimazole troches and nystatin oral suspension. First-line oral treatment is with fluconazole, although there is emerging resistance in *Candida* species, including *Candida albicans*, the most common species associated with thrush. Second-line treatment consists of oral itraconazole, although it is unclear whether pulsed therapy is preferable.

Dermatophytes

The prevalence of dermatophyte infection (Chapter 446) is not higher in HIV-infected patients than in control groups. However, increased severity and variability in the manifestations of dermatophyte infection are seen in HIV coinfection. Tinea corporis and tinea cruris can occur at all stages of immunosuppression and may be treated successfully with topical antidermatophytic preparations such as ketoconazole or terbinafine. Treatment of onychomycosis is systemic therapy with oral antifungals, although onychomycosis recurrence rates have not been studied.

Other Fungi

Cryptococcus neoformans is a yeast that tends to cause clinical problems when patients are profoundly immunosuppressed ($CD4^+$ count <100 cells/μL). It commonly affects the CNS and causes meningitis, but it can affect the skin and give rise to papules indistinguishable from molluscum contagiosum. *Histoplasma capsulatum* and *Penicillium marneffei* may morphologically resemble molluscum. Patients who have had these diseases need long-term suppressive doses of antifungal medications.

Infestations

Scabies

Scabies (Chapter 367) is caused by infestation with the mite *Sarcoptes scabiei* and is commonly seen in HIV-infected individuals. It can be manifested as the classic rash of scabies with burrows affecting the finger and toe webs and widespread excoriated papules with a predilection for the axillae, nipples, and genitalia. It can also appear as crusted scabies with hyperkeratotic plaques that tend not to be pruritic. Combination treatment with a topical agent such as permethrin or benzoyl benzoate and systemic treatment with ivermectin tablets is recommended for crusted scabies. Topical agents may be sufficient for classic scabies. Lindane lotion is often used to treat scabies, but there have been reports of lindane-resistant scabies and neurologic side effects attributed to this treatment.

TUMORS

Kaposi's Sarcoma

KS is the most common HIV-associated malignancy (Chapter 400), but since the introduction of ART, there has been a significant decrease in its incidence. It is characterized by dusky, purple nodules and plaques with

FIGURE 399-4. Kaposi's sarcoma.

a predilection for the extremities and the oral mucosa (Fig. 399-4). Poor prognostic factors include lymphedema and internal organ involvement. It is caused by human herpesvirus 8, also known as Kaposi's sarcoma–associated virus. The virus may be transmitted vertically, sexually, or casually, and its presence is necessary for the development of KS. First-line treatment consists of ART, with the addition of chemotherapy for aggressive or unresponsive KS.

Malignant Melanoma and Nonmelanoma Skin Cancer

Malignant melanoma (Chapter 210) may develop at an increased incidence in HIV-positive patients. The behavior of melanoma in the ART era is unclear. There appears to be a three-fold increased risk for the development of nonmelanoma skin cancer in patients with HIV disease. The clinical manifestations of squamous cell carcinoma (SCC) and basal cell carcinoma (BCC) do not appear to be any different than those in the uninfected population (Chapter 210). However, in the context of HIV infection, SCC behaves more aggressively and is associated with reduced survival. Management of SCC is surgical excision, whereas curettage and electrodesiccation may be appropriate for BCC lesions on the extremities or trunk. Surgical excision should be the treatment of choice for BCC on the face.

INFLAMMATORY MANIFESTATIONS

Immune Reconstitution Inflammatory Syndrome

After commencement of ART, a subset of patients experience unmasking of new skin disease or paradoxical worsening of existing dermatologic conditions, attributable to IRIS (also see Chapter 402). The list of skin manifestations of IRIS continues to grow, with the current literature highlighting the emergence of tropical skin diseases, such as leishmaniasis and leprosy, manifested in the context of immune recovery. Increasingly, we are recognizing that common skin eruptions such as acne may be associated with IRIS. *Mycobacterium avium* infection can be associated with cutaneous ulceration and an epidermodysplasia verruciformis–like eruption of warts.

Certain cutaneous diseases are more common in early versus late IRIS, such as herpes zoster. Cutaneous KS can be manifested as organ involvement during IRIS. Eosinophilic folliculitis is one of the more common manifestations of IRIS and can be seen within the first 16 weeks of ART. It may be confused with a drug reaction, but the distribution of urticarial papules on the scalp, neck, face, upper part of the chest, and upper part of the back is a distinguishing factor. HSV disease may be seen 3 to 4 months into treatment and is thought to appear in the later stages of immune reconstitution.

Seborrheic Dermatitis

Seborrheic dermatitis is a common dermatosis in the general population, but it has a strikingly increased prevalence in HIV-infected patients, and its frequency increases with more severe immunosuppression. It appears as orange-red scaly patches affecting the scalp, eyebrows, nose, and cheeks. Seborrheic dermatitis can also affect the central portion of the chest and genitalia. It responds well to a combination of topical antifungals such as econazole or ketoconazole and low-potency corticosteroids. The condition also tends to improve with ART.

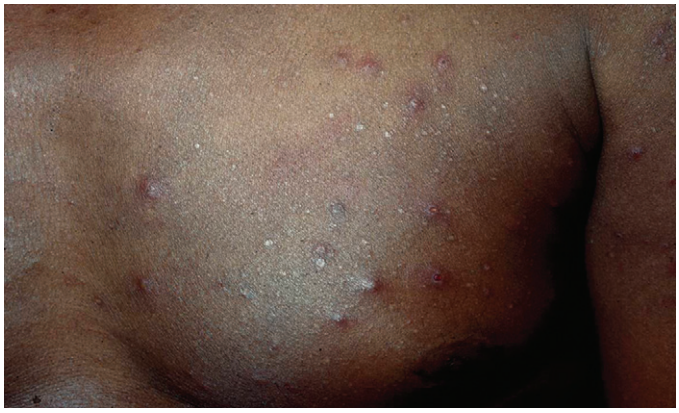

FIGURE 399-5. Eosinophilic folliculitis.

Atopic Dermatitis

Atopic dermatitis is common in HIV-infected patients. As with other dermatoses, it improves with ART, but in patients who had a $CD4^+$ nadir of less than 200 cells/μL, it tends to be more persistent, even with ART. Treatment consists of topical steroids and emollients as in the non–HIV-infected population. Topical pimecrolimus and tacrolimus are licensed for the treatment of atopic dermatitis, but their safety has not been demonstrated in patients with HIV infection.

Psoriasis

HIV infection can be associated with severe psoriasis (Chapter 446) as the $CD4^+$ count drops. This observation is paradoxical because psoriasis is thought to be a T-cell-mediated disease but may be explained by immune dysregulation. Topical treatments, systemic retinoids, and ultraviolet phototherapy are all reasonable treatment options. Immunosuppressive agents such as methotrexate and cyclosporine should be avoided if possible. ART invariably reduces the severity of psoriasis.

Papular Pruritic Eruption of HIV

Papular pruritic eruption is commonly seen in Africa and Asia in association with HIV. It should be considered in the differential diagnosis of any widespread itchy dermatosis, but it does appear to be a separate entity. Papular pruritic eruption has a rather nondescript appearance of red excoriated papules on the trunk and limbs. Other itchy skin diseases such as eczema or eosinophilic folliculitis should be considered in the differential diagnosis. Recent evidence has suggested that exaggerated arthropod bite reactions may be the predominant cause. Potent topical corticosteroids and, anecdotally, ART have been of benefit.

Eosinophilic Folliculitis

Eosinophilic folliculitis is characterized by edematous papules and pustules on the face and upper part of the trunk (Fig. 399-5). These lesions are intensely itchy, and skin biopsy is helpful in ruling out other causes of folliculitis. Eosinophilic folliculitis tends to be seen when $CD4^+$ counts are lower than 200 cells/μL and may improve with ART. It can also be seen as a manifestation of IRIS within the first 16 weeks of ART. Treatments such as itraconazole, permethrin, retinoids, and phototherapy are all effective.

Prurigo Nodularis

In patients with prurigo nodularis, symmetrically distributed papules and nodules develop on the limbs and trunk with sparing of the midportion of the back (because of inaccessibility for scratching). It is commonly seen in HIV-infected persons, is sometimes associated with hepatitis C virus coinfection, and may be exacerbated by light. Standard treatment options include emollients, potent topical steroids, and sedating antihistamines such as chlorpheniramine or hydroxyzine. Thalidomide is often effective in recalcitrant cases but requires careful monitoring for peripheral neuropathy, and women of childbearing potential require effective contraception.

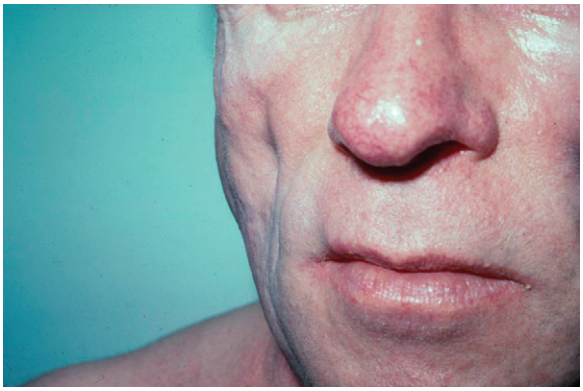

FIGURE 399-6. HIV-associated facial lipoatrophy.

TABLE 399-3 MOST COMMON SKIN DISEASES SINCE THE ADVENT OF ANTIRETROVIRALS

Acne
Staphylococcal infections of soft tissue and skin
Erythema nodosum
Eosinophilic folliculitis
Lipodystrophy

METABOLIC MANIFESTATIONS

HIV Lipodystrophy Syndrome

Lipodystrophy syndrome consists of peripheral lipoatrophy, central lipohypertrophy, lipid abnormalities, and insulin resistance. It is likely that it is caused by a number of factors, including ART (Chapter 396) (Table 399-3), although it is unlikely that a single agent is responsible. Cutaneous facial lipoatrophy tends to be the most problematic dermatologic aspect, with significant associated psychological morbidity (Fig. 399-6). Currently, no treatments are effective for lipodystrophy syndrome, although surgical correction with dermal fillers may improve the cosmetic appearance.

HEMATOLOGY AND ONCOLOGY IN PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION

PAUL A. VOLBERDING

A wide variety of cancers and hematologic disorders remain important clinical complications of infection with human immunodeficiency virus (HIV) despite advances in HIV suppression with antiretroviral (ARV) drug regimens. Hematologic abnormalities can be caused by HIV infection itself, be a consequence of immune deficiency and related opportunistic infections, or result from side effects of drugs used to manage HIV disease. Acquired immunodeficiency syndrome (AIDS)-defining cancers (ADCs) usually occur in patients with advanced immune deficiency and a second infection in addition to HIV. Recently, reports have described an increased incidence of a widening spectrum of other non–AIDS-defining cancers (NADCs), possibly caused by continued immune activation/inflammation, even in the setting of seemingly successful ARV therapy. Cancers and hematologic disorders have changed with the advent of effective ARV therapy. Study of these clinical problems affords insight into the consequences of immune deficiency and its reversal and highlights the benefits and limitations of ARV treatment.

HIV HEMATOLOGY

Disorders in all major blood cell lines were recognized early in the HIV epidemic. The underlying biology of HIV-associated hematologic disease is complex and often involves multiple lineages and mechanisms of pathogenesis. HIV itself infects cells involved in hematopoiesis or disturbs the bone marrow microenvironment. HIV infection also causes both immune activation and immune deficiency. The former, analogous to inflammation, can cause anemia of chronic disease (also called *anemia of inflammation,* Chapter 161), whereas the dysregulation of lymphocyte subsets can disrupt the balance of cytokines and other factors needed for normal myelopoiesis. The combination of immune activation and dysregulation can also contribute to hypergammaglobulinemia and reticuloendothelial activation and result in accelerated blood cell destruction. The effect of ARV therapy on HIV-associated hematologic disease is similarly complex. ARV drugs, fortunately ones less commonly prescribed today, have well-described direct hematologic toxicities, but their ability to reverse established immune deficiency and to control HIV infection within marrow reduces the incidence and severity of many HIV-associated hematologic disorders.

Red Blood Cell Disorders and Anemia

The prevalence of anemia in HIV-infected patients varies by threshold definition and demographics. Before the advent of effective ARV therapy, estimates ranged as high as 75%.

EPIDEMIOLOGY

Anemia in HIV-infected patients can be caused by many factors (Table 400-1). Those unrelated to HIV infection, such as the hemoglobinopathies, should always be considered in the differential diagnosis, as should those associated with the mode of HIV acquisition, particularly injection drug use.

HIV-associated anemia is usually caused by decreased red blood cell (RBC) production. RBC loss from bleeding or intravascular hemolysis can occur but is less common. Decreased RBC production is seen with chronic inflammation, nutritional deficiencies, erythropoietic defects, and marrow suppression as a result of infection or drug therapy.

Anemia of chronic disease (anemia of chronic inflammation) follows ineffective iron utilization in the setting of an underlying chronic inflammatory process (Chapter 161). Iron studies generally show reductions in serum iron and transferrin concentrations. RBCs are typically normochromic and normocytic. In HIV-infected patients, this anemia presumably reflects the chronic infection of lymphocytes and ongoing immune activation and cytokine dysregulation. Direct HIV infection of precursor hematopoietic cells may also be involved. The frequency and severity of this anemia are often reduced with the use of effective ARV therapy.

Relative or absolute hypogonadism is common in persons with HIV infection and probably contributes to the reduced erythropoietic effect. This anemia may respond to testosterone replacement. Total and free serum levels of testosterone should be measured in HIV-infected men with anemia. The role, if any, of testosterone deficiency in HIV-infected women with anemia is uncertain.

PATHOBIOLOGY

Infections and Malignancies within Marrow

Bone marrow can be infected by a variety of opportunistic pathogens, especially *Mycobacterium avium-intracellulare* and *Mycobacterium tuberculosis*. The causative relationship of such infections to anemia is complicated by the advanced stage of HIV disease in many of these patients, which may itself cause marrow failure. Fortunately, these serious opportunistic infections are much less common in the era of effective ARV but still occur in patients

TABLE 400-1 CAUSES OF ANEMIA IN HIV-INFECTED PATIENTS

CAUSED PREDOMINANTLY BY DECREASED RED BLOOD CELL PRODUCTION
Anemia of chronic disease (anemia of inflammation)
Hypogonadism and decreased erythropoietic effect
Infections and cancers in marrow
Mycobacterium-avium intracellulare
Mycobacterium tuberculosis
Parvovirus B-19
Bartonella henselae
Bartonella quintana
Non-Hodgkin's lymphoma
Hodgkin's lymphoma
Nutritional deficiency
Iron deficiency
Drug effects
Zidovudine
Trimethoprim-sulfamethoxazole
Ganciclovir
Amphotericin
Cytotoxic chemotherapeutics
Others
CAUSED PREDOMINANTLY BY ACCELERATED RED BLOOD CELL LOSS
Hypersplenism
HIV
Portal hypertension from hepatitis C, hepatitis B with cirrhosis
Hemolysis
Microangiopathy—thrombotic thrombocytopenic purpura
Others
Intravascular hemolysis secondary to oxidative stress in glucose-6-phosphate dehydrogenase deficiency and exposure to dapsone and other drugs

unable to access or maintain expert HIV care. The hematologic effects of these infections are reversed with the initiation of ARV therapy and specific treatment of the complicating infection. Chronic parvovirus B19 infection in an HIV-infected patient can cause normocytic anemia as a result of pure red cell aplasia (Chapters 168 and 379). This uncommon cause of HIV-related anemia is rarely seen with effective ARV therapy. It responds to intravenous immunoglobulin that contains parvovirus B19 antibodies. Bacillary angiomatosis, seen with *Bartonella henselae* or *Bartonella quintana* infection (Chapter 323), can also result in anemia. This condition can cause skin lesions resembling those of Kaposi's sarcoma (KS) and responds to antibiotic therapy. HIV-associated cancers, particularly non-Hodgkin's lymphoma (NHL), can involve bone marrow. Extensive marrow replacement by lymphoma may result in anemia or other cytopenias, but it is uncommon.

Nutritional Deficiencies

The presence of severe and complex nutritional deficiencies with extreme wasting is a feature of untreated HIV infection. It was common in the United States before the advent of effective ARV therapy but is now rare. Wasting remains common globally, of course, especially since HIV infection occurs against a backdrop of societal nutritional deficits (Chapter 222). Although severe wasting is less common, many patients have poor diets or other conditions, and deficiencies of vitamins such as folate and B_{12} should be considered, although they are less common than iron deficiency as a cause of anemia in individuals infected with HIV.

Iron Deficiency

Iron deficiency is not uncommon as a cause of anemia in HIV-infected persons. It is most often seen in women and injection drug users. Submucosal KS lesions are seen frequently in the gastrointestinal tract in advanced stages, although they rarely cause sufficient gastrointestinal blood loss to lead to iron deficiency.

Drug Toxicity

In early ARV development, anemia was often seen as a drug toxicity, particularly with zidovudine (or azidothymidine [AZT]). Stavudine (or d4T) can also cause anemia but is most frequently associated with macrocytosis. Stavudine is seldom used outside resource-limited settings because of serious toxicities, and AZT is also seldom used, again because less toxic drugs are now available. Newer ARV drugs rarely cause anemia.

A variety of drugs used to treat HIV-associated conditions can cause bone marrow suppression with resulting anemia, neutropenia, thrombocytopenia, or any combination of these disorders. Such drugs include trimethoprim-sulfamethoxazole, ganciclovir, amphotericin, and many cytotoxic chemotherapeutic agents. These side effects are very common, especially since the infections for which they are prescribed occur in late-stage HIV infection, which is itself a cause of anemia and other hematologic disorders.

Red Blood Cell Antibodies

HIV infection is associated with polyclonal gammopathy as a result of dysregulation and altered balance of the $CD4^+$ and $CD8^+$ cell populations of T lymphocytes and corresponding B-cell function. RBC autoantibodies are not uncommon in patients with HIV infection and cause a positive direct Coombs antiglobulin test (Chapter 163). This is not usually associated with hemolysis and requires no specific therapy.

CLINICAL MANIFESTATIONS

Anemia from accelerated RBC loss in HIV infection is uncommon. Frank bleeding is rare in HIV-infected patients, except in those with concomitant conditions such as portal hypertension from coincident cirrhosis associated with hepatitis B virus (HBV) or hepatitis C virus (HCV) infection. Hypersplenism, most often also seen with portal hypertension, may lead to anemia and other types of cytopenia. Finally, hemolytic anemia (as well as methemoglobinemia) can occur with microangiopathic disease or as a consequence of oxidative stress from some drugs, particularly dapsone, when used in patients with underlying glucose-6-phosphate dehydrogenase deficiency.

Anemia in HIV-infected persons is associated with accelerated disease progression and shortened survival. This association is seen even after adjusting for baseline $CD4^+$ cell counts and plasma HIV load.

Clinical evaluation of anemia in HIV infection is similar to that in other disease settings (Chapter 161), and both HIV-related and HIV-unrelated causes should be explored. Reversible causes are especially important to identify. Peripheral cell counts, including reticulocytes, are determined, as well as careful review of the peripheral blood smear. Iron studies can help differentiate between anemia of chronic disease and iron deficiency. Underlying malignancies and opportunistic infections must be considered, as should exposure to drugs with potential bone marrow suppression, especially AZT. Bone marrow biopsy is rarely indicated specifically for anemia.

TREATMENT Rx

Potent ARV therapy has changed the frequency and severity of anemia in individuals with HIV infection, although it has not eliminated this problem.

Anemia in HIV is managed according to its etiology. Reversible causes such as iron deficiency or unnecessary exposure to a toxic drug should be addressed, as should bone marrow infections or malignancies. ARV therapy should be started if other indications exist. Replacement therapy with testosterone in the case of hypogonadism should be recommended. RBC transfusion is indicated for the acute onset of severe anemia, especially in a patient with underlying cardiovascular disease. Transfusion carries its own set of risks and should be performed only when other options are limited.

The use of replacement erythropoietin in HIV-infected patients is approved in the United States solely for AZT-associated anemia. It has not been shown to prolong survival and is rarely if ever needed because ARV options not associated with anemia are now so available and preferred by HIV treatment guidelines.

White Blood Cell Disorders

Apart from lymphocytes, the primary pathogenic target of HIV infection, the white blood cell population is relatively spared in HIV disease in comparison to other cell lines. Neutrophils are affected to some degree, whereas eosinophils and monocytes usually remain normal in number and function.

Even though neutropenia is not uncommon, it is rarely severe. Neutropenia in HIV infection is most commonly a manifestation of drug toxicity, although HIV infection within bone marrow might contribute to reduced myelopoiesis. Drugs used to treat or prevent opportunistic infections (such as trimethoprim-sulfamethoxazole) or malignancies are common offenders. Neutrophil function is well preserved in HIV infection, especially in earlier-stage disease. Although mucocutaneous candidal infections are very common in patients with HIV disease, dissemination is extremely rare, even with advanced $CD4^+$ cell depletion. Presumably, preserved neutrophil function prevents these and related infections.

Lymphocyte subset analysis, possible even early in the HIV epidemic, highlights the striking $CD4^+$ cell depletion associated with HIV infection, although the mechanism for this loss remains, surprisingly, an active research question. The total lymphocyte count may be decreased in advanced HIV disease but is not a reliable surrogate for actual $CD4^+$ cell enumeration. This is unfortunate because the cost of $CD4^+$ counts remains an important barrier to effective ARV therapy in many global settings, although new devices for easy testing in the field may overcome this hurdle.

$CD8^+$ lymphocytes are activated, not destroyed, in HIV infection. $CD8^+$ cell number is relatively preserved until the most advanced disease stage. This cell population is, however, of research interest because $CD8^+$ activation may accelerate disease progression.

Immune Thrombocytopenia

HIV infection is associated with thrombocytopenia. Immune thrombocytopenic purpura (ITP), though never common, was more often seen in the early years of the epidemic—in up to 8.7% of individuals with advanced AIDS. Its severity varies, but as with non–HIV-associated autoimmune or idiopathic thrombocytopenic purpura, life-threatening bleeding is uncommon (Chapter 175).

Increased splenic clearance of platelets (sometimes associated with hypersplenism) is the major mechanism of thrombocytopenia in these HIV-infected patients, but whether platelets are coated with nonspecific antibodies from immune activation and polyclonal gammopathy or with specific antiplatelet autoantibodies remains uncertain. Although HIV may directly infect megakaryocytes, accelerated platelet loss appears to be more important than decreased production. Further anecdotal evidence supporting increased platelet destruction is the observation that platelet counts tend to normalize in late HIV disease, presumably because of decreased reticuloendothelial function and hence less platelet clearance.

TREATMENT

Rx

Therapy for HIV-associated ITP (HIV-ITP) resembles that for ITP without HIV infection (Chapter 175), but effective HIV suppression should be established whenever possible before treating the thrombocytopenia per se. Splenectomy is successful in many cases. Splenectomy also results in an increase in peripheral $CD4^+$ cell counts. Corticosteroids are likewise effective in treating HIV-ITP, although many fear the use of immunosuppressants in the setting of an acquired immunodeficiency disease. Other treatments with some reported success in HIV-ITP include interferon alfa, danazol, intravenous IgG/RhoGAM, and plasmapheresis.

The advent of effective ARV regimens has reduced the incidence of severe HIV-ITP. HIV-ITP should prompt initiation of ARV therapy if other indications exist. It should otherwise be managed essentially as it is in non–HIV-infected persons, with corticosteroids in a tapering dose as the initial management strategy.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP), often involving some combination of microangiopathy, renal disease, and neurologic disorders, has been reported to occur at increased frequency in persons with HIV infection. Most of these series, however, are very small, with an uncertain relationship to HIV. Presumably, HIV triggers TTP, as do many other infectious diseases (Chapter 175). Management and outcome in these reports resemble those for TTP in patients without HIV infection. Response to plasma exchange is typically rapid. The effect of effective ARV therapy on this condition—either on its incidence or on its disease course—is unknown.

Thrombosis

Reports of increased deep vein thrombosis in HIV-infected patients are relatively rare, which is perhaps surprising in the setting of a chronic viral infection and persistent elevation in markers of immune activation and inflammation. Reports may reflect the overlap between two relatively common diseases. Deep vein thrombosis in an HIV-infected person should be evaluated and managed as for noninfected patients (Chapter 81).

Bone Marrow in HIV Infection

Numerous reports early in the HIV epidemic identified alterations in bone marrow morphology and suggested ways in which bone marrow biopsy might affect management. These conclusions may require adjustment in the era of effective ARV therapy. In the absence of opportunistic infections or malignancies, bone marrow is not strikingly abnormal. Relative RBC aplasia may be seen in anemic patients, and plasma cell number is often increased, but not usually to a striking degree. The marrow findings may resemble mild cases of myelodysplasia. Marrow has been considered a site for the diagnosis of systemic opportunistic infections but has little added utility over peripheral blood culture. Marrow can be affected by HIV-related malignancies, and biopsy of marrow is commonly performed to stage HIV-related lymphoma. Bone marrow biopsy is not required for the evaluation of KS.

HIV ONCOLOGY

HIV is strongly associated with cancers, but even after 25 years of investigation no direct causal relationship has been established. Most ADCs seem to result from interaction of HIV with a second viral coinfection, especially human herpesvirus 8 (HHV-8). Other causative factors may include defects in "immune surveillance" or activation of the immune system.

In addition to ADCs, persons infected with HIV are at increased risk for the development of a widening spectrum of other malignancies that have not been considered to be AIDS defining. Such NADCs may include anal neoplasms, colorectal cancer, Hodgkin's lymphoma, liver and lung cancer, melanoma, oropharyngeal cancer, leukemia, and renal carcinoma. The association of HIV infection with NADCs is a field of intense interest because this risk appears to increase with the duration of HIV infection. In addition, much interest focuses on the role of a second infection—usually viral—in the pathogenesis of NADCs. These include cancers associated with human papillomavirus (HPV), Epstein-Barr virus (EBV), HCV, HBV, and the recently described Merkel cell virus. HIV-infected men have reduced risk for at least one cancer, that of the prostate gland, itself possibly virally related.

ADCs have been profoundly affected by the common use of effective ARV therapy. The incidence of some has declined sharply, and even advanced-stage KS has regressed after the initiation of ARV therapy. Some cancers are less affected, whereas others, such as cervical cancer—perhaps reflecting a longer period of development—have been less immediately affected by HIV treatment.

Kaposi's Sarcoma

Reports of KS in previously healthy young men heralded the onset of the AIDS epidemic. The striking novelty of this cancer in this population, along with simultaneous reports of previously rare infections, allowed almost immediate recognition of underlying immune impairment.

Before the HIV epidemic, KS was uncommon in the United States. It typically affected very elderly men or recipients of solid organ transplants. In Africa, KS was common in a region overlapping an area with a high incidence of Burkitt's lymphoma. As a result, KS was speculated to arise from immune deficiency, along with intriguing suggestions of genetic, environmental, or hormonal factors explaining the predominance of affected men in all settings.

EPIDEMIOLOGY

In the case of HIV, especially before the use of effective ARV therapy, KS affected a very specific subpopulation in the Western world. Women and children were almost always spared, and men with KS typically reported sexual contact with other men as their probable source of HIV infection. These and other observations fueled early speculation that an agent, sexually transmitted between men, might be involved in the pathogenesis of KS. These predictions have proved true with the identification of a new human herpesvirus, HHV-8, as a causative agent of KS and other malignancies.

In the early HIV epidemic, KS was a common initial manifestation of AIDS and was included as an AIDS-defining condition. In the population of men who have sex with other men (MSM), it was present in nearly 50% of new AIDS cases before the use of effective ARV therapy. In contrast, KS was seen in only 2% of new AIDS cases in women, and most of them reported sexual contact with MSM. KS rarely developed in HIV-infected children in the United States.

PATHOBIOLOGY

The viral etiology of KS, later shown to be due to HHV-8 infection, was suggested by its distinctive epidemiology. HHV-8, a gamma herpesvirus, was discovered after viral gene sequences characteristic of this viral family were found in KS lesions, but not in adjacent normal tissue. HHV-8 infects B lymphocytes, macrophages, and endothelial cells. Lytic and latent forms are

FIGURE 400-1. Kaposi's sarcoma.

seen in KS lesions. The precise mechanism of oncogenesis remains unclear, but it is dramatically accelerated in the setting of HIV coinfection.

HHV-8 is a common infection, although serologic diagnosis remains nonstandardized, with wide variation from study to study. In one multicenter study its prevalence in all U.S. blood donors was estimated to be 3.5%. In HHV-8–endemic areas of sub-Saharan Africa, children are infected by puberty, probably from salivary transmission. In San Francisco, the prevalence of HHV-8 was already high in MSM before the HIV epidemic. In the United States, the higher prevalence in MSM suggests sexual transmission.

Active HHV-8 infection, as opposed to simple seropositivity, is required for the development of KS, and HHV-8 serum titers correlate with KS incidence and disease progression rates. Together, these observations suggest a rationale for HHV-8 therapy to prevent or treat KS. The incidence of KS was reduced in several clinical trials of antiherpes therapy in HIV-infected adults. These studies, however, were very small and not powered to detect this effect, and gamma herpesviruses, including HHV-8, are relatively resistant to antiviral control. Whether such approaches offer promise for prevention or treatment of KS requires further research.

KS results from the proliferation of endothelial cells. At least in its later stages it appears to be a true malignancy and typically shows monoclonality and growth independence. Histologically, KS is characterized by both proliferation of spindle-shaped cells and poorly formed vascular channels, often with extensive RBC extravasation.

CLINICAL MANIFESTATIONS

KS lesions typically involve the visible skin surface (Fig. 400-1), although internal lesions may be seen in essentially any organ. Cutaneous lesions are generally violaceous, occasionally with surrounding ecchymosis. They are nodular and range in size from several millimeters to 2 cm in diameter, although multiple lesions can coalesce into large tumor plaques. Lesions are nonpruritic and painless except in advanced stages. KS lesions can appear simultaneously in widely separated regions rather than as a primary site with metastatic spread. Lesions may appear in clusters, may be symmetrical, and may be somewhat linear and appear to follow skin creases. KS lesions may appear on scars or other sites of previous trauma. Lesions are also common in the oral cavity, where they correlate with gastrointestinal involvement.

KS commonly involves the gastrointestinal tract, and bulky disease can cause obstruction. Frank hemorrhage is uncommon. Pulmonary KS involvement is typically evidenced by reticulonodular, patchy infiltrates on chest radiographs. Pleural effusions, if seen, are often hemorrhagic and frequently cytologically "benign." Advanced KS disease can cause intractable lymphedema, especially common in the lower extremities and head and neck.

TREATMENT

KS lesions are usually quite distinct in appearance, but biopsy confirmation is essential. HHV-8 is invariably present. Bacillary angiomatosis may resemble KS morphologically but is distinguishable histologically.

ARV therapy is currently regarded as the treatment of choice for HIV-associated KS because it is remarkably active. The incidence of KS has fallen precipitously (5- to 10-fold) with wide use of ARV therapy. Moreover, established KS often responds rapidly after initiation of ARV therapy. In one series 90% of patients responded, with complete and durable resolution in 18 of 20 patients. ARV therapy may decrease HHV-8 viremia. Several preliminary reports suggest an especially active KS response with HIV protease inhibitors. This possibility is being explored in ongoing clinical trials. An immune reconstitution inflammatory syndrome response (Chapter 402) has also been reported in patients with KS after initiation of ARV therapy.

Before the use of effective ARV therapy, KS was treated with a variety of cytotoxic agents. Vinblastine, administered either systemically or intralesionally, was later replaced by paclitaxel, anthracyclines, or etoposide. Monotherapy is generally preferred over more aggressive drug combinations. Biologic agents, including interferon alfa, topical retinoids, and tumor necrosis factor inhibitors, are also active against KS. Radiation therapy may be useful for systematic control of bulky KS plaques causing pain or lymphatic obstruction. Despite the vascular proliferation of KS lesions histologically, experimental angiogenesis inhibitors have not yet proved active in treating KS.

Non-Hodgkin's Lymphoma

NHL (Chapter 191) is the second ADC whose incidence is clearly increased with HIV infection. NHL occurs in two distinct forms in HIV-infected patients: those of peripheral or central nervous system (CNS) origin.

EPIDEMIOLOGY

Peripheral Non-Hodgkin's Lymphoma

HIV-associated peripheral NHL (HIV-NHL) is a B-cell tumor. The malignancy is often of moderate- to high-grade classification. The most common histologic variants are intermediate-grade large cell and high-grade immunoblastic lymphomas. The most common subtype is diffuse large B-cell lymphoma; the second most common is Burkitt's lymphoma. HIV-NHL is often found to be advanced at initial evaluation. Extranodal sites, including the gastrointestinal tract, lungs, and liver, are more common with HIV-NHL than in the absence of HIV infection. NHL arising in the bile duct, in the appendix, or as a solitary parenchymal pulmonary nodule has been reported. Intravascular NHL has also been seen, occasionally in vessels within the CNS.

The epidemiology of peripheral HIV-NHL is more straightforward than that of KS. Both sexes are affected equally, as are HIV-infected children and adolescents. The $CD4^+$ cell count at diagnosis, though variable, is typically only moderately suppressed in HIV-NHL, and ARV therapy has decreased its incidence by only two-fold.

The cause of peripheral HIV-NHL is unknown. Many affected patients, but not all, are EBV positive and the tumors are HHV-8 negative except for primary effusion lymphomas (PELs).

Central Nervous System HIV-NHL

High-grade B-cell NHL can arise within the CNS in HIV-infected patients. This occurs at a much higher rate and is considered diagnostic of AIDS. HIV-related CNS lymphomas frequently exhibit leptomeningeal involvement or are associated with multiple parenchymal lesions, both unusual in the absence of HIV infection. Moreover, CNS lymphoma in HIV-infected individuals is almost always seen in those with strikingly advanced stages of immune deficiency. The median $CD4^+$ cell count in one report, for example, was 12 cells/μL. Given the close relationship between immune deficiency and risk for CNS NHL, it is not surprising that the common use of effective ARV therapy has reduced its incidence by 100-fold.

CLINICAL MANIFESTATIONS

Apart from frequent occurrence in extranodal sites, peripheral HIV-NHL closely resembles the disease in HIV-uninfected individuals. It can be an aggressive tumor with rapid enlargement, pain, and erythema. Nodes are usually asymmetrically affected and have a firm, rubbery consistency on palpation. Any unusual mass or asymmetrical lymphadenopathy in an HIV-infected patient should undergo prompt biopsy. Systemic "B" symptoms (fever, sweats, weight loss) may be present but are neither sensitive nor specific for HIV-NHL.

Peripheral HIV-NHL is typically an aggressive malignancy—unsurprising given its high-grade histology, advanced stage at diagnosis, and underlying immune deficiency. Apart from the inherent risk for opportunistic infections in these patients, the course of the disease is not specifically affected by HIV infection. Progression can occur at local or distant sites, and CNS involvement (distinct from primary CNS HIV-NHL) is seen commonly.

CNS NHL is typically associated with signs and symptoms of a space-occupying mass. Although the specific manifestations depend on the precise location, as well as the size and rate of tumor growth, sensory and

motor deficits are common, as are seizures. Headache, fever, and changes in personality are less common than in the frequent differential diagnostic considerations of CNS toxoplasmosis or cryptococcal meningitis. CNS NHL has some predilection for periventricular involvement, as well as involvement of the base of the skull.

DIAGNOSIS

Peripheral HIV-NHL is diagnosed and staged similar to the situation when HIV is not present (Chapter 191). Bone marrow biopsy, thoracic and abdominal imaging, and cerebrospinal fluid (CSF) examination are routine. Conventional histologic examination and immunoassays are used to evaluate specimens, and cell surface markers are determined by flow analysis.

CNS NHL is diagnosed by brain imaging and tissue biopsy and by detecting EBV in CSF. Although a solitary mass is common, several may be seen, especially if magnetic resonance imaging is used, which is more sensitive than computed tomography. Positron emission tomography is also useful. The most common site is deep in the white matter, and periventricular sites are disproportionately involved. CNS toxoplasmosis is more typically multicentric, but imaging alone cannot reliably differentiate most cases. CNS NHL is much more suspect if the patient has no serum *Toxoplasma* antibodies, although many patients with CNS NHL are also *Toxoplasma* antibody positive. Essentially all CNS NHL cases in the HIV setting are EBV positive. Detection of EBV on CSF polymerase chain reaction (PCR) in a patient with advanced-stage HIV and CNS imaging findings typical of CNS NHL has been considered adequate by some to establish this diagnosis, but many still demand tissue confirmation, usually obtained by stereotactic brain biopsy. CSF cytology is relatively insensitive, with 80% of patients showing no malignant cells. Flow analysis of malignant cells is characteristically diagnostic of NHL; essentially all malignant cells are $CD20^+$.

TREATMENT AND PROGNOSIS

HIV-NHL, whether diffuse large B-cell lymphoma or Burkitt's lymphoma, generally requires systemic combination chemotherapy. It is seldom so localized that it benefits from local radiation therapy and does not, itself, respond to ARV therapy as seen with KS. Various regimens have commonly been used. CHOP (cyclophosphamide, hydroxydaunomycin, Oncovin [vincristine], and prednisone) is often used in standard doses. The addition of rituximab to the CHOP regimen does not significantly increase response rates or survival and is associated with an increased risk for bacterial infection.■ A more aggressive regimen (R-EPOCH and others) based on prolonged chemotherapy infusion has been used with success and is considered the standard regimen by many experts. This regimen includes rituximab, etoposide, vincristine, doxorubicin, cyclophosphamide, and prednisone.

Because of the high risk for CNS relapse, prophylactic administration of methotrexate or cytosine arabinoside is recommended.

The use of ARV therapy in patients with HIV-NHL improves survival. Most practitioners would initiate ARV therapy with chemotherapy because the former difficulties caused by the use of AZT can now be avoided with combinations not associated with hematologic toxicity. In one series, HIV-NHL patients treated with ARV therapy had a median duration of survival of 30 months as compared with only 6.1 months in the group not receiving ARV therapy.

The common use of ARV therapy has decreased the incidence of HIV-NHL by more than two-fold. This is less of a reduction than with KS, however, and HIV-NHL has thus become the most common HIV-related malignancy, even though its absolute prevalence is reduced from that in the era before effective ARV therapy was available.

The aggressive nature of CNS NHL, the relative isolation of the body compartment affected from systemic chemotherapy, and the severe underlying immune deficiency combine to limit survival. Before the common use of ARV therapy, the median duration of survival was measured in weeks. The use of effective ARV therapy has improved this expectation and allows the implementation of more aggressive systemic therapy for CNS NHL, but it remains a serious disease. In one series, the median survival without radiation or ARV therapy was 29 days, whereas six of seven ARV-treated patients were alive 667 days after diagnosis.

Given the severe underlying immune deficiency and the high mortality rate from opportunistic infections in early series, initiation of effective ARV therapy as soon as possible is indicated. Mass lesions can be palliated with combined chemotherapy and brain irradiation, although neurologic impairment is common in longer-term survivors. The use of ARV therapy may allow high-dose systemic chemotherapy alone, particularly high-dose methotrexate with leucovorin rescue. Radiation therapy can be used to control recurrent disease, unfortunately still an expected part of this tumor's disease course.

HHV-8–RELATED LYMPHOPROLIFERATIVE DISEASES

Primary Effusion Lymphoma

PEL is an interesting HIV-related malignancy; it is often grouped with peripheral NHL but is distinct in many respects. PEL was first reported in HIV-infected patients. These lymphomas arise as a malignant, exudative effusion in essentially any body cavity and thus have also been called *body cavity lymphomas.* These cancers are quite rare. Even rarer are solid tumor variants, with only several reported cases.

PEL typically occurs in persons with advanced HIV disease. Like KS, PEL is closely associated with HHV-8 infection. HHV-8 infects B lymphocytes, but the precise mechanism of malignant transformation has not yet been established.

CLINICAL MANIFESTATIONS

PEL has been reported in many body cavities. Pleural and pericardial disease is the most frequent, but peritoneal and synovial sites are also seen. Fever and other "B" symptoms are present in many patients. The diagnosis must be considered in an HIV-infected patient with any localized effusion, and the diagnosis of PEL should prompt HIV testing in a patient not known to be so infected.

The effusion is exudative with a lymphocyte predominance. HHV-8 DNA is found by PCR in essentially all cases.

TREATMENT AND PROGNOSIS

Even though response to chemotherapy is expected, complete resolution is rare. PEL is treated with systemic chemotherapy. Although no large series or controlled trials have been reported, standard doses of CHOP regimens are often used. Some have advocated a more aggressive chemotherapeutic approach, but the rarity of these tumors has not allowed a prospective comparative clinical trial of this strategy. ARV therapy is also typically initiated, analogous to the situation with CNS NHL, but PEL does not, itself, respond to ARV treatment. Effective ARV therapy has decreased the incidence of PEL and prolongs survival, although it remains an aggressive malignancy with a short median duration of survival. Median survival in one series was 6.2 months.

Multicentric Castleman's Disease

Multicentric Castleman's disease (MCD) is a lymphoproliferative disorder associated with overexpression of interleukin-6. MCD in the HIV-infected population is associated with HHV-8 infection. Though "benign," the proliferation is often extensive, with diffuse nodal enlargement, splenomegaly, and "B" symptoms seen in the majority of patients. MCD may have a malignant phenotype and may be associated with KS, HIV-NHL, or PEL.

CLINICAL MANIFESTATIONS

MCD is commonly accompanied by diffuse lymphadenopathy, hepatic and splenic enlargement, and a variety of systemic signs and symptoms. In some series, pulmonary manifestations were common and anemia was also frequent. Lymph node biopsy is essential for diagnosis. Histologic patterns vary, but B cells predominate. EBV studies are not consistently positive, whereas HHV-8 DNA is typically detected. The course may be relapsing and remitting but in some individuals is a highly aggressive disorder that responds poorly to treatment.

TREATMENT AND PROGNOSIS

MCD carries a high risk for the simultaneous or subsequent development of an HIV-related malignancy. Depending in part on the predominant histologic pattern of MCD at biopsy, progression may be toward HIV-NHL or PEL/KS. MCD itself responds to low-dose chemotherapy, such as vinblastine, which may prolong survival but rarely results in prolonged remission. In addition to chemotherapy, other agents such as corticosteroids and antiherpesvirus drugs have provided additional benefit. More promising results have been seen with the use of rituximab, which has been associated with durable response in some patients. The effect of ARV therapy on MCD has been incompletely examined, but such therapy should be initiated.

Plasmablastic Lymphoma

Often associated with HHV-8, this lymphoproliferative disease has been recognized with increasing frequency. These are typically highly aggressive, high–growth fraction tumors with phenotypes that fall in the spectrum between B-cell NHL and plasma cell malignancies. They are frequently seen in the oral cavity. No prospective treatment studies have been reported. Aggressive treatment regimens such as those used for Burkitt's lymphoma are often recommended.

Human Papillomavirus–Associated Anal-Cervical Disease

HPV infection is transmitted sexually and, unsurprisingly, is often seen in combination with HIV, also a sexually transmitted infection. HPV-related cancers are less easily linked to HIV infection given their common occurrence in demographically similar but HIV-uninfected persons and because of their typically prolonged period of development. Both cervical and anal cellular atypia are common in patients dually infected with HIV and HPV, and several reports have found a higher frequency of higher-grade or premalignant atypia in such dually infected populations. Similarly, both cervical and anal cancers have been diagnosed in HIV-infected persons. These cancers are seen more frequently as a result of HIV infection. HPV infection is common in the MSM population (with or without HIV infection), and anal cancer is clearly more common in the MSM community, but at even higher rates in those concurrently infected with HIV. Cervical cancer is also seen in HIV-infected women at a somewhat higher frequency than in non–HIV-infected women. More effective ARV therapy has, however, not led to a declining incidence of these cancers as opposed to those more directly associated with HIV infection, possibly reflecting the very prolonged time that these cancers take to develop from lower grades of cellular atypia.

The association between HPV infection, HIV infection, and cervical and anal cancer may become even more evident as survival is prolonged with effective ARV therapy. Moreover, regardless of any cause-and-effect relationship, it is clear that proliferative changes with a potential for malignant transformation occur frequently in HIV-infected persons. These observations have led to increasingly strong recommendations for regular physical and cytologic examination of cervical and anal tissue in HIV-infected patients. Standard Papanicolaou (PAP) testing has been adapted for anal examination and is increasingly routine. Abnormal PAP cytology should prompt further diagnostic and therapeutic approaches, although proof of improved outcome with specific algorithms remains under investigation. Detection of HPV by molecular techniques is also a promising way to establish risk for disease and may be applied in settings globally where PAP testing is unavailable. The role and prophylactic effect of HPV vaccine have not yet been fully evaluated in HIV-infected persons, but it is generally anticipated to play a major role in the prevention of both cervical and anal cancer as it is made available internationally.

Hepatitis C, Hepatitis B, and Hepatocellular Cancer

HIV infection accelerates the course of disease of both hepatitis B and hepatitis C. Both are associated with an increased risk for hepatocellular cancer (HCC) (Chapter 202). In the case of HCV infection, this risk requires underlying cirrhosis. HCC in an HBV-infected patient can arise without cirrhosis. It is not clear that screening for HCC should be affected by HIV infection because of the relative insensitivity and nonspecific nature of all techniques. Perhaps more importantly, this association should increase interest in ensuring wide use of HBV vaccination at an early age and in developing effective antivirals for HBV and HCV infection. If effective, such antivirals would presumably prove useful in decreasing the risk for malignancy, particularly with the potential curability of each infection.

Cancers in HIV-Infected Persons Not Proved to Be Linked Causally (NADCs)

A wide variety of cancers have been diagnosed in HIV-infected persons. This may, of course, represent the coincidence of common diseases. Such cancers may, in fact, increase in frequency as a larger number of people survive HIV infection for prolonged periods as a result of effective ARV therapy. Moreover, HIV-infected persons may have higher exposure to cancer through smoking or other cancer risk behavior. Some causal relationship may exist, though difficult to prove, and the natural history of cancers may be altered by HIV infection.

Hodgkin's lymphoma (Chapter 192) has most closely been linked to HIV infection, and most of these tumors are EBV positive. Several epidemiologic studies have shown an increased incidence in HIV-infected persons. Other reports suggest an altered histology with less favorable subtypes, including mixed cellularity and lymphocyte depletion seen at higher frequency with an associated impact on outcome. Not all reports show a causative relationship, however, and the management of individual patients is probably not specifically changed in the setting of HIV infection.

The questions surrounding NADCs have generated substantial research interest, particularly as the population of those living with treated HIV infection increases along with their duration of infection. It does appear clear from numerous cohort studies that the incidence and variety of NADCs are increasing in HIV-infected persons. A frequent suggestion is that this may result from continuing inflammation and immune activation in these patients, even with the use of potent ARV therapy, as opposed to those who are not infected with HIV. In addition, many cancers seen in HIV-infected persons but not strictly AIDS defining are associated with a second infection in addition to HIV. Examples include Hodgkin's lymphoma and EBV, esophageal cancer and anal cancer with HPV, and Merkel cell carcinoma with the Merkel virus. Research may be able to clarify the nature of these associations, particularly through use of the large and well-characterized patient cohorts now being monitored in many countries. Pending clarification, physicians treating HIV-infected patients must be increasingly vigilant to prevent, screen, and treat a widening spectrum of cancers and to avoid overconfidence that these diseases are prevented simply by the use of ARV therapy.

FUTURE DIRECTIONS

HIV-related hematologic and malignant diseases were vital indicators of the AIDS epidemic. They remain significant clinical problems, although their severity and frequency have changed, in some cases dramatically, after the widespread use of effective ARV therapy. Research will continue to investigate the relationship between HIV infection and these problems. This research may also be able to elucidate the general relationship between inflammation, immune activation, and immune deficiency and oncogenesis. Because many HIV-related cancers require the participation of a second virus, this work will also provide strong motivation for the development of vaccines and antivirals directed at these pathogens. Such research, if positive, could well benefit an even broader population.

NEUROLOGIC COMPLICATIONS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

JOSEPH R. BERGER AND AVINDRA NATH

The neurologic complications of human immunodeficiency virus (HIV) infection can affect any portion of the neuraxis. They can be broadly divided into two large groups: those that are the consequence of HIV infection and those that are secondary in nature and occur chiefly as a result of the associated immunosuppression (Table 401-1). With respect to the former group, some of these disorders, such as acute HIV meningitis, are relatively rare, whereas others, such as HIV-associated neurocognitive disorders (HAND) and HIV-associated peripheral neuropathy, are common. HIV meningitis generally occurs at the time of seroconversion, but other disorders, such as HAND, HIV myelopathy, and HIV peripheral neuropathy, are typically not observed until advanced stages of immunosuppression.

The most common neurologic complications occurring as a secondary consequence of the virus are opportunistic infections. The most frequent of such infections are central nervous system (CNS) toxoplasmosis (Chapter 357), cryptococcosis (Chapter 344), tuberculosis (Chapter 332), cytomegalovirus encephalitis (Chapter 384), JC virus infection that results in progressive multifocal leukoencephalopathy (Chapter 378), and varicella-zoster virus encephalitis or myelitis (Chapter 383). However, many noninfectious complications occur as well. The incidence of primary CNS lymphoma is remarkably high. Unlike non–AIDS-associated primary CNS lymphoma, in which Epstein-Barr virus can be recovered from only 50% of tumors (Chapter 191), all AIDS-related primary CNS lymphomas have been associated with Epstein-Barr virus infection (Chapter 400). A wide variety of toxic and metabolic complications have been observed in HIV-infected patients, including Wernicke's encephalopathy and vitamin B_{12} deficiency. Drugs, particularly antiretroviral agents, have also been associated with neurologic complications. Certain nucleoside analogues (e.g., the "d" drugs didanosine [ddI], dideoxycytidine [ddC], and stavudine [d4T]; see Table 401-5) are frequently associated with peripheral neuropathy. Finally, a wide variety of cerebrovascular disorders have been associated with HIV infection. Thrombotic ischemic stroke in this population has been attributed to an as yet undefined procoagulant tendency. Certain infections seen with increased frequency in patients infected with HIV, such as syphilis, tuberculosis, and cryptococcosis, may be associated with stroke. In addition, CNS vasculitis has occasionally been observed with HIV infection, either from HIV or from an associated varicella-zoster infection.

In recent years, it is being increasingly recognized that in a few weeks or months after initiation of combination antiretroviral therapy (ART), some patients will clinically deteriorate even when there is a robust drop in plasma viral load and recovery of CD4 cell counts. In these patients, the recovery of immune function may result in an inflammatory syndrome termed immune reconstitution inflammatory syndrome (IRIS; Chapter 402). This most often occurs when a patient has an underlying opportunistic infection, in which case the inflammation is targeted to the site of the infection. On occasion, IRIS may occur in the brain without any identifiable opportunistic infection.

TABLE 401-1 CLASSIFICATION OF THE NEUROLOGIC COMPLICATIONS OF HIV INFECTION

DIRECT	INDIRECT
Acute meningitis	Opportunistic infections
Chronic meningitis	Neoplasms
Encephalopathy	Toxic/metabolic
Myelopathy	Drug effects
Peripheral neuropathy	Cerebrovascular disease
Myositis/myopathy	

Few HIV-infected individuals will escape experiencing one or more of these complications during their lifetime. They are responsible for a significant amount of morbidity and mortality. Not infrequently, more than one neurologic condition coexists in the same patient, which is often a source of confusion because one of the illnesses may be appropriately diagnosed and treated, yet the patient continues to deteriorate. Furthermore, one must also consider that any neurologic abnormalities observed are the consequence of more pedestrian disorders, such as radiculopathy secondary to disc herniation, and are unrelated to the HIV infection. In patients not responding to appropriate therapy for a proven disorder, careful clinical reevaluation is essential.

HIV-ASSOCIATED NEUROCOGNITIVE DISORDERS

DEFINITION

HIV dementia has been referred to by a number of names, including *subacute encephalitis, multinucleated giant cell encephalitis, AIDS dementia complex,* and *HIV-associated neurocognitive disorders (HAND)*.

A spectrum of increasing cognitive impairment has been described in association with HIV infection. An acquired impairment in cognitive function involving two ability domains, with a performance at least 1.0 SD below the mean for norms on standardized neuropsychological tests but no cognitive impairment in everyday function, has been referred to as *asymptomatic neurocognitive impairment*. Patients with mild neurocognitive disorder have a similar disorder on neuropsychological testing but exhibit problems with daily functions. Those with HIV dementia have marked impairment (≥2 SD) on at least two domains in neuropsychological testing and marked interference in day-to-day activities because of cognitive impairment. By definition, the diagnosis of HAND requires that there be no delirium and no other etiology to explain the deficit.

EPIDEMIOLOGY

In the pre-ART era, HIV dementia was observed more commonly. Early studies suggested that it was evident in more than 50% of preterminal patients. The Multicenter AIDS Cohort Study found an incidence of 4% coincident with the diagnosis of AIDS, and dementia developed in 7% within 1 year of the development of AIDS and in 14% within 2 years. Other studies have found slightly higher rates. After the introduction of combination ART in 1996, the incidence rate of HIV dementia declined substantially but the prevalence of the disorder increased; this finding may be the result of prolonged survival of affected patients. Studies suggest that the incidence of HAND may be climbing to involve as many as 50% of patients with HIV infection, but most patients have milder forms of cognitive impairment. Risk factors for HAND include low CD4 cell counts, concurrent anemia, extremes of age, and history of substance abuse or addiction. Depression is also a common comorbidity. Congenitally or perinatally infected children may exhibit delayed development. Genetic factors such as *APOE4* and polymorphisms in chemokine monocyte chemotactic protein-1 and tumor necrosis factor receptor have been identified as risk factors for the development of HAND.

PATHOBIOLOGY

HIV enters the brain early after the initial infection. In all likelihood, the virus enters the brain in infected mononuclear cells, although it is possible that it also enters as cell-free virus. HIV can be demonstrated in the brain as early as 2 weeks after infection. The viral infection predominates in invading macrophages in the brain, microglial cells, and multinucleated giant cells, usually in perivascular areas. HIV can also infect astrocytes, and studies suggest that in patients with cognitive impairment, 16 to 19% of astrocytes may be infected. HIV may remain latent for extended periods. Infection of other cell types is a rare event. The brain may thus be an important reservoir for HIV. Certain proteins of the virus, Tat and gp120, have been demonstrated to have a significant pernicious effect on neuronal function and viability either through direct toxic effects on neurons or by stimulation of glial cells, which in turn produce neurotoxic metabolites—cytokines and chemokines. Similarly, the perivascular, HIV-infected inflammatory cells produce a wide variety of chemokines and cytokines that also have similar deleterious effects. Therefore, there appear to be parallel paths, direct viral neurotoxicity and toxicity from inflammatory byproducts that lead to the development of HAND. Drugs of abuse, such as opiates, cocaine, and methamphetamine, can

stimulate HIV replication in glial cells and synergize with the HIV proteins to cause neurotoxicity and glial cell activation.

On gross examination, the brain typically exhibits cortical atrophy, sulcal widening, and ventricular dilation. Histopathologic examination shows multinucleated giant cells, microglial nodules, white matter pallor, astrogliosis, and perivascular inflammation (Fig. 401-1). The multinucleated giant cell, which is a syncytium of macrophages, has been regarded as the hallmark of infection, but it is not uniformly present in patients with HAND. The pathologic changes are most prominent in the basal ganglia, prefrontal cortex, and hippocampus. Concomitant vacuolar myelopathy is seen in as many as 40% of patients, although it has become less common since the introduction of ART.

CLINICAL MANIFESTATIONS

Most commonly, patients describe impaired memory, poor concentration, impairment of executive function, and difficulty reading. They often find it difficult to recall a passage recently read. Other frequent symptoms include gait problems, depression, and tremors, and patients may appear apathetic and slow or become socially withdrawn. Headaches, fatigue, and sexual dysfunction are frequent. The most commonly observed physical findings are psychomotor slowing with bradyphrenia and impaired rapid repetitive and alternating movements, hyperreflexia, increased tone, facial masking, frontal release signs (snout, glabellar, involuntary grasp), and abnormal ocular motility. The dementia has the features of a subcortical dementia not inconsistent with the relatively marked disease burden observed in dopaminergic basal ganglia. Screening tools for HAND have been proposed (Table 401-2) and a battery of specific neuropsychological tests used (Table 401-3). Staging of the disease along a continuum has been widely adopted (Table 401-4).

DIAGNOSIS

Computed tomography of the head typically shows brain atrophy, but findings may be normal. Central atrophy is generally more pronounced than cortical atrophy. In children, calcification of the basal ganglia is often observed. Similar findings are seen on magnetic resonance imaging. Basal ganglia hyperintensity is seen rarely on T2-weighted images and may resolve during the course of ART. White matter hyperintensities are also commonly detected on T2-weighted images and fluid-attenuated inversion recovery (FLAIR) sequences (Fig. 401-2). These lesions may be discrete and focal or large and confluent. They are generally symmetrically distributed and may be confused with lesions of progressive multifocal leukoencephalopathy (Chapter 378). Unlike progressive multifocal leukoencephalopathy lesions, they are typically not hypointense on T1-weighted sequences.

TREATMENT

Rx

Whether ART needs to cross the blood-brain barrier for a better neurocognitive outcome remains uncertain. Higher cerebrospinal fluid (CSF) penetrant ability is associated with lower levels of HIV RNA in the CSF. Prudence dictates that highly CNS penetrant ARTs would best be used, although other factors should be considered (e.g., the drug's pharmacokinetics, protein binding, and

IC_{95}). Newer CCR5 antagonists, maraviroc and vicriviroc, demonstrate good CSF penetration and may be uniquely suited for the treatment of HAND. Table 401-5 provides a list of ARTs with their respective CSF-plasma ratios, which may provide a proxy for CNS penetration. A variety of other therapies have been proposed for the treatment of HAND that chiefly addresses the proposed inflammatory pathway of the pathogenesis of the disorder. To date, none has been established to be effective. The flow chart in Figure 401-3 provides an algorithm for the management of HAND. Careful attention to treatment of comorbidities is also essential.

PROGNOSIS

In the pre-ART era, the life expectancy of patients with HIV dementia was less than 6 months. The institution of effective ART has considerably increased the life expectancy of affected patients, and partial recovery of neurocognitive deficits may be seen.

HIV MYELOPATHY

A broad spectrum of myelopathies occurs with HIV infection (Table 401-6). HIV causes a distinct myelopathy referred to as *HIV vacuolar myelopathy*. Evident in 20 to 55% of autopsies, this myelopathy is underrecognized clinically. It is characterized by an insidious onset of leg weakness and gait abnormality that usually occurs during the course of advanced HIV infection. Sensory complaints include vague leg discomfort and distal paresthesias. Bowel and bladder dysfunction is frequent. Physical examination reveals spastic paraparesis with lower extremity hyperreflexia, a spastic-ataxic gait, and impaired sensation with vibratory and position perception disproportionately affected. The sensory loss may be asymmetrical, but the presence of a discrete sensory level should suggest an alternative cause of the myelopathy. Magnetic resonance imaging of the spinal cord is usually normal but may show cord atrophy or hyperintense signal abnormalities within the cord on T2-weighted images. The value of spinal magnetic resonance imaging lies in exclusion of other diagnostic possibilities, particularly structural abnormalities of the cord. Somatosensory evoked potentials generally demonstrate delayed conduction. Although findings on gross examination of the cord and dura are usually normal, histopathologic examination typically reveals loss of myelin with spongy degeneration, axonal preservation, microglial nodules, and multinucleated giant cells involving the lateral and posterior columns of the spinal cord. The pathogenesis of this disorder remains obscure. The clinical and pathologic features are suggestive of vitamin B_{12} deficiency (Chapter 167), but no consistent abnormalities are found in serum levels of vitamin

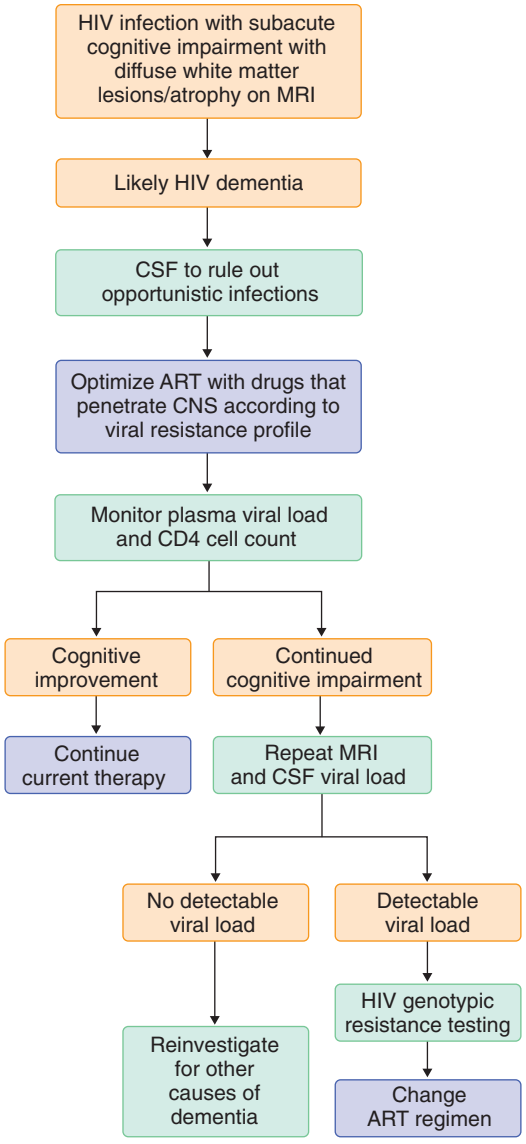

FIGURE 401-3. Flow chart for the treatment of HIV dementia. ART = antiretroviral therapy; CNS = central nervous system; CSF = cerebrospinal fluid; HIV = human immunodeficiency virus; MRI = magnetic resonance imaging.

B_{12} or its metabolites, and replacement therapy with cyanocobalamin or *S*-methyl-L-methionine has not proved to be beneficial. The most effective management appears to be ART coupled with physical therapy.

HIV PERIPHERAL NEUROPATHY

Although a large number of peripheral neuropathies have been described in association with HIV infection, the one most commonly observed is a distal symmetrical sensorimotor peripheral neuropathy that ultimately affects at least a third of all HIV-infected persons. This neuropathy is seen more often in advanced disease. The patient typically complains of "burning feet." Distal paresthesias and numbness are reported, and the pain may be debilitating. Distal vibratory, pinprick, and temperature sensory perceptions are diminished, and the Romberg sign is often present. Ankle jerks are depressed or absent, and mild weakness of the toes with associated atrophy of the intrinsic muscles of the foot is frequently noted. Nerve conduction studies show reduced sensory nerve action potentials and conduction velocities. Nerve conduction amplitudes are reduced disproportionately to the reduction in conduction velocity. Electromyography may demonstrate features consistent with either acute or chronic denervation. Skin biopsy shows a reduction in cutaneous nerve fibers.

A clinically indistinguishable neuropathy may be seen with some of the antiretroviral agents, particularly with ddI, ddC, and d4T. The neuropathy associated with these agents appears to be dose dependent. Other drugs used in treatment of AIDS or its complications, such as hydroxyurea, isoniazid, vincristine, and thalidomide, may also result in a similar peripheral neuropathy. Discontinuation of the use of these drugs should result in improvement in the neuropathic features; however, a phenomenon referred to as *coasting*, in which continued worsening of the neuropathy occurs after discontinuation of the offending agent, may be observed for a period of several months.

Shortly after seroconversion, a demyelinating peripheral neuropathy identical to Guillain-Barré syndrome or chronic inflammatory polyradiculoneuropathy (Chapter 428) may be observed if it progresses for a duration of 3 weeks or more. An autoimmune process is the probable pathogenesis, and these neuropathies respond to therapy routinely used in the treatment of these conditions. In rare instances, mononeuritis multiplex (Chapter 428) may be seen with HIV infection.

CNS = central nervous system; HTLV = human T-lymphotropic virus.

HIV MYOPATHY

Several forms of muscle disease occur with HIV infection and, like other neurologic disorders, may be due to HIV or be secondary to other processes. Among the latter are myopathies associated with drugs such as zidovudine and cholesterol-lowering agents, opportunistic infections, neoplastic infiltrates, and vasculopathies. HIV myopathy mirrors the clinical and laboratory findings of classic polymyositis (Chapter 277). It is characterized by a progressive symmetrical weakness of the limb girdle and neck flexor muscles. Fatigue, myalgias, and wasting are observed in up to 50% of affected persons. Muscle enzymes, including creatine kinase and aldolase, are elevated, and the electromyogram shows short, brief, polyphasic unit action potentials. Muscle biopsy reveals myofibrillar necrosis, phagocytosis, variation in fiber size, and regeneration and degeneration typically with endomysial inflammatory infiltrates. This myopathy is rare, with an incidence of less than 1%, and has been observed in any stage of HIV infection. All patients with weakness who are taking a nucleoside reverse transcriptase inhibitor (NRTI) should have blood lactate levels measured because of an association between a recently described neuromuscular weakness syndrome and lactic acidosis in patients taking

NRTIs. The contribution of zidovudine to the genesis of HIV-associated myopathy remains controversial. As in non-HIV polymyositis, corticosteroid therapy is beneficial and can be administered with tolerable side effects.

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME IN HIV/AIDS

ROBERT COLEBUNDERS AND MARTYN A. FRENCH

DEFINITION

Treatment of human immunodeficiency virus (HIV) infection with combination antiretroviral therapy (ART) results in the restoration of protective pathogen-specific immune responses and the regression or prevention of opportunistic infections (OIs) and cancers (Chapter 396). However, restoration of an immune response against a pathogen may also result in immunopathology at body sites infected by the pathogen. This has been referred to as *immune restoration disease* (IRD) to differentiate it from immunodeficiency disease, but it is now commonly known as *immune reconstitution inflammatory syndrome* (IRIS) because an inflammatory illness is the most common clinical feature.

Essentially any pathogen that causes an infection as a result of HIV-induced cellular immunodeficiency may be associated with IRIS after ART is commenced. However, the clinical characteristics and severity of IRIS associated with each type of pathogen vary greatly (Table 402-1). For example, IRIS associated with *M. tuberculosis*, cryptococcal, or JC polyomavirus (JCV) infection is manifested differently from an OI caused by these pathogens, and the resulting illness is often severe and may result in death. In contrast, herpes zoster after ART is usually indistinguishable from that occurring before ART, and it is only the timing of onset that suggests that it results from IRIS.

IRIS develops mainly during the first 3 months of ART but occasionally later. Two patterns are recognized. *Paradoxical IRIS* refers to the worsening or atypical manifestation (or both) of an established OI after ART is commenced. In most cases the infection had been treated before ART was initiated, and the immune response appears to be against residual antigens of the pathogen. *Unmasking IRIS* refers to disease that occurs for the first time after ART is commenced and appears to result from an immune response against a subclinical infection by an opportunistic pathogen.

EPIDEMIOLOGY

The reported incidence of IRIS has varied from 8% to greater than 40% in different studies. To some extent, the large variation reflects the lack of universally accepted diagnostic criteria. It also probably reflects differences in risk factors in the populations of patients studied. The most important risk factors for IRIS are a low $CD4^+$ T-cell count when ART is initiated and, in patients in whom paradoxical IRIS develops, disseminated infection and a short time between treatment of the infection and commencement of ART.

TABLE 402-1 EXAMPLES OF IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME

PATHOGEN	NOMENCLATURE	TYPICAL CHARACTERISTICS OF THE DISEASE
Mycobacterium tuberculosis	TB-IRIS	Paradoxical exacerbation of TB
Nontuberculous mycobacteria (NTM)	NTM immune reconstitution syndrome	Mainly lymphadenitis, also pulmonary disease and hepatitis
Bacille Calmette-Guérin (BCG)	BCG-IRIS	Necrotizing regional lymphadenitis
Mycobacterium leprae	Leprosy-related IRIS	Borderline and type 1 reactional state
Cryptococcus neoformans	Cryptococcal-IRIS	Mainly meningitis, also lymphadenitis
Pneumocystis jirovecii	*Pneumocystis*-IRIS	Paradoxical exacerbation of pneumonitis
Cytomegalovirus (CMV)	CMV retinitis after ART or immune recovery uveitis	Acute retinitis after commencing ART or uveitis
JC polyomavirus	Inflammatory PML	Multifocal leukoencephalopathy with inflammatory features
Human herpesvirus 8	KS-IRIS	Rapid progression of existing and/or new KS lesions
Hepatitis B or C virus	Some cases of ART-associated hepatotoxicity	Hepatitis flare and/or liver enzyme elevation
Herpes-zoster virus		Mainly dermatomal or multidermatomal zoster, occasionally myelitis
Molluscum contagiosum virus	Inflammatory molluscum contagiosum	Inflamed molluscum lesions
Pityrosporon sp	Inflammatory seborrheic dermatitis	Abnormally inflamed seborrheic dermatitis

ART = antiretroviral therapy; IRIS = immune reconstitution inflammatory syndrome; KS = Kaposi's sarcoma; PML = progressive multifocal leukoencephalopathy; TB = tuberculosis.

PATHOBIOLOGY

Information about the pathogenesis of IRIS has been obtained mostly by studying patients who experience disease associated with a mycobacterial infection. Both clinicopathologic and immunologic studies have shown an association with a T_H1 cellular immune response against mycobacterial antigens, which has been demonstrated by measuring delayed-type hypersensitivity skin test responses or the frequency of circulating antigen-specific T cells that produce interferon-γ (IFN-γ). The immunopathogenesis of IRIS associated with other pathogens is less well understood and appears to vary depending on the provoking pathogen. For example, IRIS associated with JCV infection (inflammatory progressive multifocal leukoencephalopathy [PML]) is characterized by an inflammatory cell infiltrate in affected areas of the brain that is dominated by $CD8^+$ T cells.

CLINICAL MANIFESTATIONS

The clinical manifestations of IRIS are different for each associated pathogen and will therefore be described for each pathogen. Only disease that presents a significant patient management problem will be discussed.

Mycobacterium tuberculosis

M. tuberculosis is the most common pathogen involved in IRIS, with estimates of incidence ranging from 7 to 43% of patients with HIV infection and treated tuberculosis (TB). Most TB-IRIS develops within the first 3 months after the initiation of ART. Patients in whom paradoxical TB-IRIS develops typically

give a history of having improved with treatment of TB before initiation of ART. After starting ART, recurrent, worsening, or new clinical or radiologic manifestations of TB develop. Common manifestations include fever, enlargement of lymph nodes, and worsening radiographic pulmonary infiltrates. Tracheal compression by intrathoracic lymph nodes or massive pleural effusions can cause life-threatening dyspnea. Respiratory failure as a result of worsening pulmonary infiltrates and acute respiratory distress syndrome have occasionally been reported. In a prospective case series from South Africa, neurologic TB-IRIS accounted for 12% of cases of paradoxical TB-IRIS. Meningitis, tuberculoma, or both were the most common manifestations. TB-IRIS should be considered as a potential cause of hepatitis, especially in patients with disseminated TB who are being treated with a combination of antituberculosis therapy and ART. Peritonitis secondary to bowel perforation and splenic rupture are other unusual findings. Though usually negative, mycobacterial cultures may be positive, particularly if IRIS occurs early during antituberculosis therapy and in patients with multidrug-resistant TB. Histologic examination often reveals necrotizing granulomas.

High rates of TB have been reported during ART, especially in the initial months of treatment in ART programs in resource-limited settings. This type of TB has been referred to as ART-associated TB because the mechanisms underlying the manifestations of TB after initiating ART are likely to be heterogeneous. Diagnoses of active TB before initiation of ART may be missed because of the inherent insensitivity of TB diagnostics in this patient group and only later be diagnosed during ART. Because ART-induced immune recovery is a time-dependent process and some patients fail to respond immunologically, a proportion of cases may develop as a result of persisting immunodeficiency. Other patients may have active subclinical disease at the time of ART initiation, and progression to symptomatic disease may be accelerated by ART-induced restoration of a cellular immune response against *M. tuberculosis* antigens. Of patients in this latter group, some have exuberant inflammatory clinical features that are consistent with a diagnosis of TB-IRIS.

Nontuberculous Mycobacteria

Atypical manifestations of *Mycobacterium avium* complex (MAC) disease in patients who had commenced zidovudine monotherapy were the first indication that IRIS may be a complication of ART. MAC and other nontuberculous mycobacteria have been associated with IRIS in 3 to 4% of patients who commence combination ART with a $CD4^+$ T-cell count lower than 100/μL. Disease is usually localized, as opposed to the disseminated nontuberculous mycobacterial disease of patients with acquired immunodeficiency syndrome (AIDS), and is most commonly manifested as fever, night sweats, and lymphadenitis. Unmasking disease is most common. Peripheral lymphadenitis may suppurate and sometimes cause chronically discharging fistulas to the skin. Abdominal disease frequently causes pain, which is usually associated with lymphadenitis and occasionally with omental masses, hepatitis, and inflammation of the spleen (Fig. 402-1). Pulmonary and thoracic disease usually causes cough that is sometimes associated with chest pain. Bronchoscopy may reveal endobronchial lesions. Microscopic examination of biopsy material or aspirates from affected tissues often reveals mycobacteria, but these may not be cultured.

In HIV-seropositive children vaccinated with bacille Calmette-Guérin (BCG), a BCG-associated lymphadenitis and abscesses may develop after starting highly active antiretroviral therapy (HAART) (Fig. 402-2).

Leprosy-related IRIS is usually manifested as unmasking of previous subclinical *Mycobacterium leprae* infection, with a borderline and a type I reactional state.

Cryptococci

The proportion of patients with HIV infection and treated cryptococcosis in whom cryptococcosis-IRIS develops ranges from 8 to 42%. The majority represent a recurrence of previously treated cryptococcal meningitis. Inflammatory reactions to quiescent meningeal infection during the first few weeks of ART have also been reported. The time at onset of cryptococcosis-IRIS varies from 4 days after initiation of ART to around 3 years. Central nervous system (CNS) features of cryptococcosis-IRIS include intracranial cryptococcoma or abscesses, spinal cord abscesses, recalcitrant raised intracranial pressure, optic disc swelling, cranial nerve lesions, dysarthria, hemiparesis, and paraparesis. Extracranial manifestations of cryptococcosis-IRIS include lymphadenitis, eye disease, suppurating soft tissue lesions, and pulmonary disease that may include cavitating or nodular lesions.

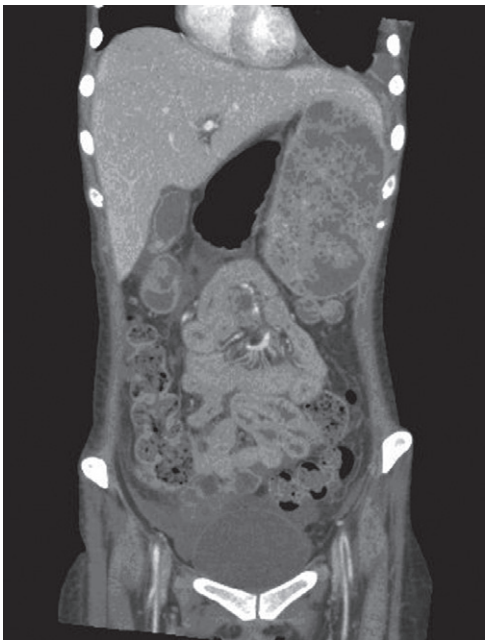

FIGURE 402-1. ***Mycobacterium avium*** **complex–associated immune reconstitution inflammatory syndrome manifested as necrotizing inflammation in the spleen and abdominal lymph nodes.**

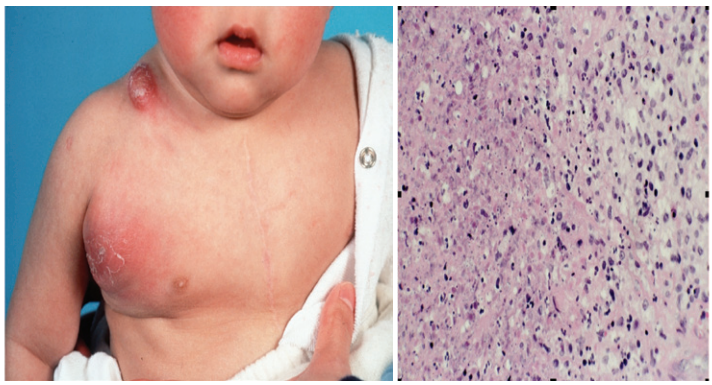

FIGURE 402-2. Bacille Calmette-Guérin (BCG)-associated immune reconstitution inflammatory syndrome after antiretroviral therapy for HIV infection in a child who received BCG vaccination shortly after birth. A biopsy specimen from the larger lesion demonstrated necrotizing granulomatous inflammation.

Cerebrospinal fluid (CSF) profiles in paradoxical cryptococcosis-IRIS may show an increased white blood cell count and an increased opening pressure of greater than 25 cm H_2O, but these features overlap significantly with those observed in patients with non–IRIS-related relapses of cryptococcal meningitis. The value of determining serum and CSF cryptococcal antigen in patients with cryptococcosis-IRIS is unclear. Direct examination of tissue or fluid samples obtained at the time of IRIS may be negative. In contrast to the unmasking form of cryptococcosis-IRIS, the paradoxical forms are often culture negative.

Pneumocystis jirovecii

Patients who have been treated for *P. jirovecii* pneumonitis (PJP) may experience pulmonary inflammation after ART is commenced. It is usually characterized by fever, cough, dyspnea, chest discomfort, and patchy alveolar infiltrates on the chest radiograph (Fig. 402-3). In some patients organizing pneumonia develops.

JC Polyomavirus

Progressive PML of the brain occurs when cellular immune responses fail to control JCV infection of oligodendrocytes and astrocytes. It is characterized by a paucity of inflammatory cells in brain lesions. ART is the only effective therapy, presumably because it enhances cellular immune responses against JCV antigens. However, ART may also result in a paradoxical worsening of established PML or in unmasking of subclinical JCV infection and

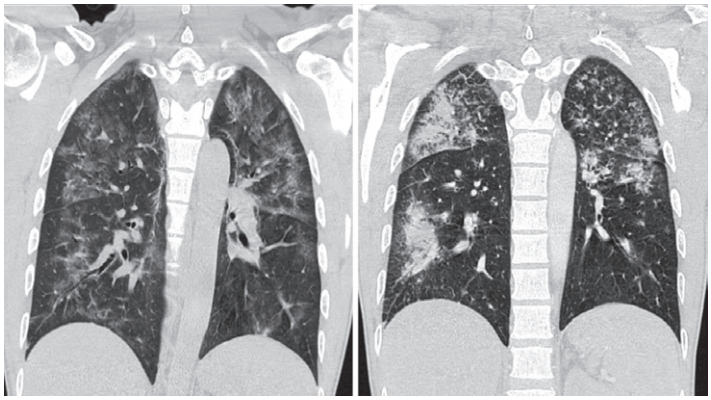

FIGURE 402-3. ***Pneumocystis jirovecii*–associated immune reconstitution inflammatory syndrome.** *Left,* Before treatment of the *P. jirovecii* infection. *Right,* After treatment of the *P. jirovecii* infection and commencing antiretroviral therapy.

appearance of PML for the first time. These manifestations of PML are often atypical in that imaging studies of the brain demonstrate changes associated with inflammation and brain biopsy specimens demonstrate inflammatory cell infiltrates with a prominence of $CD8^+$ T cells. Between 19 and 23% of cases of PML in HIV-infected patients are due to paradoxical or unmasking IRIS. The median time at onset is 7 weeks, and most cases occur within the first 3 months of ART but very occasionally as late as 26 months after commencing ART. Predictors of PML-IRIS have not been identified.

Human Herpesvirus 8

A prospective study of Kaposi's sarcoma (KS) in patients from Mozambique commencing ART found that paradoxical IRIS developed in 31% of patients with pre-ART KS and that unmasking IRIS developed in 7% of patients without pre-ART KS. Clinical manifestations included an increased number of preexisting skin lesions that sometimes exhibited increased nodularity and ulceration, new skin or mucosal lesions, and lymphedema. Independent risk factors for the development of KS-IRIS were KS before ART, human herpesvirus 8 DNA detectable in plasma, a hematocrit of less than 30%, and a plasma HIV RNA level greater than 5 $\log_{10}$ copies/mL.

Some cases of KS-IRIS will resolve without treatment, but chemotherapy is usually necessary. Doxorubicin has been used most often.

Cytomegalovirus

Eye disease is the most common manifestation of IRIS associated with cytomegalovirus (CMV) infection. Retinitis usually develops during the first few weeks of ART as a "paradoxical" worsening of treated retinitis or as a new manifestation of CMV retinitis. Previously treated CMV infection is the most common cause of immune recovery uveitis (IRU), which presumably results from the restoration of an immune response against residual CMV antigens in the eye. The risk for development of CMV-associated IRU is greatest in patients who had a large proportion of the retina affected by CMV infection. It may develop up to 21 months after ART is commenced, and the clinical manifestations vary in severity from a transient vitreitis to persistent uveitis, papillitis, cystoid macular edema, and epiretinal membranes.

Hepatitis B and C Viruses

Hepatotoxicity manifested as elevated serum liver enzyme levels occurs in up to 18% of patients after ART is initiated. Several causes have been defined, but the most important risk factor is concomitant infection with hepatitis B virus (HBV) or hepatitis C virus (HCV). In a prospective study of patients with HIV and HBV infection who commenced ART that was effective against both viruses, 8 of 36 (22%) patients experienced a "flare" of hepatitis that was associated with increased plasma levels of several immune mediators, thus suggesting that it was a manifestation of IRD in the liver. Patients who experienced hepatitis "flares" had higher plasma HBV DNA levels and serum alanine transaminase levels before ART was commenced. There are also data from retrospective studies suggesting that elevated serum enzyme levels after commencement of ART in patients with HIV and HCV infection also reflects IRD in the liver. Severe hepatotoxicity after ART in patients with HIV infection and coinfection with HBV or HCV is uncommon but can occasionally result in liver decompensation and death.

Herpes Simplex Virus

Exacerbation of mucocutaneous herpes simplex virus (HSV) disease may occur after ART is initiated. Sometimes, lesions become hemorrhagic and exhibit tissue necrosis. Rarely, HSV infection of the brain may be unmasked by commencing ART and be manifested as encephalitis.

DIAGNOSIS

Immunologic tests for diagnosing IRIS are currently not available for routine use, although there are data suggesting that whole blood IFN-γ release assays might be of value in predicting and diagnosing TB-IRIS. In the absence of diagnostic tests, IRIS may be established with diagnostic criteria that take into consideration the timing, clinical characteristics, and pathology of the disease, as well as the virologic response to the ART.

TREATMENT

Rx

The general approach to the treatment of IRIS is to continue ART and provide antimicrobial therapy for the provoking infection when it is active (usually in unmasking IRIS). Cessation of ART should be considered only in patients with life-threatening disease when all other measures have failed. Anti-inflammatory therapy should not be given routinely but be reserved for patients with severe inflammation, particularly when it is life-threatening. Corticosteroid therapy is used most often, but its effectiveness may vary from one type of IRIS to another. Thus, a randomized controlled trial in South Africa demonstrated that corticosteroids (prednisone 1.5 mg/kg/day for 2 weeks, then 0.75 mg/kg/day for 2 weeks) are a safe and effective treatment option for paradoxical TB-IRIS.■ In contrast, in an analysis of data from previously reported cases of PML-IRIS, it was suggested that corticosteroid therapy is not effective, although it was indicated that only early use of corticosteroid therapy is likely to be effective. There is anecdotal evidence suggesting that corticosteroid therapy can be effective in other types of IRIS, but there are potential risks to using corticosteroid therapy in HIV patients who are very immunodeficient, and it should only be used after weighing all considerations and should be based on evidence from clinical trials if available. Corticosteroid therapy for IRIS affecting the eye should be supervised by an ophthalmologist.

PREVENTION

Given that a low $CD4^+$ T-cell count is a major risk factor for the development of IRIS, commencing ART at a $CD4^+$ T-cell count higher than 350/μL, as recommended by many treatment guidelines, will prevent most cases. However, this is not possible in patients who are seen for the first time with an OI or in many patients from countries with limited resources. Other strategies to prevent paradoxical IRIS are therefore under investigation.

Observations that disseminated OIs and a shorter duration of treatment of the OI are risk factors for IRIS suggest that the pathogen load is an important factor. Therefore, delaying the introduction of ART so that the OI can be fully treated might be beneficial. However, doing so may increase the risk for the development of other OIs or cancers. The results of the AIDS Clinical Trial Group study A5164 provided evidence supporting the introduction of ART at the same time as antimicrobial therapy, particularly in patients with PJP.■ In addition, randomized studies in patients with TB have provided evidence that survival is better in patients who commence ART at the same time as treatment of TB (Starting Antiretroviral Therapy at Three Points in Tuberculosis [SAPIT] study).■ In contrast, commencing ART at the same time as treatment of cryptococcal meningitis has been shown to reduce long-term survival when compared with delaying ART until the meningitis has been treated. It seems probable that IRIS affecting the CNS is more likely than other types of IRIS to result in morbidity and mortality. Therefore, a single approach to this issue may not be possible, and a strategy for commencing antimicrobial therapy and ART may have to be determined for each pathogen or for infections of the CNS.

PROGNOSIS

The prognosis for patients in whom IRIS develops is highly variable because of differences in the extent of the infection by the provoking pathogen, the characteristics of the immunopathology caused by the restored immune response, and the body site affected. Most cases of IRIS are self-limited and outcomes are usually good. However, mortality rates of up to 66% have been reported for cryptococcosis-IRIS. The mortality rate for TB-IRIS is much lower at about 1%, but hospital admissions are common. Mortality and hospitalization rates are particularly high when TB- or cryptococcosis-IRIS

affects the CNS. Indeed, involvement of the CNS by any type of IRIS may result in death or permanent neurologic disability. For example, mortality rates of 53% have been reported for paradoxical PML-IRIS and 31% for unmasking PML-IRIS. Furthermore, patients who survive PML-IRIS may have neurologic sequelae, such as hemiparesis or seizures. Patients with lymphadenitis resulting from TB-IRIS and those with meningitis resulting from cryptococcosis-IRIS occasionally undergo recurrent relapses and can become steroid dependent.

Autoimmune Disease and Sarcoidosis

Patients with HIV infection who are receiving ART have an increased susceptibility to some autoimmune diseases, mainly Graves' disease, and sarcoidosis. Although sometimes referred to as types of IRIS, they appear to have a different immunopathogenesis.

APPROACH TO THE PATIENT WITH NEUROLOGIC DISEASE

ROBERT C. GRIGGS, RALPH F. JÓZEFOWICZ, AND MICHAEL J. AMINOFF

CLINICAL MANIFESTATIONS

The symptoms of nervous system diseases are a part of everyday experience for most normal people. Slips of the tongue, headaches, backache and other pains, dizziness, lightheadedness, numbness, muscle twitches, jerks, cramps, and tremors all occur in totally healthy persons. Mood swings with feelings of elation and depression, paranoia, and displays of temper are equally a part of the behavior of completely normal people. The rapid increase in information about neurologic diseases coupled with the intense interest of people in all walks of life in medical matters has focused public attention on both common and rare neurologic conditions.

Most older people are concerned that they or their spouse have or are developing Alzheimer's disease or stroke. The almost ubiquitous tremor of the elderly prompts concern about Parkinson's disease. Many younger patients are concerned about multiple sclerosis or brain tumor, and few normal people lack one or more symptoms suggesting the diagnosis of a serious neurologic disease. For most of these and other common diagnoses, the results of imaging and other tests are typically normal when symptoms first appear, and such tests should not be performed to reassure the patient or physician. Moreover, the widespread availability of neurodiagnostic imaging and electrophysiologic, biochemical, and genetic testing has led to the detection of "abnormalities" in many young and most elderly persons. In evaluating a patient's symptoms, it is imperative that a clinical diagnosis be reached without reference to a neurodiagnostic laboratory finding. Patients with disorders such as headache, anxiety, and depression do not usually have abnormal laboratory results. Abnormalities noted on various neurodiagnostic studies are often incidental findings whose treatment may be justified and necessary, but they do not improve the patient's symptoms. Abnormalities detected incidentally that are not accompanied by signs or symptoms may, as for disorders such as hypertension, require aggressive evaluation and treatment, but in general, the adage that it is difficult to improve an asymptomatic patient should be kept in mind. Thus, in elderly patients, few imaging or electrophysiologic studies are interpreted as "normal," but in the absence of specific complaints consistent with the findings, treatment and even further evaluation should reflect an estimate of the specificity and sensitivity of the test as well as the likelihood that the patient will require and benefit from treatment. It is a good rule of thumb that one should never perform (or refer to the result of) a neurodiagnostic procedure without a specific diagnosis or at least a differential diagnosis in mind.

It is important to allow patients to describe any symptoms in their own words. Direct questions are often necessary to fully characterize the problem, but suggested terms or descriptors for symptoms are frequently grasped by a patient unfamiliar with medical terminology and then parroted to subsequent interviewers. The patient's terms should always be used in recording symptoms. Terms such as *lameness, weakness, numbness, heaviness, cramps*, and *tiredness* may each mean pain, weakness, or alteration of sensation to some patients.

DIAGNOSIS

History

In neurologic diagnosis, the history usually indicates the nature of the disease or the diagnosis, whereas the neurologic examination localizes it and quantitates its severity. For many diseases, the history is almost the only avenue to explore. Examples of such disorders include headaches, seizures, developmental disorders, memory disorders, and behavioral diseases. In arriving at a diagnosis, the following points are useful. Consider the entire medical history of the patient. Early life events or long-standing processes such as head or spine trauma, unilateral hearing or visual loss, poor prowess in sports, poor performance in school, spinal curvature, and bone anomalies are easily overlooked but may point to the underlying disease process.

Consider the tempo and duration of the symptoms. Have the symptoms been progressive without remission, or have there been plateaus or periods of return to normal? Cerebral mass lesions (tumor, subdural) tend to have a progressive but fluctuating course; seizures and migraine, an episodic course; and strokes, an abrupt, ictal onset with worsening for 3 to 5 days, followed by partial or complete recovery.

Can one disease account for all of the symptoms and signs? The clinician should formulate a diagnostic opinion in anatomic terms. Is the history suggestive of a single (e.g., stroke or tumor) focus or multiple sites of nervous system involvement (e.g., multiple sclerosis), or is the process a disease of a system (vitamin B_{12} deficiency, myopathy, or polyneuropathy)?

The neurologic history is the most important component of neurologic diagnosis. A careful history frequently determines the cause and allows one to begin localizing the lesions, which aids in establishing whether the disease is diffuse or focal. Symptoms of acute onset suggest a vascular cause or seizure; symptoms that are subacute in onset suggest a mass lesion, such as a tumor or abscess; symptoms that have a waxing and waning course with exacerbations and remissions suggest a demyelinating cause; and symptoms that are chronic and progressive suggest a degenerative disorder.

The history is often the only way of diagnosing neurologic illnesses that typically have normal or nonfocal findings on neurologic examination. These illnesses include many seizure disorders, narcolepsy, migraine and most other headache syndromes, the various causes of dizziness, and most types of dementia. The neurologic history may often provide the first clues that a symptom is psychological in origin. The following are points to consider in obtaining a neurologic history.

- *Carefully identify the chief complaint or problem.* Not only is the chief complaint important in providing the first clue to the physician about the differential diagnosis, but it is also the reason that the patient is seeking medical advice and treatment. If the chief complaint is not properly identified and addressed, the proper diagnosis may be missed and an inappropriate diagnostic work-up may be undertaken. Establishing a diagnosis that does not incorporate the chief complaint frequently focuses attention on a coincidental process irrelevant to the patient's concerns.
- *Listen carefully to the patient for as long as necessary.* A good rule of thumb is to listen initially for at least 5 minutes without interrupting the patient. The patient often volunteers the most important information at the start of the history. During this time, the examiner can also assess mental status, including speech, language, fund of knowledge, and affect, and observe the patient for facial asymmetry, abnormalities in ocular movements, and an increase or a paucity of spontaneous movements as seen with movement disorders.
- *Steer the patient away from discussions of previous diagnostic test results and the opinions of previous caregivers.* Abnormal results of laboratory studies may be incidental to the patient's primary problem or may simply represent a normal variant.
- *Take a careful medical history, medication history, psychiatric history, family history, and social and occupational history.* Many neurologic illnesses are complications of underlying medical disorders or are due to adverse effects of drugs. For example, parkinsonism is a frequent complication of the use of metoclopramide and most neuroleptic agents. A large number of neurologic disorders are hereditary, and a positive family history may establish the diagnosis in many instances. Occupation plays a major role in various neurologic disorders, such as carpal tunnel syndrome (in machine operators and people who use computer keyboards) and peripheral neuropathy (caused by exposure to lead or other toxins).
- *Interview surrogate historians.* Because patients with dementia or altered mental status are generally unable to provide exact details of the history, a family member may need to provide the key details required to make an accurate diagnosis. This situation is especially common with patients who have dementia and certain right hemispheric lesions with various agnosias (lack of awareness of disease) that may interfere with their ability to provide a cogent history. Surrogate historians also provide missing historical details for patients with episodic loss of consciousness, such as syncope and epilepsy.
- *Summarize the history for the patient.* Summarizing the history is an effective way to ensure that all details were covered sufficiently for a tentative diagnosis to be made. Summarizing also allows the physician to fill in historical gaps that may not have been apparent when the history was initially taken. In addition, the patient or surrogate may correct any historical misinformation at this time.
- *End by asking what the patient thinks is wrong.* This question allows the physician to evaluate the patient's concerns about and insight into the

condition. Some patients have a specific diagnosis in mind that spurs them to seek medical attention. Multiple sclerosis, amyotrophic lateral sclerosis, Alzheimer's disease, and brain tumors are diseases that patients often suspect may be the cause of their neurologic symptoms.

Diagnostic Challenges

Two common situations provide special challenges to the diagnostic skills of the physician.

Physical Abuse as a Cause of Neurologic Symptoms

Traumatic injury inflicted by family members or others is usually difficult to detect by the medical history and examination. Physically battered babies, abused children, battered women, and traumatized seniors are often unable or unwilling to complain of this cause or contribution to symptoms. The only method to prevent overlooking of this frequent cause of common problems is systematic consideration of the possibility in every patient and awareness of the often subtle signs that suggest physical trauma: ecchymoses or fractures (often attributed to a logical cause), denial of expected symptoms, failure to keep appointments, and unexplained intensification of neurologic symptoms (headache, dizziness, ringing in the ears, blackouts).

Alcoholism and Drug Abuse

See Chapters 32 and 33. A host of neurologic disorders can be the result of intentional ingestion of toxins (Chapter 110). Patients do not give an accurate account of their use of these agents. Consequently, physical signs and laboratory screening test results that give evidence of drug-related hepatic and other metabolic abnormalities may point to a major underlying problem.

ACUTE NEUROLOGIC DISORDERS REQUIRING IMMEDIATE DIAGNOSIS AND TREATMENT

Most neurologic diagnoses are arrived at by a careful, thorough history and an appropriately complete examination. However, the tempo of illness and the availability of life-saving treatment that is effective only if it is administered within minutes of first evaluating a patient dictate rapid action in several specific circumstances. Coma (Chapter 411), repetitive seizures (Chapter 410), acute stroke (Chapters 414 and 415), suspected meningitis and encephalitis (Chapters 420 and 422), head and spine trauma (Chapter 406), and acute spinal cord compression are diagnosed by clinical and laboratory assessment, and urgent treatment must be instituted as soon as ventilation and cardiac status are stabilized.

NEUROLOGIC EXAMINATION

The neurologic examination is always tailored to the clinical setting of the patient. A complete neurologic examination of a child is much different from that of an elderly adult, and the examination of a patient with specific complaints focuses on findings pertinent to that patient. Thus, more detailed testing of cognition is indicated in patients with behavioral or memory disturbance, and more detailed testing of sensation should be performed in patients with complaints of pain, numbness, or weakness.

However, many tests of neurologic function are routinely indicated in all patients because they provide a baseline for future examination and are frequently helpful in detecting unsuspected neurologic disease in apparently normal persons or in patients whose symptoms initially suggest disease outside the nervous system. It is particularly important to perform all routine tests in patients with abnormalities in one sphere of neurologic dysfunction; otherwise, erroneous localization of a lesion or disease process is likely. For deviations from normal to be recognized and quantitated, it is essential for a physician to have extensive experience in the routine assessment of normal persons.

The General Examination

Specific neurologic symptoms or signs should prompt attention to the assessment of general findings. Head circumference should be measured in patients with central nervous system (CNS) or spinal cord disease (normally 55 ± 5 cm in adults). Head enlargement is occasionally a normal, often hereditary variant but should suggest a long-standing anomaly of the brain or spinal cord. The skin should be inspected for cafe au lait maculae, adenoma sebaceum, vascular malformations, lipomas, neurofibromas, and other lesions (Chapter 426). Neck range of motion, straight leg raising, and spinal curvature (scoliosis) should be assessed. Carotid auscultation for bruits is indicated in all older adults; carotid palpation is seldom informative. In patients with bladder, bowel, or leg symptoms, a rectal sphincter examination for tone and ability to contract voluntarily is usually indicated. Limitation of joint range of motion or painless swelling of joints is often a sign of an unsuspected neurologic lesion.

Neurologic Examination

The various aspects of the detailed neurologic examination are considered in specific symptom and disease sections noted later. The five major divisions of the examination should be assessed in all patients. During a careful medical history, mental status is often adequately assessed: level of consciousness, orientation, memory, language function, affect, and judgment. If any of these functions are abnormal, more detailed testing is needed. Cranial nerve function that should be tested in all patients includes visual acuity (with and without correction); optic fundi; visual fields; pupils (size and reactivity to direct and consensual light); ocular motility; jaw, facial, palatal, neck, and tongue movement; and hearing.

Examination of the motor system (Chapter 429) is essential in all patients because incipient weakness is generally overlooked by the patient. Muscle tone (flaccid, spastic, or rigid), muscle size (atrophy or hypertrophy), and muscle strength can be assessed rapidly. Muscle strength testing should always assess specific functional activities, including the ability to walk on heel and toe, to sit up from a supine position, to rise from a deep knee bend or deep chair, to lift the arms over the head, and to make a tight fist. Gait, stance, and coordination are assessed. The patient should be observed for tremor and other abnormal movements and the muscles inspected for fasciculations.

Sensory testing (Chapter 428) need not be detailed unless there are sensory symptoms. However, vibration perception in the toes and the normality of perception of pain, temperature, and light touch in the hands and feet should be assessed.

Muscle stretch reflexes and plantar responses should always be assessed by evaluating right-left symmetry and disparity between proximal and distal reflexes or arm and leg reflexes. Biceps, triceps, brachioradialis, quadriceps, and ankle reflexes should be quantitated from 1 to 4 (4 = clonus; 3 = spread; 2 = brisk; 1 = hypoactive).

The Comatose Patient

The rapid examination required for a patient with an altered state of consciousness is much different from that of an alert, aware individual (Chapter 411). Many aspects of the neurologic examination cannot be tested: cognitive function, subtleties of sensory perception, specific motor functions, coordination, gait, and stance. Moreover, the muscle stretch reflexes are likely to fluctuate from one moment to the next, and minor asymmetries are much less important than in an awake patient. Instead, attention should focus on examination of the level of consciousness, respiratory pattern, eyelid position and eye movements, pupils, corneal reflexes, optic fundi, and motor responses. Particular elements of the general examination must also be assessed quickly: evidence of cranial and spine trauma, tenderness of the skull to percussion, nuchal rigidity (but not in patients with head or neck trauma), and evidence of physical abuse.

COMMON COMPLAINTS OF POSSIBLE NEUROLOGIC ORIGIN

Weakness

It is axiomatic that patients typically have motor signs before motor symptoms and, conversely, sensory symptoms before sensory signs. Thus, patients with even severe weakness may not report symptoms of weakness. Somewhat paradoxically, patients who complain of "weakness" often do not have confirmatory findings on examination that document the presence of weakness.

Weakness, when it is actually a symptom of neurologic disease, is frequently caused by diseases of the motor unit (Chapters 418, 429, and 430) and is usually reported by a patient in terms of loss of specific functions, for example, difficulty with tasks such as climbing stairs, rising from a chair, sitting up, lifting objects onto a high shelf, or opening jars. Symptoms may also reflect the consequences of weakness, such as frequent falls or tripping. Such symptoms can be remarkably quantitative. A patient with leg muscle weakness who is falling even as infrequently as once a month almost invariably has severe weakness of the knee extensor muscles and can be shown on examination to have a knee extension lag, an inability to lift the leg fully against gravity and to lock the knee.

The symptom of weakness without findings of weakness on examination is not generally the result of neuromuscular disease but can be a sign of neurologic disease outside the motor unit or, more commonly, a symptom of disease outside the nervous system altogether (Table 403-1).

TABLE 403-1 DISORDERS COMMONLY ACCOMPANIED BY WEAKNESS

Disorders of the motor unit
Upper motor neuron lesions—spasticity
Basal ganglia disorders—rigidity
General medical conditions
  Heart failure
  Respiratory insufficiency
  Renal, hepatic, and other metabolic disease
  Alcoholism and other toxin-related disease
Psychiatric and behavioral disorders
  Depression
  Malingering

Fatigue

The complaints of "fatigue," "tiredness," and "lack of energy" are even less likely than the symptom of weakness to reflect definable neurologic disease. With the exception of neuromuscular junction disorders such as myasthenia gravis, fatigue is rarely a complaint of diseases of the motor unit. Fatigue can be a sign of upper motor neuron disease (corticospinal pathways) and is a common complaint of established multiple sclerosis and other multifocal CNS disease. Similarly, any process that produces bilateral corticospinal tract or extrapyramidal disease can cause fatigue. Examples include motor neuron disease (Chapter 418), spinal cord disease in the cervical cord region (Chapter 407), and Parkinson's disease (Chapter 416). In addition, disorders that impair sleep (Chapter 412) may include fatigue as a complaint.

Fatigue, like weakness, is much more often than not a sign of disease outside the central and peripheral nervous system. Depression and other psychiatric and behavioral disorders (Chapter 404) as well as the medical illnesses associated with a complaint of weakness are all frequent causes of fatigue.

Chronic fatigue syndrome and many cases of fibromyalgia (Chapter 282) have fatigue as a dominant, disabling symptom. These disorders are defined in part by the absence of consistent neurologic findings and lack of demonstrable disease in the nervous system.

Spontaneous Movements

Muscle tremors, jerks, twitches, cramps, and spasms (Chapter 417) are frequent symptoms. The cause of spontaneous movements can reside at any level of the nervous system. In general, movements that occur in an entire limb or in more than one muscle group concurrently are caused by CNS disease. Movements confined to a single muscle are likely to be a reflection of disease of the motor unit (including the motor neurons of the brain stem and spinal cord). When spontaneous movements of a muscle are associated with severe pain, patients often use the term *cramp.* Cramp is a medically defined disorder that reflects the intense contraction of a large group of motor units. Leg cramps are occasionally a sign of an underlying disease of the anterior horn cell, nerve roots, or peripheral nerve; however, cramps are frequent in normal persons and particularly common in older patients, and they are usually benign. When they are severe, cramps can produce such intense muscle contraction that muscle injury is caused and muscle enzyme (e.g., creatine kinase) levels are elevated in blood.

The rare muscle diseases in which an enzyme deficiency interferes with substrate use as fuel for exercise (e.g., McArdle's disease) are often associated with severe, exercise-provoked muscle *contractures.* These contractures are electrically silent on electromyography, in contrast to the intense motor unit activity seen with cramps. Contractures must not be confused with the limitation of joint range of motion resulting from long-standing joint disease or long-standing weakness—also termed contractures.

The intense muscle contractions of *tetany* are frequently painful. Although tetany is usually a reflection of hypocalcemia (Chapter 253), it can occasionally be seen without demonstrable electrolyte disturbance. Tetany results from hyperexcitability of peripheral nerves. Similarly, in the syndrome of *tetanus* produced by a clostridial toxin (Chapter 304), intensely painful, life-threatening muscle contractions arise from hyperexcitable peripheral nerves. A number of toxic disorders, such as strychnine poisoning and black widow spider envenomation, produce similar neurogenic spasms.

Muscle Pain

Acute muscle pain in the absence of abnormal muscle contractions is an extremely common symptom. When such pain occurs after strenuous exercise or in the context of an acute viral illness (e.g., influenza), it probably reflects muscle injury. In such patients, the serum creatine kinase level is often raised. It is uncommon for this frequent and essentially normal sign of muscle injury to be associated with weakness or demonstrable ongoing muscle disease. *Chronic* muscle pain is a common symptom but is seldom related to a definable disease of muscle.

TABLE 403-2 CHARACTERISTIC GAIT DISORDERS

SPECIFIC DISORDER	LOCATION OF LESION	CHARACTERISTICS
Spastic gait	Bilateral corticospinal pathways within the thoracic or cervical cord or in the brain	Legs stiff, feet turning inward, "scissoring"
Hemiparetic gait	Unilateral central nervous system, cervical cord, or brain	Affected leg circumducted, foot extended, arm flexed
Sensory ataxia	Posterior columns of the spinal cord or peripheral nerve	Wide-based, high steps; Romberg's sign present
Cerebellar ataxia	Brain stem or cerebellum	Wide-based steps; Romberg's sign absent
Parkinsonian gait	Basal ganglia	Shuffling, small steps
Dystonic gait	Basal ganglia; also corticospinal pathways	Abnormal posture of the arms, head, neck
Gait disorder of the elderly	Multifactorial: bihemispheric disease, spinal cord disease, impaired proprioception, muscle weakness	Stooped posture, wide-based steps; often retropulsion
Steppage gait	Distal muscle weakness	High steps ("steppage")
Waddling gait	Proximal muscle weakness	Both legs circumducted to allow locking of the knees
Antalgic gait	Non-neurologic; reflects disease of joints, bones, or soft tissue	Minimizes pain in the hip, spine, leg
Hysterical gait	Psychiatric or behavioral disorder	Reeling side to side, associated astasia-abasia, bizarre arm and trunk movements

Episodic and Intermittent Weakness

The complaint of attacks of severe weakness or paralysis occurring in a patient with baseline normal strength is an uncommon symptom. It is typical of the periodic paralyses and may also be seen with episodic ataxias and myotonic disorders (Chapter 429). All of these disorders are ion channelopathies. These channelopathies (e.g., the calcium channelopathy hypokalemic periodic paralysis) are rare but treatable disorders (Chapter 429). Episodic weakness is also seen in patients with neuromuscular junction disorders, such as myasthenia gravis and the myasthenic syndrome (Chapter 430). On occasion, patients with narcolepsy complain of intermittent paralysis as a reflection of *sleep paralysis* (Chapter 412).

Loss of Balance

Unsteadiness of gait is a common symptom. When it is associated with complaints of dizziness or vertigo (Chapter 436), disease of the labyrinth, the vestibular nerve, the brain stem, or the cerebellum is a probable cause. When unsteadiness and loss of balance are unassociated with dizziness, particularly if the unsteadiness appears to be out of proportion to other symptoms of the patient, a widespread disorder of sensation or motor function is likely.

Abnormal Gait and Posture

The ability to stand and to walk in a well-coordinated, effortless fashion requires the integrity of the entire nervous system. Relatively subtle deficits localized to one part of the central or peripheral nervous system produce characteristic abnormalities (Table 403-2).

Sensory Symptoms

Sensory symptoms can be negative or positive. Negative symptoms represent a loss of sensation, such as a feeling of numbness. Positive symptoms, by contrast, consist of sensory phenomena that occur without normal

stimulation of receptors and include paresthesias and dysesthesias. *Paresthesias* may include a feeling of tingling, crawling, itching, compression, tightness, cold, or heat and are sometimes associated with a feeling of heaviness. The term *dysesthesias* is used correctly to refer to abnormal sensations, often tingling, painful, or uncomfortable, that occur after innocuous stimuli, whereas *allodynia* refers to painful perception from a stimulus that is not normally painful. For some patients, it may be difficult to distinguish paresthesias and dysesthesias from pain. *Hypesthesia* and *hypalgesia* denote a loss or impairment of touch or pain sensibility, respectively. By comparison, *hyperesthesia* and *hyperalgesia* indicate a lowered threshold to tactile or painful stimuli, respectively, such that there is increased sensitivity to such stimuli.

With the use of a wisp of cotton, a pin, and a tuning fork, the trunk and extremities are examined for regions of abnormal or absent sensation. Certain instruments are available for quantifying sensory function, such as the computer-assisted sensory examination, which is based on the detection of touch, pressure, vibratory, and thermal sensation thresholds.

Alterations in pain and tactile sensibility can generally be detected by clinical examination. It is important to localize the distribution of any such sensory loss to distinguish between nerve, root, and central dysfunction. Similarly, abnormalities in proprioception can be detected by clinical examination when patients are unable to detect the direction in which a joint is moved. In severe cases, there may be pseudoathetoid movements of the outstretched hands, sensory ataxia, and sometimes postural and action tremors.

Disorders of peripheral nerves commonly lead to sensory disturbances that depend on the population of affected nerve fibers (Chapter 428). Some neuropathies are predominantly large-fiber neuropathies. Appreciation of movement and position is impaired, and paresthesias are common. Examination reveals that vibration, position, and movement sensations are impaired, and movement becomes clumsy and ataxic. Pain and temperature appreciation is relatively preserved. The tendon reflexes are lost early. In other neuropathies, it is the small fibers especially that are affected; spontaneous pain is common and may be burning, lancinating, or aching in quality. Pain and temperature appreciation is disproportionately affected in these neuropathies, and autonomic dysfunction may be present. Examples of small-fiber neuropathies include certain hereditary disorders, Tangier disease, and diabetes. Most sensory neuropathies are characterized by a distal distribution of sensory loss, whereas sensory neuronopathies are characterized by sensory loss that may also involve the trunk and face and tends to be particularly severe. Sensory changes in a radiculopathy conform to a root territory; in cauda equina syndromes, sensory deficits involve multiple roots and may lead to saddle anesthesia and loss of the normal sensation associated with the passage of urine or feces.

Lesions of the *posterolateral columns* of the cord, such as occur in multiple sclerosis (Chapter 419), vitamin B_{12} deficiency (Chapter 425), and cervical spondylosis (Chapter 407), often lead to a feeling of compression in the affected region and to a Lhermitte sign (paresthesias radiating down the back and legs on neck flexion). Examination reveals ipsilateral impairment of vibration and joint position senses, with preservation of pain and temperature appreciation. Conversely, lesions of the *anterolateral region* of the cord (as by cordotomy) or *central* lesions interrupting fibers crossing to join the spinothalamic pathways (as in syringomyelia; Chapter 426) lead to impairment in pain and temperature appreciation with relative preservation of vibration, joint position sense, and light touch. Motor deficits may also be present and help localize the lesion. Upper motor neuron dysfunction (Chapter 407) from cervical lesions leads to quadriplegia, whereas more caudal lesions lead to paraplegia; lesions below the level of the first lumbar vertebra may simply compress the cauda equina and result in lower motor neuron deficits from a polyradiculopathy as well as impairment of sphincter and sexual function.

NEUROLOGIC DIAGNOSTIC PROCEDURES

Lumbar Puncture

Sampling of cerebrospinal fluid (CSF) by lumbar puncture is crucial for accurate diagnosis of meningeal infections and carcinomatosis (Fig. 403-1). CSF analysis is also helpful in evaluating patients with central or peripheral nervous system demyelinating disorders and with intracranial hemorrhage, particularly when imaging studies are inconclusive.

The CSF formula often provides an important clue to the pathologic process involved (Table 403-3). An elevated white blood cell count is seen with infections and other inflammatory diseases as well as with carcinomatosis. The differential white blood cell count may point to a specific class of pathogen; polymorphonuclear leukocytes suggest a bacterial process, whereas mononuclear cells suggest a viral, fungal, or immunologic cause. The CSF glucose concentration is typically reduced in bacterial and fungal infections as well as with certain viral infections (e.g., mumps virus) and with sarcoidosis. The CSF protein concentration is elevated in a variety of disorders, including most infections and demyelinating neuropathies.

Specialized tests that can be performed on CSF include oligoclonal bands, a pathologic pattern of bands on CSF electrophoresis that is seen in up to 90% of patients with multiple sclerosis. The bands, which represent monoclonal immunoglobulins that are locally synthesized in the CNS, are not specific for multiple sclerosis and may be seen with other inflammatory and noninflammatory conditions, including systemic lupus erythematosus, human immunodeficiency virus infection, and stroke.

CSF polymerase chain reaction is a rapid, sensitive, and specific test for the diagnosis of herpes simplex encephalitis (Chapter 422), for which it has replaced brain biopsy as the diagnostic procedure of choice. The CSF VDRL (Venereal Disease Research Laboratory) assay is a specific although insensitive test for neurosyphilis (Chapter 327).

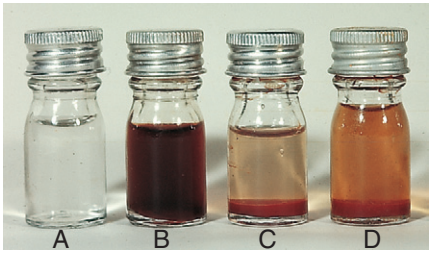

FIGURE 403-1. Cerebrospinal fluid examination. A, Normal crystal-clear CSF. **B**, Blood in the CSF, which could result from a traumatic (bloody) tap or from subarachnoid hemorrhage. In a traumatic tap, subsequent tubes of CSF are usually less bloody. **C**, Centrifuged CSF in a traumatic tap. The supernatant is nearly clear. **D**, CSF from a patient with subarachnoid hemorrhage. There is blood at the bottom of the tube and the supernatant is yellow (xanthochromic) as a result of breakdown of blood cells in the CSF before the lumbar puncture. (From Forbes CD, Jackson WD. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003, with permission.)

TABLE 403-3 CHARACTERISTIC CEREBROSPINAL FLUID FORMULAS

	TURBIDITY AND COLOR	OPENING PRESSURE	WBC COUNT	DIFFERENTIAL CELLS	RBC COUNT	PROTEIN	GLUCOSE
Normal	Clear, colorless	70-180 mm H_2O	0-5 cells/μL^3	Mononuclear	0	<60 mg/dL	> ⅔ serum
Bacterial meningitis	Cloudy, straw colored	↑	↑↑	PMNs	0	↑↑	↓
Viral meningitis	Clear or cloudy, colorless	↑	↑	Lymphocytes	0	↑	Normal
Fungal and tuberculous meningitis	Cloudy, straw colored	↑	↑	Lymphocytes	0	↑↑	↓↓
Viral encephalitis	Clear or cloudy, straw colored	Normal to ↑	↑	Lymphocytes	0 (herpes ↑)	Normal to ↑	Normal
Subarachnoid hemorrhage	Cloudy, pink	↑	↑	PMNs and lymphocytes	↑↑	↑	Normal (early); ↓ (late)
Guillain-Barré syndrome	Clear, yellow	Normal to ↑	0-5 cells/μL^3	Mononuclear	0	↑	Normal

PMN = polymorphonuclear leukocyte; RBC = red blood cell; WBC = white blood cell.

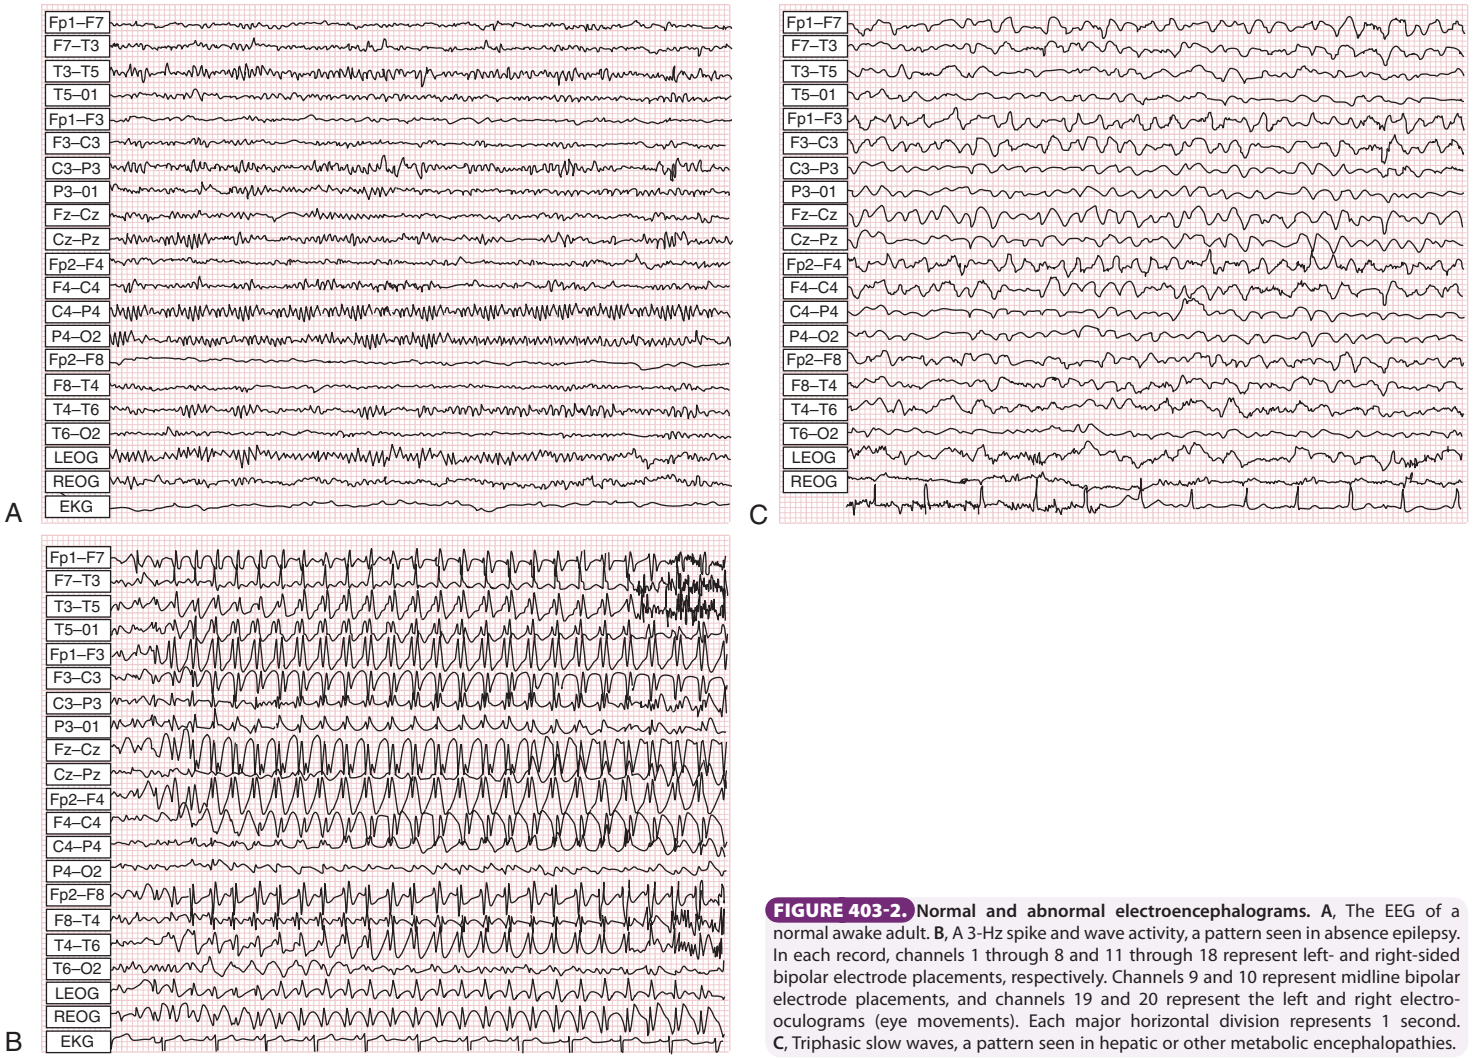

FIGURE 403-2. Normal and abnormal electroencephalograms. A, The EEG of a normal awake adult. **B**, A 3-Hz spike and wave activity, a pattern seen in absence epilepsy. In each record, channels 1 through 8 and 11 through 18 represent left- and right-sided bipolar electrode placements, respectively. Channels 9 and 10 represent midline bipolar electrode placements, and channels 19 and 20 represent the left and right electrooculograms (eye movements). Each major horizontal division represents 1 second. **C**, Triphasic slow waves, a pattern seen in hepatic or other metabolic encephalopathies.

A lumbar puncture should not be performed in patients who have an obstructive, noncommunicating hydrocephalus or a focal CNS mass lesion causing raised intracranial pressure because reducing CSF pressure acutely in these settings by lumbar puncture may result in cerebral or cerebellar herniation. Lumbar puncture may be safely performed in patients with a *communicating* hydrocephalus, such as with idiopathic intracranial hypertension (pseudotumor cerebri), and it may even be an effective treatment in selected patients with this condition.

Electroencephalography

Electroencephalography is the recording and measurement of scalp electrical potentials to evaluate baseline brain functioning and paroxysmal brain electrical activity suggestive of a seizure disorder.

Electroencephalography is performed by securing 20 electrodes to the scalp at predetermined locations based on an international system that uses standardized percentages of the head circumference, the "10-20 system." Each electrode is labeled with a letter and a number, the letter identifying the skull region (Fp = frontopolar; F = frontal; P = parietal; C = central; T = temporal; O = occipital) and the number identifying the specific location, with odd numbers representing left-sided electrodes and even numbers right-sided electrodes. These electrodes are then connected in various combinations of pairs to generate voltage potential differences, and the potentials are recorded on a chart recorder.

To delineate the spatial distribution of the changing electrical field for an electroencephalogram (EEG), an orderly arrangement of electrode pairs is used, and each specific arrangement is known as a montage. Montages are generally of two types: *referential,* in which each electrode is connected to a single reference electrode, such as the ear; and *bipolar,* in which electrodes are connected sequentially to one another to form a chain. A standard EEG generally records about 30 minutes of brain activity, both in the awake state and in the first two stages of sleep. Various activating procedures are used during the recording of an EEG, including hyperventilation and photic stimulation. These activating procedures may precipitate seizure discharges in some patients with seizure disorders, thereby increasing the sensitivity of the test.

The amplitudes of scalp electrical potentials are quite low, averaging 30 to 100 μV. They represent a summation of excitatory postsynaptic potentials and inhibitory postsynaptic potentials that are largely generated by the pyramidal cells in layer 4 of the cerebral cortex. Action potentials are of too brief a duration to have an effect on the EEG.

The EEG is analyzed with respect to symmetry between each hemisphere; wave frequency and amplitude; and the presence of spikes (20 to 70 msec) and sharp waves (70 to 200 msec), which may indicate a seizure focus. Electroencephalographic frequencies are divided into four categories as follows: delta: <4 Hz; theta: 4-7 Hz; alpha: 8-13 Hz; beta: >13 Hz.

The normal waking EEG (Fig. 403-2A) in a patient with eyes closed contains rhythms of alpha frequency in the occipital leads and beta frequency in the frontal leads. Normal sleep causes a generalized slowing of electroencephalographic frequencies and an increase in amplitude in each stage of sleep such that stage 4 sleep consists of more than 50% large-amplitude delta rhythms. Electroencephalographic abnormalities are of two types: abnormalities in background rhythm and abnormalities of a paroxysmal nature (Table 403-4).

The major usefulness of electroencephalography is for diagnosis and categorization of a seizure disorder (Fig. 403-2B). EEGs are neither highly sensitive nor completely specific for diagnosis of seizures. Because seizures are paroxysmal events, it is not unusual for an EEG to be normal—or only minimally abnormal—in a patient with epilepsy if it is recorded during an interictal phase (the period between seizures). Only about 50% of patients with seizures show epileptiform activity on the first EEG. Repeating the EEG with provocative maneuvers, such as sleep deprivation, hyperventilation, and photic stimulation, may increase this percentage to 90%. Conversely, about

TABLE 403-4 ELECTROENCEPHALOGRAPHIC ABNORMALITIES

ELECTROENCEPHALOGRAPHIC ABNORMALITY	CLINICAL CORRELATE
BACKGROUND RHYTHM ABNORMALITIES	
Generalized slowing	Most metabolic encephalopathies
Triphasic waves	Hepatic, renal, and other metabolic encephalopathies
Focal slowing	Large mass lesions (tumor, large stroke)
Electrocerebral inactivity with lack of response to all stimuli	Brain death
PAROXYSMAL ABNORMALITIES	
3-Hz spike and wave, augmented by hyperventilation	Absence epilepsy
3- to 4-Hz spike and wave in light sleep or with photic stimulation	Primary generalized epilepsy
Central to midtemporal spikes	Benign rolandic epilepsy, other partial epilepsies
Anterior temporal spikes or sharp waves	Simple or complex partial seizures of mesial temporal origin
Hypsarrhythmia (high-voltage chaotic slowing with multifocal spikes)	Infantile spasms (West's syndrome)
Burst suppression	Severe anoxic brain injury, barbiturate coma

1% of adults and 3.5% of children who are neurologically normal and who never had a seizure have epileptiform activity on an EEG.

The EEG may provide clues to the diagnosis of certain neurologic conditions, including viral encephalitis, prion disorders, and some forms of coma. In each of these situations, the EEG can have specific patterns that suggest a specific neurologic diagnosis. In herpes simplex encephalitis, periodic lateralizing epileptiform discharges emanating from the temporal lobes are frequently present. Triphasic slow waves are common in hepatic encephalopathy (Fig. 403-2C) but are a nonspecific finding. Creutzfeldt-Jakob disease is characterized by the presence of bilateral synchronous repetitive sharp waves. The EEG is also helpful in evaluating comatose patients, in confirming brain death when an apnea test cannot be performed because of cardiac instability, and for staging sleep in polysomnography.

In the past, the EEG was often used to localize neurologic lesions such as stroke, brain tumor, and abscess. With the advent of neuroimaging, EEG is almost never used for these purposes.

Nerve Conduction Study

A nerve conduction study (NCS) is the recording and measurement of the compound nerve and muscle action potentials elicited in response to an electrical stimulus.

To perform a motor NCS, a surface (active) recording electrode is placed over the belly of a distal muscle that is innervated by the nerve in question. A reference electrode is placed distally over the tendon. The nerve is then supramaximally stimulated at a predetermined distance proximal to the active electrode, and the resultant compound motor action potential (CMAP) is recorded. The terminal latency, amplitude, and duration of the evoked potential are measured directly, and the conduction velocity is calculated from the latencies of the evoked potentials with stimulation at two different points; the distance between the two points (conduction distance) is divided by the difference between the corresponding latencies (conduction time) to derive a calculated velocity (conduction velocity = distance ÷ time).

To perform a sensory NCS, the active recording electrode is placed over the portion of the skin innervated by the nerve in question, and a sensory nerve action potential is recorded after electrical stimulation of the nerve, similar to that noted for a motor NCS. NCS abnormalities include reduced amplitudes, prolonged terminal latencies, conduction block, and slowed conduction velocities (Table 403-5).

The NCS is helpful in documenting the existence of a neuropathy, quantifying its severity, and noting its distribution (i.e., whether it is distal, proximal, or diffuse). In addition, the NCS can provide information on the modality involved (i.e., motor versus sensory) and can suggest whether the lesion is axonal or demyelinating. The NCS is also helpful in diagnosis of compressive mononeuropathies, such as carpal tunnel syndrome, ulnar palsy, peroneal nerve palsy, and tarsal tunnel syndrome.

TABLE 403-5 NERVE CONDUCTION STUDY ABNORMALITIES

ABNORMALITY	CLINICAL CORRELATE
Reduced CMAP amplitude	Axonal neuropathy
Prolonged terminal latency	Demyelinating neuropathy Distal compressive neuropathy
Conduction block	Severe focal compressive neuropathy Severe demyelinating neuropathy
Slowed conduction velocity	Demyelinating neuropathy

CMAP = compound muscle action potential.

F Wave and H Reflex

The F wave and H reflex are ways of looking at the conduction characteristics for proximal portions of nerves, including the nerve roots. The F wave is a late CMAP evoked intermittently from a muscle by a *supramaximal* electrical stimulus to the nerve, and it is due to antidromic activation (backfiring) of alpha motor neurons. F waves can be elicited from practically all distal motor nerves. The H reflex is a late CMAP that is evoked regularly from a muscle by a *submaximal* stimulus to a nerve, and it is due to stimulation of Ia afferent fibers (a spinal reflex). The H reflex can be routinely obtained from calf muscles only with stimulation of the tibial nerve in the popliteal fossa.

F waves are helpful in diagnosis of Guillain-Barré syndrome, in which demyelination is often confined to the proximal portions of nerves early in the course of the disease. The H reflex is often absent in patients with acute S1 radiculopathy.

Repetitive Stimulation Study

A repetitive stimulation study is a method of measuring electrical conduction properties at the neuromuscular junction. To perform a repetitive stimulation study, a surface recording electrode is placed over a muscle belly, and the nerve innervating that muscle is electrically stimulated with a supramaximal stimulus at a certain frequency. A series of electrical potentials are then recorded whose amplitude is roughly proportional to the number of muscle fibers that are being activated.

A repetitive stimulation study is helpful in diagnosis of neuromuscular junction disorders, such as myasthenia gravis and myasthenic syndrome (Lambert-Eaton syndrome). In myasthenia gravis, the amplitudes of evoked potentials become progressively smaller with repetitive stimulation in clinically involved muscles. Clinically uninvolved muscles often do not demonstrate this decrement. In myasthenic syndrome, an *increment* is seen in the amplitudes of evoked potentials with rapid repetitive electrical stimulation.

Electromyography

Electromyography (EMG) is the recording and study of insertional, spontaneous, and voluntary electrical activity of muscle. It allows physiologic evaluation of the motor unit, including the anterior horn cell, peripheral nerve, and muscle.

EMG is performed by insertion of a needle electrode into the muscle in question and evaluation of the motor unit action potentials both visually (on the oscilloscope screen) and aurally (over the loudspeaker). Muscles are typically studied at rest and during voluntary contraction. During EMG, the electrical activity of muscle is studied in four settings (Table 403-6): *insertional activity* (occurring within the first second of needle insertion), *spontaneous activity* (electrical activity at rest), *voluntary activity* (electrical activity with muscle contraction), and *recruitment pattern* (change in electrical activity with maximal contraction).

EMG is helpful in evaluation of patients with weakness in that it can help determine whether the weakness is due to anterior horn cell disease, nerve root disease, peripheral neuropathy, or an intrinsic disease of muscle itself (myopathy). EMG can differentiate acute denervation from chronic denervation and may thus give an indication about the time course of the lesion causing the neuropathy. In addition, on the basis of which muscles have an abnormal EMG pattern, it is possible to determine whether the neuropathy is due to a lesion of a nerve root (radiculopathy), the brachial or lumbosacral plexus (plexopathy), an individual peripheral nerve (mononeuropathy), or multiple peripheral nerves (polyneuropathy).

EMG is also helpful in differentiation of active (inflammatory) myopathies from chronic myopathies. Active myopathies include dermatomyositis, polymyositis, inclusion body myositis, and some forms of muscular dystrophy, such as Duchenne's dystrophy. Chronic myopathies include the other muscular dystrophies, the congenital myopathies, and some metabolic myopathies. Myotonic dystrophy and myotonia congenita produce characteristic myotonic discharges.

It may take several weeks for a muscle to develop EMG signs of acute denervation after nerve transection. For this reason, EMG performed in the acute setting after nerve injury should be interpreted with caution, and it may need to be repeated at a later date.

Evoked Potentials

Evoked potentials are ways of measuring conduction velocities for sensory pathways in the CNS by means of computerized averaging techniques. Three types of evoked potentials are routinely performed: visual, brain stem auditory, and somatosensory.

Pattern Reversal Visual Evoked Responses

The pattern reversal visual evoked response (PVER) assesses the function of central visual pathways, in particular the optic nerves. To perform this test, EEG electrodes are placed over the occipital regions of the scalp, and the patient is asked to look at the center of a black-and-white checkerboard screen with one eye patched. The color of the checks alternates about twice per second, a process known as pattern reversal. The scalp potentials elicited by approximately 100 such pattern reversals are then recorded and signal averaged by a computer. This signal averaging cancels the random EEG activity and differentially amplifies the evoked potential. A single waveform (P 100) is recorded for each eye, and its latency is measured. Normal latency for the P 100 waveform is approximately 100 msec. A prolonged P 100 latency in one eye, in the absence of ocular disease, implies slowed conduction velocity in the optic nerve and suggests demyelination of that nerve. PVER testing is helpful when multiple sclerosis is suspected clinically and it is necessary to document the presence of a second demyelinating lesion in the CNS that may not be clinically evident (Fig. 403-3).

TABLE 403-6 ELECTROMYOGRAPHIC ABNORMALITIES

ABNORMALITY	CLINICAL CORRELATE
INSERTIONAL ACTIVITY	
Prolonged	Acute denervation Active (usually inflammatory) myopathy
SPONTANEOUS ACTIVITY	
Fibrillations and positive waves	Acute denervation Active (usually inflammatory) myopathy
Fasciculations	Chronic neuropathies Motor neuron disease (rare fasciculations may be normal)
Myotonic discharges	Myotonic disorders Acid maltase deficiency
VOLUNTARY ACTIVITY	
Neuropathic potentials: large-amplitude, long-duration, polyphasic potentials	Chronic neuropathies and anterior horn cell diseases
Myopathic potentials: small-amplitude, short-duration, polyphasic potentials	Chronic myopathies Neuromuscular junction disorders
RECRUITMENT	
Reduced	Chronic neuropathic disorders
Rapid	Chronic myopathies

Brain Stem Auditory Evoked Responses

The brain stem auditory evoked response (BAER) assesses function in the central auditory pathways in the brain stem. EEG electrodes are placed over the vertex and mastoid process, and a series of clicks at a frequency of 5 Hz are delivered to each ear separately for 3 minutes. The scalp potentials elicited by the clicks are then recorded and signal averaged by a computer. This signal averaging cancels the random EEG activity and differentially amplifies the evoked potential. A series of five waves are recorded for each ear, and each wave corresponds to a different point in the central auditory pathway (Table 403-7). The wave latencies for the right and left ears are compared, and a delay in any of the latencies suggests a lesion at that point in the central brain stem auditory pathway. BAER testing is helpful in diagnosis of acoustic schwannoma and other tumors in the cerebellopontine angle.

Somatosensory Evoked Responses

The somatosensory evoked response (SER) assesses conduction in the central somatosensory pathways in the posterior columns of the spinal cord, brain stem, thalamus, and primary sensory cortex in the parietal lobes. To perform SER testing, recording electrodes are placed over Erb's point and the

TABLE 403-7 BRAIN STEM EVOKED RESPONSE WAVE GENERATORS

WAVE	LOCATION

V	Inferior colliculus

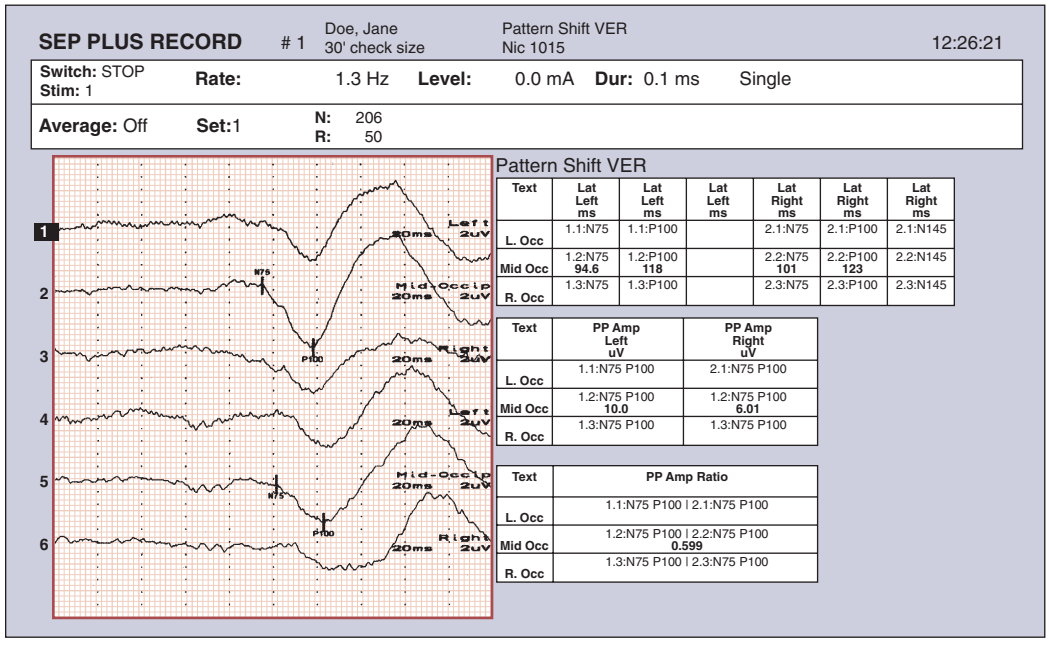

FIGURE 403-3. Abnormal pattern reversal visual evoked response in a patient with multiple sclerosis. The prolonged P 100 wave latency with left eye stimulation suggests a conduction defect in the left optic nerve. The top three channels represent right eye stimulation, and the bottom three channels represent left eye stimulation. Each horizontal division represents 20 msec.

TABLE 403-8 STRENGTHS AND WEAKNESSES OF SELECTED IMAGING MODALITIES

MODALITY	STRENGTHS	WEAKNESSES
Computed tomography (CT)	Fast; best test for acute intraparenchymal or subarachnoid hemorrhage and calcification; easy to monitor patients; excellent for bones	Less sensitive to parenchymal lesions than MRI; potential for significant reaction to contrast material; radiation exposure
Conventional angiography	Best imaging modality for aneurysms, vascular malformations, and vasculitis	Invasive and often lengthy; risk of stroke and other complications
Conventional myelography	Good images of nerve roots and small osteophytic lesions; accurate for bony stenosis; useful in patients with contraindications to MRI	Invasive, with risk of complications from lumbar puncture and instillation of contrast material; does not image intramedullary lesions well
CT myelography	Excellent for imaging nerve roots and detecting root compression from degenerative processes	Invasive, with risk of complications from lumbar puncture and instillation of contrast material
Magnetic resonance imaging (MRI)	Noninvasive; no radiation; multiplanar; extremely sensitive, safe contrast agent	Less sensitive than CT for detection of subarachnoid hemorrhage and calcification; less sensitive for bony skull fractures; contraindicated in patients with implanted metallic devices or foreign bodies; the patient must be able to cooperate and tolerate confined space; time-consuming relative to CT
Magnetic resonance angiography (MRA)	Noninvasive; good for screening for extracranial and intracranial vascular disease; may be performed with or without contrast agent	Need cooperative patient; technically demanding; may overestimate the degree of vascular stenosis (noncontrast MRA); cannot image distal vessels optimally without contrast agent; may miss small lesions (e.g., aneurysms)
Positron emission tomography (PET)	Limited role in helping to distinguish radiation necrosis from tumor; sometimes helpful in the diagnosis of Alzheimer's disease and epilepsy	Requires a cyclotron to generate radioisotopes with a short half-life; lower resolution and less available than MRI or CT
Single-photon emission computed tomography (SPECT)	Occasionally useful in epilepsy; sensitive for diffuse pathologic processes; easier to use than PET	Lower resolution than PET, MRI, or CT
Proton magnetic resonance spectroscopy	Localization of seizure focus; may help diagnose and classify dementias, such as Alzheimer's disease; may distinguish brain tumors from other mass lesions; may distinguish radiation necrosis from recurrent tumor	Specificity not yet determined; not routinely available; lower resolution; time-consuming
Ultrasonography	Fast; easy to use; can be performed at the bedside to assess vessel patency	Does not assess the vertebral arteries; less sensitive and specific than MRA; cannot visualize vessels in the upper neck and cranial base
Transcranial Doppler (TCD)	Fast; easy to use; assesses vascular velocities quantitatively; can assess cerebral vasospasm and occluded vessels	Does not provide images of vessels

Reproduced and modified from Hackney D. Radiologic imaging procedures. In: Goldman L, Ausiello D, eds. *Cecil Medicine,* 23rd ed. Philadelphia: Saunders Elsevier; 2008:2623-2627.

cervical spine (for medial or ulnar nerve stimulation), over the popliteal fossa and lumbar spine (for peroneal or tibial nerve stimulation), and over the scalp. A series of 1000 to 2000 electrical shocks at a frequency of 5 Hz are delivered to the median or ulnar nerve (for an upper extremity SER) or to the peroneal or tibial nerve (for a lower extremity SER). The scalp potentials elicited by the electrical shocks are then recorded and signal averaged by a computer. This signal averaging cancels the random EEG activity and differentially amplifies the evoked potential. A series of waves are recorded for each nerve stimulated, with each wave corresponding to a different point in the somatosensory pathways in the spinal cord, brain stem, and cerebral cortex. The wave latencies for the right and left limbs are compared, and a delay in any of the latencies suggests a lesion at that point in the somatosensory pathways.

SER testing, like PVER, is helpful when multiple sclerosis is suspected clinically and it is necessary to document the presence of a second demyelinating lesion in the CNS that may not be clinically evident. SER testing is also useful for monitoring of spinal cord function intraoperatively in patients undergoing spinal surgery.

Electronystagmography

Electronystagmography accurately records eye movements and nystagmus after certain provocative maneuvers. To perform this test, disc electrodes are placed over the bridge of the nose and lateral to each outer canthus, and the electrical leads from these discs are connected to an oscilloscope. Because the cornea is electropositive and the retina is electronegative, these electrodes accurately record lateral eye movements. The patient is first observed for spontaneous nystagmus with the eyes open and closed and then for nystagmus evoked with lateral gaze, for nystagmus induced by hot and cold air instilled in the outer ears (caloric induced), and for positional nystagmus. The last is performed by rotating the patient in a specialized chair. Spontaneous nystagmus suggests a vestibular pathologic lesion, as does an imbalance in the nystagmus evoked by these maneuvers in the right and left ears.

Imaging

On the basis of the relative advantages and disadvantages of computed tomography (CT), magnetic resonance imaging (MRI), and other neuroimaging modalities, different clinical entities can and should be assessed differently (Table 403-8). In acute ischemic stroke (Chapter 414) without bleeding, CT abnormalities typically appear within 4 to 12 hours and are seen even earlier with larger infarctions and embolic infarctions. CT detects hemorrhagic stroke (Chapter 415) acutely and can estimate its age. CT is also the preferred initial imaging modality for detection of intraparenchymal hemorrhage and subarachnoid hemorrhage, and it often suggests whether an aneurysm is the likely cause. Either CT angiography or magnetic resonance arteriography can display the three-dimensional anatomy of aneurysms with sufficient detail for therapy to be planned, but surgical treatment generally requires pre-procedure catheter arteriography. CT is the first-line method for evaluation of brain trauma and diagnosis of a subdural or epidural hematoma (Chapter 406), usually without requiring intravenous contrast material. However, MRI is better than CT to delineate the anatomy of a subdural hematoma and to estimate the age of the lesion. Many brain tumors are initially recognized on CT scans, but MRI is the preferred modality for detection and characterization of all brain tumors (Chapter 195).

404 PSYCHIATRIC DISORDERS IN MEDICAL PRACTICE

JEFFREY M. LYNESS

OVERVIEW

Disorders in Psychiatry

Psychiatric disorders, also known as mental illnesses, are extraordinarily common and have a profound impact on well-being and functional status. Collectively, psychiatric disorders account for more aggregate disability than do those involving any other organ system, with depression alone being second only to cardiovascular disorders.

Psychiatric disorders are defined as *disorders of the psyche*, that is, as conditions that affect *thoughts*, *feelings*, or *behaviors*. By definition, such mental disturbances must be sufficient to produce significant *distress* in the patient or *impairment in role or other functioning*. Because the causes and pathogenesis of most psychiatric disorders are incompletely understood, current classification is based on clinical syndromes, which are defined by diagnostic criteria that have high inter-rater reliability because they emphasize discrete reportable or observable symptoms and signs.

Specific Syndromes

Because many *psychiatric disorders* result from the direct influence of neurologic conditions, systemic diseases, or drugs on brain functioning, assessment of any new or worsened psychiatric condition must include evaluation for their potential contributions (Table 404-1). Delirium (Chapter 27) and dementia (Chapter 409), which are *cognitive disorders* that are always the result of one or more neurologic, systemic, or drug causes, are defined by impairment in intellectual functions such as attention, memory, or language. Although cognitive impairment is the hallmark of cognitive disorders, these conditions may also be manifested as alterations in other aspects of mental status, including mood, thought content, thought process, and behavior. If a noncognitive psychiatric syndrome is caused by an identifiable underlying condition, it is known as a *secondary psychiatric disorder* (e.g., depression secondary to hypothyroidism).

The major nonsecondary, noncognitive psychiatric syndromes (Table 404-2) can coexist with multiple syndromes; for example, a patient with severe depression may have depressive, anxiety, and psychotic syndromes simultaneously. Substance use disorders, also known as addictions, are considered in Chapters 32 and 33.

Comorbid Conditions in Psychiatry

It is common for persons who suffer from mental disorders to meet the diagnostic criteria for more than one condition. Although such comorbidity may reflect the limitations of current approaches to diagnosis, psychiatric comorbidity influences the choices or sequence of indicated treatments and may worsen the overall prognosis. Comorbidity with general medical conditions, probably reflecting complex bidirectional causal relationships between physical and mental illnesses, is also common, and such comorbidity often worsens the overall prognosis for both conditions.

Treatments in Psychiatry

Treatments in psychiatry are intended to reduce or eliminate symptoms, thereby improving the patient's distress and dysfunction and averting suicidal behavior. Pharmacotherapy remains an evidence-based mainstay of the treatment of many psychiatric conditions despite the previously underestimated side effects of some drugs. The evidence for a number of forms of psychotherapy, administered in individual, group, or family contexts, supports its use as primary treatment or as co-treatment of many conditions. Other psychosocial interventions, ranging from self-help groups to the use of structured treatment or residential programs, are often important adjuncts to treatment.

TABLE 404-2 IMPORTANT PSYCHIATRIC SYNDROMES AND DISORDERS

SYNDROME	MAIN SYMPTOMS AND SIGNS	MAY OCCUR AS PART OF THESE DISORDERS
Cognitive	Deficits in intellectual functions, e.g., level of consciousness, orientation, attention, memory, language, praxis, visuospatial, executive functions	Cognitive disorders Mental retardation (if onset in childhood)
Mood	Depressive: lowered mood, anhedonia, negativistic thoughts, neurovegetative symptoms *or* Manic: elevated or irritable mood, grandiosity, goal-directed hyperactivity with increased energy, pressured speech, decreased sleep need	Cognitive disorders Mood disorders (primary or secondary) Psychotic disorders (schizoaffective disorder)
Anxiety	All include anxious mood and associated physiologic symptoms (e.g., palpitations, tremors, diaphoresis). May include various types of dysfunctional thoughts (e.g., catastrophic fears, obsessions, flashbacks) and behavior (e.g., compulsions, avoidance behavior)	Cognitive disorders Mood disorders (primary or secondary) Psychotic disorders (primary or secondary) Anxiety disorders (primary or secondary)
Psychotic	Impairments in reality testing: delusions, hallucinations, thought process derailments	Cognitive disorders Mood disorders (primary or secondary) Psychotic disorders
Somatoform	Somatoform symptoms: physical symptoms resulting from unconscious psychogenic causes	Mood disorders (primary or secondary) Anxiety disorders (primary or secondary) Somatoform disorders
Personality pathology	Enduring patterns of dysfunctional emotional regulation, thought patterns, interpersonal behavior, impulse regulation	Cognitive disorders (dementia) Change in personality because of general medical condition Personality disorders

Based on categories and criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*, 4th ed. Washington, DC: American Psychiatric Association; 2000.

Nonpharmacologic evidence-based therapies include electroconvulsive therapy or light therapy for particular forms of major depression, and encouraging data are emerging to support deep brain stimulation for severe depressive or obsessive-compulsive disorders.

Mood Disorders

Mood disorders are categorized as either *unipolar*, characterized by depressive episodes only, or *bipolar*, characterized by manic or hypomanic episodes but typically also including depressive episodes.

MAJOR DEPRESSIVE DISORDER

DEFINITION

Major depressive disorder is characterized by one or more episodes of idiopathic major depressive syndrome (Table 404-3).

TABLE 404-3 SYMPTOMS/SIGNS OF AN EPISODE OF MAJOR DEPRESSIVE SYNDROME

DIAGNOSTIC CRITERIA (*EACH MUST BE PRESENT PROMINENTLY, MOST OF THE DAY AND NEARLY EVERY DAY FOR A MINIMUM OF 2 CONSECUTIVE WEEKS*)
Depressed mood (may be irritable mood in children and adolescents) *or* Diminished interest or pleasure *and* Weight loss or change in appetite (decrease or increase) Change in sleep (insomnia or hypersomnia) Psychomotor agitation or retardation Fatigue or anergia Feeling of worthlessness or guilt Diminished concentration or indecisiveness Recurrent thoughts of death or suicidal ideation, a suicide attempt, or a specific suicide plan
MNEMONIC TO AID RECALL OF DIAGNOSTIC CRITERIA
SIG: E CAPS (*i.e., prescribe energy capsules*) for depressed mood **S**leep change **I**nterests **G**uilt **E**nergy **C**oncentration **A**ppetite/weight **P**sychomotor changes **S**uicide
DEPRESSIVE SYMPTOMS/SIGNS GROUPED CONCEPTUALLY, WITH ADDITIONAL COMMON PHENOMENA
Emotional
Depressed mood, sadness, tearfulness Irritability (*seen in all ages, perhaps most commonly in children/adolescents and the elderly*) Anxiety Loss of interests or pleasure (anhedonia)
Ideational
Worthlessness/lowered self-esteem Guilt Hopelessness/nihilism Helplessness Thoughts of death, dying, suicide
Somatic/Neurovegetative
Change in appetite/weight Change in sleep Anergia Decreased libido Trouble concentrating Diurnal variation in symptoms (*mornings—worst pattern is most characteristic*)
Other
Ruminative thinking (*tendency to dwell on one* [*negativistic*] *theme*) Somatoform symptoms or somatic worry Psychotic symptoms (*negativistic delusions most characteristic*)—defines the subtype "Major Depression with Psychotic Features"

Based on criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*, 4th ed. Washington, DC: American Psychiatric Association; 2000.

EPIDEMIOLOGY

In the United States, major depression has a point prevalence of approximately 3 to 5% in males and 8 to 10% in females. Lifetime prevalence is up to 10% in males and 20 to 25% in females. It is difficult to determine the true incidence rates of a new depressive disorder, but new episodes have an annual incidence of approximately 3%. Despite minor variations, similar rates are found in most industrialized nations. Depression accounts for more than twice as much disability in midlife as any other medical condition does, and its overall cumulative burden is greater than that from all but cardiovascular disorders. The economic impact is also enormous, with U.S. estimates of annual costs for depression exceeding $12 billion for treatment, $8 billion for associated morbidity, and $33 billion for lost earnings and work productivity.

PATHOBIOLOGY

Major depression is probably not a single disease entity but rather a heterogeneous group of conditions with multiple pathogenic mechanisms. It is both multifactorial and polygenic: genetic factors account for up to 50% of the risk for depression, but multiple gene loci, most of which are currently unknown, are probably involved in a complex interplay with developmental and environmental influences. Alterations in the brain's noradrenergic and serotonergic systems are present and are most likely related to the efficacy of current antidepressant medications. The hypothalamic-pituitary-adrenal axis is hyperactive in depression, as evidenced by a nonsuppressed response to the dexamethasone suppression test, although this test is too insensitive and nonspecific for clinical use as a diagnostic tool. Neuroimaging studies in subjects with depression show an array of findings, including smaller hippocampal volumes, which are thought to be the result of exposure to elevated cortisol levels, and altered regional cerebral metabolic activity of the frontal-striatal circuitry and anterior cingulate cortex. Cognitive psychology studies have demonstrated dysfunctional patterns of negative thinking, with distorted thoughts about self, the future, and the environment. Poor quality or absence of social relationships and stressful life events, particularly events such as deaths, separations, or functional impairment, are powerfully associated with depression as well.

CLINICAL MANIFESTATIONS

The symptoms of depression (see Table 404-3) may be conceptually grouped as alterations in mood, ideation (i.e., thought content), and somatic/neurovegetative functioning. Importantly, patients with depressive illness may be seen without a depressed mood, albeit by definition they must have loss of interest or pleasure in their usually desired activities. They may also exhibit prominent anxiety, irritability, or somatization. Although mild forms of major depression in the community often remit spontaneously within a few months without medical care, patients may already have had persistent symptoms for months or years before seeking treatment.

DIAGNOSIS

The diagnosis is made clinically by elicitation of findings from the history and mental status examination to determine the presence of major depressive syndrome. The differential diagnosis includes other idiopathic disorders with episodes of major depression, such as bipolar disorder (distinguished by a history of manic episodes) and schizoaffective disorder (distinguished by a history of psychotic episodes in the absence of depression). Major depression may accompany delirium or dementia, and secondary depression also commonly accompanies serious medical illnesses; these comorbid conditions require careful, well-coordinated care.

TREATMENT

Rx

The three phases of treatment include (1) *acute*, in which treatment is provided to resolve the major depressive episode; (2) *continuation*, in which the acute treatment is continued for at least 4 to 8 months to prevent relapse; and (3) *maintenance*, for those with two to three or more episodes of recurrent depression, for whom treatment is maintained indefinitely to reduce the frequency and severity of future recurrences. Combinations of psychotherapy and medication are used for more complex or severe clinical conditions.

Acute treatment of depression includes focused psychotherapies (Table 404-4), which are more efficacious than usual care and equivalent to medications when used for patients in primary care settings. Based on the patient's preference, psychotherapy rather than medications may be the initial treatment of mild to moderate major depression with prominent psychosocial stressors. Involvement of family members for education and support and sometimes for formal family therapy may be an important adjunctive or

primary therapeutic approach. These therapies may be administered with decreased frequency during the continuation or maintenance phases of treatment. However, psychotherapies may be difficult to implement and are not likely to help patients with more severe forms of depression, including major depression with psychotic features.

Medications should be used as initial treatment for most patients with more severe forms of major depression. Antidepressant medications (Table 404-5) are also effective for acute, continuation, and maintenance therapy. A recent meta-analysis found that sertraline and escitalopram have the best profiles of efficacy and tolerability whereas mirtazapine and venlafaxine also have strong efficacy in head-to-head comparisons with other antidepressants.■ Because antidepressant medications typically do not begin to improve symptoms for at least 1 to 2 weeks, with maximal benefit accruing up to at least 6 to 8 weeks, it is crucial to see patients regularly (every 1 to 2 weeks initially) to monitor their clinical status, to provide support and education, and to foster adherence. Antidepressant medications appear to increase the relative risk for suicidal behavior in adolescents and young adults, so careful benefit/risk assessments must be made in such patients. The relative risk for suicidal behavior is not increased by drug treatment in individuals older than 25 years and is substantially lowered in older adults. Electroconvulsive therapy is preferred for the most severe forms of major depression, including major depression with psychotic features, and is also used for depression that is refractory to other forms of treatment.

Optimal care for depression in primary care settings may be enhanced by the use of on-site mental health collaborative care models. However, despite considerable evidence supporting such models,■ the lack of reimbursement mechanisms has limited their implementation in most communities and clinical settings.

PROGNOSIS

Optimal, guideline-based treatment of major depression results in full remission in at least 80% of patients, and the expectation is that patients with major depression will return to baseline functioning after resolution of the depressive episodes. However, at least 50 to 70% of patients will suffer recurrent episodes, up to 20% may experience chronic major depression, and many more will be in incomplete remission with persistent lower-level symptoms because of a variety of factors, including limited access to care, nonadherence, or insufficiently assertive treatments.

BIPOLAR DISORDER

DEFINITION AND EPIDEMIOLOGY

Bipolar disorder is characterized by recurrent episodes of idiopathic mania. Most persons with bipolar disorder also have recurrent episodes of major depression.

The point prevalence of bipolar disorder is approximately 1%. Males and females are affected equally. The average age at first onset is late adolescence or early adulthood. Childhood onset is possible, but diagnosis may be difficult because of symptomatic overlap with other conditions of childhood, including attention-deficit/hyperactivity disorder. Onset in midlife to late life is also possible, although most persons in whom mania develops in later life have mania secondary to medical conditions or drugs rather than idiopathic bipolar disorder.

PATHOBIOLOGY

Even though the pathogenesis of bipolar disorder remains unclear, genetic factors play a greater role than in unipolar depressive conditions. Heritability has been traced to several specific loci in rare families, but genetic screening is not clinically useful and the gene associations have, to date, revealed no unifying pathophysiologic themes. Most cases of bipolar disorder are polygenic and multifactorial, with nongenetic factors accounting for approximately 50% of the risk for the disorder. Dysregulation of the frontostriatal systems is probably involved in the manifestations of the illness. Though not specific enough to be diagnostic, structural neuroimaging studies show increased ventricular-brain ratios suggestive of parenchymal atrophy. Phase advance of central circadian rhythms can precipitate episodes of mania, so the decreased sleep of persons with incipient mania may produce a vicious cycle in which phase-advanced circadian cycles lead to a further decreased need for sleep, thereby resulting in further phase advancement. Psychosocial stressors also often play a role in precipitating episodes of both mania and depression.

TABLE 404-4 TREATMENTS OF DEPRESSION

NAME OF PSYCHOTHERAPY	APPROACH
Cognitive psychotherapy	Identify and correct negativistic patterns of thinking
Interpersonal psychotherapy	Identify and work through role transitions or interpersonal losses, conflicts, or deficits
Problem-solving therapy	Identify and prioritize situational problems; plan and implement strategies to deal with top-priority problems
Psychodynamic psychotherapy	Use therapeutic relationship to maximize use of the healthiest defense mechanisms and coping strategies

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The symptoms of mania include a distinct period of abnormally and persistently elevated (euphoric) or irritable mood; goal-directed hyperactivity, often for pleasurable activities with poor judgment that leads to long-lasting adverse financial, psychosocial, or medical consequences, such as sprees of spending, sexual activity, or gambling; decreased need for sleep; pressured speech; and distractibility.

As with major depression, the diagnosis is based on findings from the history and examination revealing a pattern of recurrent manic episodes (Table 404-6), which are usually interspersed with major depressive episodes and cannot be explained by general medical conditions, medications, or other substances. Although persons with bipolar disorder may become psychotic while in manic or depressed states, a history of psychotic symptoms in the absence of mania or depression indicates a diagnosis of schizoaffective disorder rather than bipolar disorder. Manic and depressive episodes may also be seen in the course of delirium (Chapter 27) and dementia (Chapter 409), in which case the psychiatric symptoms are accompanied by the cognitive impairment that is the hallmark of the latter conditions.

TREATMENT Rx

The mainstay of treatment of bipolar disorder is mood stabilizer medications to reduce the frequency and severity of recurrent manic and depressive episodes. Traditional mood stabilizers with substantial evidence base to support their use include lithium (typical dose of 600 to 1500 mg/day or higher given in two or three divided doses as needed to achieve plasma levels of 0.6 to 1.2 mEq/L [up to 1.4 mEq/L in acute mania]), valproic acid (typical dose of 500 to 1500 mg/day or higher as tolerated to achieve plasma levels of 50 to 100 μg/mL), and carbamazepine (typical dose of 400 to 1200 mg/day as tolerated to achieve plasma levels of 4 to 12 μg/mL). The combination of lithium plus valproate is superior to valproate alone for prevention of relapses.■ A number of other anticonvulsants have been tried, but generally with less empirical support for their use, although lamotrigine (starting at 25 mg/day, maximum dose of 200 mg/day, titrated slowly to minimize the risk for Stevens-Johnson syndrome) can be used for prophylaxis against depressive episodes. Even though several second-generation antipsychotic medications have received approval by the Food and Drug Administration for their mood-stabilizing properties, their potential to precipitate metabolic syndrome and, to a lesser extent, tardive dyskinesia should limit their use as *maintenance* medications to patients for whom true mood stabilizers are inefficacious or poorly tolerated. For *acute* episodes of mania, second- or first-generation antipsychotics are more rapidly efficacious than mood stabilizers, with doses similar to their use for acute psychosis (see Table 404-12). For acute treatment of depressive episodes, antidepressants may be required, but they may precipitate mania; therefore, patients should receive therapeutic doses of a mood stabilizer first, and exposure to antidepressant medication should be for the minimum dose and duration required to reach euthymia. Electroconvulsive therapy is useful for refractory mania or depression and for patients with relative contraindications to medications, such as pregnant women. Standard psychotherapeutic approaches for unipolar depression may also be used for bipolar patients during depressive episodes. Ongoing psychotherapy may be important to encourage compliance with maintenance therapies and to help patients manage psychosocial stressors in order to minimize their impact on precipitating acute manic or depressive decompensations.

PROGNOSIS

Although the classically described course of bipolar disorder includes return to baseline functioning between episodes, some patients may experience frequent debilitating episodes (known as "rapid cycling," defined as four or more episodes per year), whereas others may experience a deterioration in overall functioning over time.

TABLE 404-5 COMMONLY USED ANTIDEPRESSANT MEDICATIONS

NAME OF CLASS/ SPECIFIC MEDICATION	IMMEDIATE MECHANISM OF ACTION	INITIAL DOSE	TARGET DOSE RANGE*	SIDE EFFECTS	COMMENTS
SSRIs (selective serotonin re-uptake inhibitors)	Inhibit presynaptic re-uptake of serotonin			Nausea, diarrhea, sexual dysfunction, serotonin syndrome	
Citalopram		20 mg qd	20-60 mg qd		Few drug-drug interactions
Escitalopram		10 mg qd	10-20 mg qd		Enantiomer of citalopram
Fluoxetine		20 mg qd	20-40 mg qd (depression), up to 80 mg qd (OCD)		Long half-life; tends to be activating
Paroxetine		20 mg qd	20-50 mg qd	Anticholinergic effects	Tends to be sedating
Sertraline		25-50 mg qd	50-200 mg qd		Few drug-drug interactions
SNRIs (serotonin and norepinephrine re-uptake inhibitors)	Inhibit presynaptic re-uptake of serotonin and norepinephrine			Nausea, diarrhea, serotonin syndrome, sinus tachycardia, mild elevation in blood pressure, tremor	
Duloxetine		30-60 mg qd	30-60 mg qd on a twice-daily schedule, maximum of 120 mg/day		
Venlafaxine		37.5 mg bid	150-375 mg/day on bid schedule		XR form allows once-daily dosing
Desvenlafaxine		50 mg qd	50 mg qd, maximum of 100 mg ER qd		Metabolite of venlafaxine
TCAs (tricyclic antidepressants)	Inhibit presynaptic re-uptake of serotonin and norepinephrine (in varying proportions depending on the specific TCA)			Anticholinergic effects, sedation, orthostatic hypotension, tremor, cardiac conduction delays, ventricular arrhythmias	
Amitriptyline		25-75 mg qhs	150-300 mg qhs		Strongly anticholinergic and sedating; aim for combined amitriptyline/ nortriptyline blood level of 120-250 ng/mL
Desipramine		25-75 mg qd	150-300 mg qd		Aim for blood level of 115-250 ng/mL
Doxepin		25-75 mg qhs	150-300 mg qhs		Strongly sedating
Imipramine		25-75 mg qd	150-300 mg qd		Strongly anticholinergic; aim for combined imipramine/ desipramine blood level of 180-350 ng/mL
Nortriptyline		25-50 mg qhs	50-150 mg qhs		Aim for blood level of 50-150 ng/mL; least anticholinergic of the TCAs
MAOIs (monoamine oxidase inhibitors)	Inhibit monoamine oxidase, the enzyme that catalyzes oxidative metabolism of monoamine neurotransmitters			Need for tyramine-free diet to avoid sympathomimetic (hypertensive) crisis; sedation, anticholinergic effects, tremor, orthostatic hypotension	
Isocarboxazid		10 mg bid	20-60 mg/day in bid-qid dosing		
Phenelzine		15 mg tid	45-90 mg/day in tid or qid dosing		
Selegiline	(selective MAO-B inhibitor)	5 mg bid	5 mg bid	Tyramine-free diet not required	Take with meals
Tranylcypromine		10 mg tid	30-60 mg/day in tid dosing		
Other					
Bupropion	Unknown, although it is a weak inhibitor of presynaptic re-uptake of norepinephrine and dopamine	75-150 mg/day	300-450 mg/day	Activating; risk for seizures reduced by divided dosing and careful dosage titration	Divided dosing required unless using SR or XR forms
Mirtazapine	Antagonist at α_2 and 5-HT_2 receptors	15 mg qhs	30-45 mg qhs; maximum of 45 mg qhs	Sedation, hyperphagia	Becomes more stimulating at higher doses
Trazodone	Inhibits presynaptic re-uptake of serotonin; antagonist at 5-HT_2 and 5-HT_3 receptors	25-50 mg qhs	300-600 mg qhs for depression, 25-100 mg qhs for insomnia	Sedation, priapism	Few sexual side effects

*Target doses in the elderly may be lower.
ER = extended release; 5-HT_2 = 5-hydroxytryptamine; OCD = obsessive-compulsive disorder; qhs = at bedtime; SR = sustained release; XR = extended release.

OTHER MOOD DISORDERS

Although chronic major depression should be the diagnosis in patients with long-lasting major depressive episodes, others may have chronic (≥2 years) lower-level depressive symptoms, known as *dysthymic disorder*, that can be treated with a combination of antidepressant medication and psychotherapy. A significant minority (perhaps 20 to 40%) of such patients will improve substantially with aggressive treatment. Other patients may have "less than major depression" of shorter duration, increasingly being referred to as "subsyndromal" or "subthreshold" depression; growing evidence suggests that broad psychosocial interventions (e.g., bibliotherapy, social activation) may improve outcomes in such patients.

Less severe bipolar spectrum disorders include *bipolar II disorder*, which is characterized by episodes of hypomania (i.e., low-level manic symptoms

TABLE 404-6 SYMPTOMS/SIGNS OF AN EPISODE OF MANIA

DIAGNOSTIC CRITERIA
A distinct period of abnormally, persistently elevated, expansive, or irritable mood lasting ≥1 week *and*
3 or more of the following symptoms/signs (4 or more if the mood abnormality is only irritability):
Inflated self-esteem/grandiosity
Decreased need for sleep
More talkative or pressure to keep talking
Subjective experience of racing thoughts or flight of ideas observed on examination
Distractibility
Increase in goal-directed activity or psychomotor agitation
Excessive involvement in pleasurable activities with high potential for painful consequences
MANIC SYMPTOMS/SIGNS GROUPED CONCEPTUALLY, WITH ADDITIONAL COMMON PHENOMENA
Emotional
Euphoria
Irritability
Labile affect
Ideational
Grandiosity
Somatic/Neurovegetative
Psychomotor agitation
Decreased need for sleep
Distractibility
Other
Goal-directed hyperactivity
Pressured speech
Impaired judgment
Flight of ideas
Psychotic symptoms (may include delusions, hallucinations, or derailment of thought processes such as loose associations)—defines the subtype "mania with psychotic features"

Based on criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*, 4th ed. Washington, DC: American Psychiatric Association; 2000.

TABLE 404-7 TYPES OF ANXIETY DISORDERS

ANXIETY DISORDER	MAJOR CLINICAL CHARACTERISTICS
Panic disorder	Recurrent unexpected panic attacks, typically with anticipatory anxiety and avoidance behavior
Obsessive-compulsive disorder (OCD)	Recurrent obsessions (distressing thoughts experienced as ego-alien) and compulsions (mental or physical actions in an attempt to neutralize obsessions or in response to rigid rules)
Acute stress disorder and post-traumatic stress disorder (PTSD)	Responses to a severely traumatic event, including re-experiences of the trauma, avoidance behavior, and hyperarousal
Generalized anxiety disorder	Excessive anxiety and worry, not meeting the criteria for other anxiety disorders, lasting ≥6 months
Phobias	
Agoraphobia	Anxiety about or avoidance of places or situations from which escape might be difficult or embarrassing or in which help might not be available in the event of panic symptoms
Social phobia	Anxiety provoked by exposure to social situations, typically with ensuing avoidance behavior; may be generalized (i.e., in response to many interpersonal situations) or specific in response to a particular social situation (e.g., using a public restroom, public speaking)
Specific phobia	Anxiety provoked by exposure to a specific feared object or (nonsocial) situation, typically with ensuing avoidance behavior

Based on categories and criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*, 4th ed. Washington, DC: American Psychiatric Association; 2000.

without substantial functional impairment and without psychosis) and episodes of major depression. Such patients typically seek care during depressive episodes rather than during hypomania, but antidepressant medication may worsen the manic symptoms. It is therefore imperative to ask about a history of manic or hypomanic symptoms in the evaluation of all patients with depression. *Cyclothymic disorder*, which includes episodes of hypomania and low-level depressive episodes, may be difficult to distinguish from the mood instability seen in "cluster B" personality disorders (see later).

ANXIETY DISORDERS

DEFINITION

The anxiety disorders (Table 404-7) are a group of conditions whose hallmark is idiopathic anxiety, typically accompanied by psychological (i.e., thought content) and somatic symptoms. Anxiety is a common accompanying symptom in many other psychiatric disorders, but the primary anxiety disorders lack the cognitive deficits, depressive or manic symptoms, or psychosis seen in these other disorders.

EPIDEMIOLOGY

Panic disorder and obsessive-compulsive disorder (OCD) each have point prevalence rates of approximately 1 to 2%. The prevalence of acute stress disorder and post-traumatic stress disorder (PTSD) varies widely by population. Generalized anxiety disorder has a prevalence of approximately 2 to 3%, whereas the phobias collectively have a prevalence of 10% in the adult population. Clear data on incidence rates are not available. Most primary anxiety disorders have an age at first onset in late adolescence through the mid-30s. Most anxiety symptoms with new onset in later life are due to mood or cognitive disorders or are secondary to medical illnesses or drugs; true late-onset primary anxiety disorders are often triggered by traumatic or other stressful life events.

PATHOBIOLOGY

Most of the anxiety disorders may be understood as inappropriate triggering of the stress response system, which is commonly referred to as the "fight or flight" response. However, it is important to recognize that the responses involve a wide range of cognitive, motor, neuroendocrine, and autonomic systems and thus are not limited to manifestations of sympathetic nervous system activity. The central nucleus of the amygdala is believed to play a crucial role in coordinating the anxiety response. The amygdala receives excitatory glutamatergic input from several cortical areas and from the thalamus, thereby allowing it to respond to a wide variety of stimuli, including sensory input from the external world, as well as stressors that are processed and recognized by cortical association areas. The amygdala in turn projects to the many brain regions that subserve the clinical manifestations of the anxiety response, in part through its direct projections to the important centers of monoaminergic systems: dopaminergic neurons of the ventral tegmental area in the midbrain, noradrenergic neurons in the locus caeruleus, and serotonergic neurons in the raphe nuclei.

From a cognitive psychology perspective, the pathogenesis of many anxiety disorders, particularly panic, may be understood as catastrophic misinterpretations of normal somatic sensations. A vulnerable individual may become aware of a normal or minimally abnormal body sensation, which is interpreted as something concerning, thereby leading to sympathetic and other autonomic arousal, which in turn leads to further somatic sensations (e.g., tachycardia, sweating) in what becomes a vicious cycle of thoughts and somatic symptoms. The pathogenesis of acute stress disorder and PTSD may be understood from psychodynamic perspectives as psychological attempts to cope with or master a traumatic life event that is difficult or impossible to "master" and integrate into one's sense of self and the world.

OCD appears to have a pathogenesis distinct from that of the other anxiety disorders. It probably involves altered functioning of the striatofrontal systems, as well as a prominent role of the serotonergic systems. The obsessions and compulsions of OCD may represent inappropriate triggering of neural "scripts" involving thoughts and behaviors that have been analogized to the scripts involved in animal grooming and other complex behavior. Patterns of heritability and symptomatic comorbidity strongly suggest that the pathogenesis of OCD is more closely related to that of movement disorders, such as tic disorders (Chapter 417), than to the other primary anxiety disorders.

CLINICAL MANIFESTATIONS

Most individuals experience one or more somatic symptoms (Table 404-8) that accompany the psychic anxiety, regardless of whether the anxiety is normal or part of a pathologic condition. Such somatic symptoms may be referable to virtually every body organ system.

TABLE 404-8 COMMON SOMATIC MANIFESTATIONS OF ANXIETY

CARDIORESPIRATORY
Palpitations
Chest pain
Dyspnea or sensation of being smothered
GASTROINTESTINAL
Sensation of choking
Dyspepsia
Nausea
Diarrhea
Abdominal bloating or pain
GENITOURINARY
Urinary frequency or urgency
NEUROLOGIC/AUTONOMIC
Diaphoresis
Warm flushes or chills
Dizziness or presyncope
Paresthesias
Tremor
Headache

TABLE 404-9 COMMON TYPES OF OBSESSIONS AND COMPULSIONS IN OBSESSIVE-COMPULSIVE DISORDER

OBSESSIONS
Aggressive (fears of harming self or others, of blurting out obscenities, or of other unwanted aggressive acts; unwanted violent or horrific images)
Contamination (concerns about dirt, germs, body waste or secretions, environmental contaminants, or animals/insects)
Sexual (concerns about unwanted sexual images or impulses)
Hoarding/saving
Religious (*scrupulosity*) (excessive concerns about sacrilege, blasphemy, right/wrong, morality)
Need for symmetry/exactness
Somatic (excessive concern about illness, body part, or appearance)
COMPULSIONS
Cleaning/washing (excessive or ritualized handwashing, showering, or other grooming)
Checking (checking locks, stove, appliances; checking body in relation to somatic obsessions; checking that did not or will not harm self or others)
Repeating rituals (rereading or rewriting; routine activities such as going through a door or arising from a chair)
Counting
Ordering/arranging
Hoarding/saving

Adapted from Goodman WK, Price LH, Rasmussen SA, et al. The Yale-Brown Obsessive Compulsive Scale. I. Development, use, and reliability. *Arch Gen Psychiatry*. 1989;46:1006-1011.

Many anxiety disorders include acute, discrete periods of symptoms known as *panic attacks*. In a panic attack, the patient experiences a rapid rise in anxiety, fear-related thoughts, and somatic symptoms in the space of a few minutes, known as a crescendo onset. The acute symptoms resolve quickly, typically within an hour or less.

Panic Disorder

Panic disorder consists of *recurrent panic attacks*. Although some panic attacks may be precipitated by situations known to be stressful, at least some attacks must be *unexpected* ("out of the blue"). Patients also exhibit *anticipatory anxiety*, in which they experience ongoing psychic distress by worrying about their next panic attack or the attack's effects (e.g., humiliation if the attack were to happen in public view). In addition, patients manifest *avoidance behavior* by staying away from known triggers or from situations in which having a panic attack might be dangerous (e.g., driving) or particularly distressing (e.g., in public spaces). For many patients, the anticipatory anxiety and avoidance behavior may be more disabling than the panic attacks themselves. Avoidance behavior may overlap with *agoraphobia*, which is defined as a distressing and disabling fear of places or situations from which escape might be difficult or embarrassing or from which help might not be available in the event of a panic attack. Common agoraphobic foci include being outside one's home alone, being on bridges or in tunnels, traveling by vehicle, or being in crowds or lines. Up to 40 to 50% of patients with panic disorder have agoraphobia (termed *panic disorder with agoraphobia*), whereas the others have agoraphobia without panic disorder (termed *agoraphobia without history of panic disorder*).

Obsessive-Compulsive Disorder

Patients with OCD have recurrent *obsessions* or *compulsions* (Table 404-9); the vast majority of patients have both. OCD should not be confused with obsessive-compulsive personality traits or disorder, described later under Personality Disorders. *Obsessions*, not to be confused with obsessing (ruminating) on a topic, are recurrent distressing (ego-dystonic) thoughts that at some point during the course of the disorder are experienced as intrusive and inappropriate (ego-alien). Patients may describe their obsessions in language such as "I don't know where this thought comes from" or "I don't know why I have this thought, I would never actually do such a thing!" However, it is important to recognize that the ego-alien quality of obsessions may not be reported by children with OCD or by those with chronic OCD symptoms; for such patients the thought is merely experienced as distressing. *Compulsions* are recurrent mental or physical actions, typically related to the content of obsessions or to rigid rules that must be obeyed; for example, compulsive handwashing may relate to obsessional thoughts about germs or contamination. Again, most adults, at least early in the course of the disorder, experience the compulsions as intrusive and inappropriate or excessive. Patients with OCD typically attempt to ignore, suppress, or neutralize their obsessions and compulsions, but doing so causes great psychic distress, including anxiety until "giving in" and experiencing the unpleasant thought or performing the action. OCD patients may spend many hours per day engaged in or attempting to resist their obsessions and compulsions.

Acute Stress Disorder and Post-traumatic Stress Disorder

Acute stress disorder and PTSD are specific manifestations of symptoms referable to an extremely traumatic event. The event by definition must involve exposure to actual or threatened death, serious injury, or destruction of the physical integrity of the patient or others such that the patient's immediate reaction includes intense fear, helplessness, or horror. Formerly, definitions of the traumatic event involved descriptions such as "beyond usual human experience." It is important to recognize that acute stress disorder or PTSD does not develop in all individuals exposed to a common traumatic event (e.g., a natural or man-made disaster)—major depression may develop in some; other anxiety disorders may develop in others; mania, psychosis, or other conditions may develop in a few; and diagnosable psychopathology may never develop at all in some or many. In acute stress disorder, the patient develops a sense of numbing or emotional detachment, a reduction in awareness of the surroundings ("in a daze"), and dissociative symptoms such as derealization, depersonalization, or dissociative amnesia, as well as symptoms similar to those seen in PTSD. However, PTSD symptoms, by definition, persist for more than 1 month after the traumatic event and include three types of clinical phenomena: (1) re-experiencing the trauma (e.g., intrusive memories, dreams, or flashbacks or intense distressing psychological or physiologic responses to reminders of the trauma), (2) avoidance (e.g., avoiding specific reminders of the trauma; more generalized social withdrawal, emotional detachment, or blunting; or a sense of a foreshortened future), and (3) hyperarousal (e.g., insomnia, irritability, difficulty concentrating, or exaggerated startle response). Several PTSD symptoms overlap considerably with those of major depression, which is commonly a comorbid condition and should also be diagnosed when the diagnostic criteria are met.

Generalized Anxiety Disorder

This diagnostic term encompasses a more heterogeneous group of conditions, defined by the presence of clinically significant anxiety and associated somatic symptoms for 6 or more months. Generalized anxiety disorder is not diagnosed if the anxiety is part of a diagnosable anxiety, mood, or other psychiatric disorder; that is, it is superseded in the diagnostic hierarchy by other conditions that produce anxiety.

Phobias

The phobias are a group of conditions defined by the consistent ability of a specific environmental stimulus to elicit a pathologic anxiety response. Exposure to such a stimulus nearly always produces this response, so the patient avoids the stimulus whenever possible or endures the stimulus with

considerable distress. In addition to agoraphobia, the other main types of phobias are *social phobia* and *specific phobias* (see Table 404-7).

DIAGNOSIS

Diagnosis of anxiety disorders must rest on consideration of both syndromic and etiologic perspectives. From a syndromic perspective, a careful history and mental status examination are required to determine the pattern of anxiety and associated symptoms and to determine whether the phenomenology fits the pattern for any of the anxiety disorders as described earlier. The history and mental status examination must also assess for the presence of any other psychiatric disorder that might truly be comorbid with the anxiety disorder but might also supersede the anxiety disorder in the diagnostic hierarchy. For example, generalized anxiety may be seen as part of cognitive disorders (delirium or dementia), mood disorders (depressed or manic phases), and psychotic disorders; if the generalized anxiety is present only during the cognitive, mood, or psychotic disorder, a separate diagnosis of generalized anxiety disorder is not warranted. As another example, however, major depression may develop in a patient with long-standing PTSD or OCD symptoms, perhaps partly as a consequence of the social and other disability conferred by the PTSD or OCD; in such cases, both the anxiety disorder and major depression would be diagnosed.

From an etiologic perspective, it is important to determine whether the anxiety disorder is primary (idiopathic) or secondary to a systemic or neurologic condition (see Table 404-1), drug intoxication, or withdrawal state. The evaluation should include laboratory tests, such as a toxic drug screen, as guided by the differential diagnosis that is generated from the clinical evaluation.

TREATMENT

Rx

Considerable empirical evidence from controlled trials demonstrates the efficacy of cognitive-behavioral psychotherapies for most of the anxiety disorders. Such therapies, which use the principles of learning theory to extinguish unhelpful behavior and positively reinforce more functional behavior, help the patient learn to identify and correct the dysfunctional patterns of thinking ("automatic thoughts") that underlie or trigger the cognitive-physiologic cascade of pathologic anxiety responses. Cognitive behavioral therapy may be used as sole therapy, particularly for specific phobias, or in combination with pharmacotherapy. Frequently, cognitive behavioral therapy may be administered as part of family therapy (e.g., to help family members avoid behavior that inadvertently reinforces the patient's obsessions and compulsions) or in group therapy settings.

Although anxiolytic drugs, such as the benzodiazepines (Table 404-10), will usually relieve acute anxiety symptoms, concerns about their long-term efficacy and side effects (e.g., risk for abuse, risk for cognitive impairment or falls) make antidepressant medications the more attractive pharmacologic agents for most anxiety disorders (see Table 404-5). Most classes of antidepressants, with the probable exception of bupropion, are helpful for panic disorder, PTSD, generalized anxiety disorder, and social phobia. For OCD, the only efficacious antidepressants are those with strong activity on the serotonergic system, such as selective serotonin re-uptake inhibitors and also the tricyclic compound clomipramine.

PROGNOSIS

In general, most persons with anxiety disorders, other than transient acute stress disorder or other situation-dependent anxiety states, tend to have a chronic course of waxing and waning symptoms. At one extreme, a small minority of patients (≈5%) with OCD have intermittent episodes alternating with periods of full remission; at the other extreme, up to 15% of OCD patients may have a continuous and progressively worsening course over time. Maintenance therapies should often be used for patients with more chronic anxiety disorders, although evidence to support long-term therapies is not as robust as for mood disorders.

PSYCHOTIC DISORDERS

Psychotic symptoms, defined as a loss of reality testing, include delusions (fixed false beliefs), hallucinations (false sensory perceptions), and major derailments in thought processes (e.g., loose associations). Psychotic symptoms may be seen in the course of cognitive, secondary, and mood disorders. The psychotic disorders are defined by the presence of psychotic symptoms in the absence of prominent mood disturbance or cognitive deficits at the level seen in delirium or dementia. In general, the diagnosis and care of most patients with psychotic disorders should be conducted in mental health specialty settings, but primary care settings are common points of entry (and re-entry) to care.

Schizophrenia

DEFINITION AND EPIDEMIOLOGY

Schizophrenia, which is the prototypical psychotic disorder, includes acute episodes of psychosis ("positive" symptoms), often accompanied by a decline in overall functioning over time because of "negative symptoms," such as affective flattening, abulia, apathy, and social withdrawal. The point prevalence of schizophrenia is approximately 1%, and its chronic, debilitating course takes a considerable toll on patients, families, and society. Peak onset is in late adolescence to young adulthood, slightly younger for males than females. The annual incidence is approximately 15 per 100,000, but with marked variability across study samples and populations; recent data suggest that the condition is slightly more common in males than in females.

PATHOBIOLOGY

The pathogenesis of schizophrenia remains unknown. Twin studies show that the disease is multifactorial. Genetic factors account for about 50% of the risk, and multiple gene loci appear to be involved. Studies of postmortem brains indicate a nongliotic neuropathologic process with subtle disruptions of cortical cytoarchitecture. It is likely that psychosocial factors and neurodevelopment interact with a nonlocalizable brain "lesion" that is either present at birth or acquired early in life. The dopaminergic mesocortical and mesolimbic pathways are important in the production of psychotic symptoms.

DIAGNOSIS

The diagnosis of schizophrenia is based on the presence of delusions, disorganized speech and behavior, and major impairment in social functioning for

TABLE 404-10 DRUGS FOR ANXIETY AND PANIC

DRUG	TRADE NAME	INITIAL DOSE	TARGET DOSE RANGE*	SIDE EFFECTS	COMMENTS
Benzodiazepines				Sedation, ataxia, risk for falls	Potential for abuse/dependence
Lorazepam	Ativan	0.5 mg bid-qid	2-6 mg/day, tid-qid dosing		Reliable IM absorption
Diazepam	Valium	2-5 mg bid-tid	10-40 mg/day, bid-tid dosing		Long half-life of drug and active metabolites
Triazolam	Halcion	0.125 mg qhs	0.125-0.25 mg qhs	Rebound insomnia	Used as hypnotic
Chlordiazepoxide	Librium	5 mg bid-tid	10-40 mg/day, bid-tid dosing		Long half-life of drug and active metabolites
Temazepam	Restoril	7.5 mg qhs	7.5-30 mg qhs		Used as hypnotic
Alprazolam	Xanax	0.25 mg tid-qid	2-8 mg/day, tid-qid dosing	Possibly greater addictive potential	
Clorazepate	Tranxene	7.5-15 mg bid-tid	15-60 mg/day, bid-tid dosing		
Flurazepam	Dalmane	15-30 mg qhs	15-30 mg qhs	Daytime somnolence	Used as hypnotic
Oxazepam	Serax	10-15 mg tid-qid	10-30 mg tid-qid		
Clonazepam	Klonopin	0.5 mg bid-tid	0.5-5 mg bid-tid		Long duration of action
Zaleplon	Sonata	5-10 mq qhs	5-20 mg qhs		"Nonbenzodiazepine" hypnotic
Zolpidem	Ambien	5-10 mg qhs	5-10 mg qhs		"Nonbenzodiazepine" hypnotic
Eszopiclone	Lunesta	1-2 mg qhs	1-3 mg qhs		"Nonbenzodiazepine" hypnotic
β-Blockers					
Propranolol	Inderal	20 mg bid	Individualize, 40-120 mg/day	Bradycardia, hypotension, potential for mental slowing	Only helps with sympathetically mediated somatic symptoms of anxiety

*Target doses in the elderly may be lower.
qhs = at bedtime.

at least 6 months (Table 404-11). In patients with single schizophrenia-like psychotic episodes of briefer duration, with subsequent return to asymptomatic baseline functioning, *brief psychotic disorder* (<1 month) or *schizophreniform disorder* (1 to 6 months) may be diagnosed.

TABLE 404-11 SYMPTOMS AND SIGNS OF MAJOR PSYCHOTIC DISORDERS

SCHIZOPHRENIA
Delusions
Hallucinations
Disorganized speech (i.e., thought process derailments)
Grossly disorganized or catatonic behavior
Negative symptoms: affective flattening, alogia, avolition
Major impairment in social or occupational functioning
Duration of at least 6 months
SCHIZOAFFECTIVE DISORDER
During the course of illness, at least one episode of schizophrenia-like psychotic symptoms *plus* a mood syndrome (either major depression, mania, or mixed episode) *and*
During the course of illness, at least 2 weeks of schizophrenia-like psychotic symptoms *in the absence of* a mood syndrome
DELUSIONAL DISORDER
Delusions that are nonbizarre (i.e., potentially plausible, such as delusions of being followed, poisoned, infected, loved at a distance, deceived by a spouse or lover, or having a disease)
Not meeting full criteria for an acute episode of schizophrenia
Functioning *not* markedly impaired other than as related to the impact of the delusion (or delusions) and its ramifications

Based on criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*, 4th ed. Washington, DC: American Psychiatric Association; 2000.

TREATMENT

Rx

Antipsychotic medications (Table 404-12), often with adjunctive benzodiazepines, are used to treat acute psychotic episodes, commonly in acute inpatient settings so that the patient can be managed safely until the acute symptoms improve. Although maintenance antipsychotic medications help reduce the severity and frequency of acute psychotic episodes, comprehensive psychosocial rehabilitation programs are required to help patients manage interpersonal and other stressors and to improve overall clinical outcomes. In the past decade, second-generation ("atypical") antipsychotic medications have replaced first-generation antipsychotics because of their greater short-term tolerability and lower rates of extrapyramidal side effects, including tardive dyskinesia, although their efficacy is not generally better than that of first-generation drugs. However, second-generation drugs contribute to the increase in obesity and metabolic syndrome in patients with chronic schizophrenia (Chapter 442). One trial found that oral long-chain ω-3 polyunsaturated fatty acids reduced the rate of onset of psychosis by more than four fifths during a 1-year follow-up of adolescents and young adults with especially high risk profiles for incipient psychosis, but the usefulness of this approach in broader populations remains to be determined.

PROGNOSIS

The prognosis of individuals with schizophrenia may often be poor, with recurrent episodes of psychotic exacerbations superimposed on progressively deteriorating baseline functioning. However, some patients may have preservation of relatively high baseline functioning, and some experience periods of prolonged remission or improvement in functioning. Prominent negative symptoms, younger age at first onset, and enduring psychosocial stressors and family discord all predict poorer outcomes. Although many patients with schizophrenia survive into later life, overall life expectancy is shortened by at least 10 to 15 years because of poor health behavior and self-care, higher rates of medical disorders, including metabolic syndrome, and a lifetime suicide risk of approximately 10%.

TABLE 404-12 COMMONLY USED ANTIPSYCHOTIC MEDICATIONS

DRUG NAME	INITIAL DOSE FOR PSYCHOSIS IN SCHIZOPHRENIA*	TARGET DOSE FOR PSYCHOSIS IN SCHIZOPHRENIA†	SIDE EFFECTS	CHLORPROMAZINE DOSAGE EQUIVALENCE (FIRST-GENERATION DRUGS ONLY)/ OTHER COMMENTS
First-generation drugs			Low-potency drugs: anticholinergic effects, orthostatic hypotension, prolongation of QT interval, cholestatic jaundice High-potency drugs: extrapyramidal side effects (dystonias, akathisia, parkinsonism, neuroleptic malignant syndrome), hyperprolactinemia with galactorrhea	
Chlorpromazine	100 mg qd	300-1000 mg/day, qd-bid dosing		100 mg
Thioridazine	50-100 mg qd	300-800 mg/day, qd-bid dosing	Pigmentary retinopathy at higher doses	100 mg
Thiothixene	2-5 mg qd	5-60 mg/day, qd-bid dosing		5 mg
Trifluoperazine	2-5 mg qd	5-40 mg/day, qd-bid dosing		5 mg
Perphenazine	4-8 mg qd	8-64 mg/day, qd-tid dosing		8 mg
Haloperidol	0.5-2 mg qd	2-10 mg/day (up to 40 mg/day or higher in refractory cases), qd-bid dosing		2 mg; available in depot IM form
Fluphenazine	1-2.5 mg qd	2.5-10 mg/day (up to 40 mg/day in refractory cases), qd-bid dosing		2 mg; available in depot IM form
Second-generation drugs			Metabolic syndrome, risk for stroke and mortality in older patients with dementia, QT prolongation	
Risperidone	0.5-1 mg qd-bid	2-4 mg/day, qd-bid dosing	Extrapyramidal side effects at higher doses	Available in depot IM form
Olanzapine	5 mg qd	5-10 mg qd (up to 20 mg/day in refractory cases)		
Ziprasidone	20 mg bid	20-80 mg bid		
Quetiapine	25-50 mg bid-tid	300-800 mg/day, bid-tid dosing		Extended-release form for qd dosing
Asenapine	5 mg bid	5-10 mg bid		Sublingual form only
Paliperidone	3-6 mg qd	6-12 mg qd		
Iloperidone	1 mg bid	2-12 mg bid		
Aripiprazole	10-15 mg qd	10-30 mg qd		Partial agonist/antagonist at D_2 receptors
Clozapine	12.5 mg qd-bid	300-900 mg/day, qd-bid (titrate dose slowly by 25-50 mg/day every 3-7 days)	Risk for agranulocytosis, requires ongoing monitoring of complete blood count	Efficacy superior to that of other antipsychotics, but hematologic risks and need for monitoring limit its use

*Doses for other indications, such as agitation in delirium or dementia, may be much lower.
†Target doses in the elderly may be lower.

Schizoaffective Disorder

Schizoaffective disorder is a chronic, recurrent disorder with a prevalence slightly lower than that of schizophrenia. It is characterized by episodes of non–mood-associated psychosis and also by mood episodes (manic or depressed) with psychotic features. As a result, the diagnosis of schizoaffective disorder cannot be based on the patient's clinical findings at any one point in time but rather requires knowledge of the overall course. Treatment is symptomatic and involves the use of antipsychotic medications (see Table 404-12), mood stabilizers (see the section on treatment of bipolar disorders), and antidepressant medications (see Table 404-5) to target specific psychotic and mood symptoms. The outcomes of schizoaffective disorder are heterogeneous but on average intermediate between those of schizophrenia and mood disorders.

Delusional Disorder

Delusional disorders are characterized by potentially plausible ("nonbizarre") delusions, such as those regarding marital infidelity, in the absence of a thought process disorder, prominent hallucinations, or the negative symptoms seen in schizophrenia. Delusional disorder has a point prevalence of approximately 0.03% and a lifetime prevalence of 0.05 to 0.1%. The pathogenesis of delusional disorder, like the other the nonschizophrenic primary psychotic disorders, remains largely unknown. It is often only partially responsive to antipsychotic medications (see Table 404-12), but patients' functioning may be largely unimpaired if they are able, with the aid of antipsychotics and psychotherapy, to avoid speaking publicly about their delusions or acting on them.

SOMATOFORM DISORDERS

Somatoform symptoms (Table 404-13), often broadly referred to as "somatization," resemble the symptoms caused by systemic or neurologic diseases but are thought to arise from unconscious psychogenic causes rather than identifiable physical causes. Somatization may range from normal human experiences (e.g., abdominal cramping in response to an acute stressor), to time-limited episodes, to chronic, disabling conditions.

The prevalence of somatoform disorders varies widely among various populations, in part based on diagnostic ascertainment. Full-fledged somatization disorder may have a lifetime prevalence of 0.2 to 2% in females and less than 0.2% in males. Prevalence estimates for conversion disorder are as low as 0.01% in the general population but may be much higher (1 to 14%) in medical/surgical inpatients and even higher in neurologic treatment settings.

Although the symptoms of somatoform disorders are not due to identifiable physical disease, they are nonetheless "real" and are just as distressing and baffling to patients as would be similar symptoms produced by physical disease. Somatoform symptoms and disorders must be distinguished from other conditions in which psychological factors lead to manifestations resembling physical disorders. *Factitious disorder* (also known as Munchausen's syndrome) is a mental disorder in which patients consciously produce stigmata of disease (e.g., simulated or artificially induced fever or hypoglycemia) for the unconscious gain of assuming the sick role. *Malingering* is the conscious feigning of illness for conscious gain and is therefore not a mental disorder.

TABLE 404-13 TYPES OF SOMATOFORM DISORDERS

TYPE	MAIN CLINICAL MANIFESTATIONS
Disorders characterized by somatoform symptoms (i.e., physical symptoms due to unconscious psychological factors)	
Somatization disorder	Also known as Briquet's syndrome: chronic recurrent disorder with multiple somatoform symptoms across multiple organ systems, including pain, neurologic, sexual, and other symptoms, beginning before the age of 30 years
Conversion disorder	Neurologic somatoform symptoms (other than pain), e.g., paralysis, blindness, dyscoordination, convulsion-like phenomena, memory or other cognitive complaints
Pain disorder	Pain (may or may not be associated with a physical disorder)
Undifferentiated somatoform disorder	Other somatoform symptoms not meeting criteria for the disorders above
Other types of somatoform disorders	
Hypochondriasis	Inappropriate worry about illness and help seeking (in the absence of somatoform symptoms per se)
Body dysmorphic disorder	Preoccupation with a perceived body defect or deformation ("imagined ugliness"); may have more in common with the obsessions of obsessive-compulsive disorder than with the other somatoform disorders

Based on criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*, 4th ed. Washington, DC: American Psychiatric Association; 2000.

TREATMENT Rx

Management of patients with somatoform disorders is often difficult because physicians must simultaneously maintain an appropriate level of vigilance for undiagnosed physical illness while avoiding unnecessary tools and therapies. Keys to ongoing care include maintaining an ongoing therapeutic alliance, setting regular office visits, conveying empathy for the patient's very real distress without colluding with the patient's belief in an identifiable physical disorder, and assertively treating depression, anxiety, or other comorbid psychopathology. Antidepressant medications may benefit selected patients (e.g., some chronic pain syndromes), even in the absence of comorbid psychiatric disorders.

PERSONALITY DISORDERS

Personality is defined as the total repertoire of enduring patterns of thinking, feeling, and behaving, including affect and impulse regulation, defense and coping mechanisms, and interpersonal relatedness. Personality and personality disorders are the result of complex interactions among genetic, environmental, and developmental factors. The cumulative point prevalence of all personality disorders in the general adult population is approximately 10 to 15%, with rates as high as 50% in patients receiving care in psychiatric treatment settings.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

A *personality disorder* is diagnosed when personality trait repertoires lead to enduring (if variable) subjective distress or dysfunction in social role performance (Table 404-14). In diagnosing personality disorders, care must be taken to distinguish personality *traits*, which by definition are enduring, from time-limited *states*. Most persons can regress to more primitive personality styles, not characteristic of their baseline personality traits, under the influence of substantial psychosocial stressors, including those posed by significant medical illnesses. For example, a patient who exhibits dependent features only while acutely ill does not have a dependent personality disorder. Similarly, patients with personality disorders are prone to mood, anxiety, eating, and substance abuse disorders, which should be diagnosed and treated assertively.

TREATMENT Rx

In most circumstances the goal is not to alter fundamental personality structure, but rather to help the patient maximize use of personality strengths (e.g., optimal defense and coping mechanisms) while minimizing the harmful effects of emotional dysregulation, dysfunctional defenses, and destructive behavior. Dialectic behavior therapy is an evidence-based, focused psychotherapy that is based on specific cognitive-behavioral techniques and has been demonstrated to reduce self-injurious behavior and suicidality in patients with borderline personality disorder.

Although pharmacotherapy is not the mainstay of treatment of most personality disorders, drugs can be useful in selected patients. Antipsychotic drugs may be used to target escalating paranoia in paranoid personality disorder or for short-term reduction in emotional and impulse regulation with a wide range of (often cluster B, see Table 404-14) personality disorders in times of crisis. For longer-term treatment of emotional dysregulation in borderline and other cluster B personality disorders, mood stabilizers or antidepressants may be used.

TABLE 404-14 PERSONALITY DISORDERS

TYPE OF PERSONALITY DISORDER	MAIN IDENTIFYING CHARACTERISTICS
CLUSTER A: ODD/ECCENTRIC	
Schizoid personality disorder	Detachment from social relationships, restricted emotional expression
Schizotypal personality disorder	Discomfort with close relationships, cognitive or perceptual distortions, eccentric behavior
Paranoid personality disorder	Pervasive distrust and suspiciousness of others' motives as malevolent
CLUSTER B: DRAMATIC/EMOTIONAL	
Borderline personality disorder	Instability of interpersonal relationships and self-image and poorly regulated emotional states and impulse control
Narcissistic personality disorder	Inflated self-esteem, need for admiration from others, and lack of empathy for others
Antisocial personality disorder	Pervasive disregard for and violation of the rights of others, lack of conscience
Histrionic personality disorder	Pervasive excessive emotionality (theatricality) and attention seeking
CLUSTER C: ANXIOUS/FEARFUL	
Avoidant personality disorder	Social inhibition because of feelings of inadequacy and sensitivity to negative views from others
Dependent personality disorder	Submissive and clinging behavior because of excessive need to be taken care of
Obsessive-compulsive personality disorder	Preoccupation with orderliness, perfectionism, and control

Based on criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*, 4th ed. Washington, DC: American Psychiatric Association; 2000.

TABLE 404-15 SOME IMPORTANT RISKS FOR SUICIDE AND SUICIDE ATTEMPTS

Mental disorder, particularly mood, substance use, psychotic, and personality disorders
Other symptoms of acute psychic distress, particularly hopelessness and panic attacks
Previous history of suicide attempt
Family history of suicide or suicide attempt (and, to a lesser degree, of any mental disorder)
Family violence, including physical or sexual abuse
Access to firearms or other lethal methods
Exposure to suicidal behavior of others (family, peers, public figures)
Social isolation
Interpersonal discord or other psychosocial stressors
Demographic factors, including male gender, non-Hispanic white or American Indian/Alaska Native race, older age

TABLE 404-16 GENERAL CONSIDERATIONS IN DECIDING TO REFER A PATIENT FOR PSYCHIATRIC SPECIALTY CARE

Diagnosis or ongoing care of severe/chronic mental disorders, including bipolar disorder, psychotic disorders such as schizophrenia, and psychotic symptoms in other disorders
Management of more severe forms of other mental disorders (as well as those refractory to treatment), including depression, anxiety disorders, and substance use disorders
Need for safety evaluation or management, including suicidality, homicidality or other aggressivity, or inability to care for self
Diagnostic uncertainty
Psychiatric comorbid conditions complicating diagnosis or treatment, including personality and substance use disorders coexisting with other psychiatric disorders
Psychiatric-medical comorbid conditions complicating diagnosis or treatment, including management of psychiatric disorders during pregnancy
Need for expertise in psychopharmacologic treatment
Need for expertise in other somatic therapies, e.g., electroconvulsive therapy
Need for expertise in psychotherapy or other psychosocial interventions

SUICIDE AND EVALUATION OF SUICIDALITY

Suicide is a leading cause of death worldwide. Suicide rates in the United States average approximately 11 per 100,000 per year, with considerable variability geographically and demographically. Of all age-, gender-, and race-based demographic groups, the highest suicide rates occur in older white men. Suicide is the 3rd leading cause of death in adolescents and young adults and the 11th leading cause of death in the population overall. Suicide attempts, which outnumber completed suicides by a factor of at least 3:1, lead to considerable morbidity and utilization of health care resources. Persons who attempt suicide represent an overlapping but distinct population from those who die by suicide. Nonetheless, a previous history of a suicide attempt is a powerful risk for subsequent death by suicide. Suicide attempts and verbal threats should always be evaluated carefully and never dismissed as "gestures" or "attention-seeking" behavior.

Suicide is a potentially preventable cause of death, but despite considerable research on risks for suicidal behavior, specific predictions about an individual's behavior cannot be made with certainty. Nonetheless, the linchpin of clinical evaluation is a methodic assessment of risks for suicide (Table 404-15), together with direct questioning of the patient regarding thoughts of death, dying, and suicide; specific plans (in ideation or action) for suicide; and the details of any attempts. Patients at significantly increased risk for suicide should immediately be referred for psychiatric evaluation, with emergency referral if the risk is deemed to be imminent or increasing.

WHEN TO REFER A PATIENT FOR PSYCHIATRIC EVALUATION

Clinical decisions to refer a patient for specialty psychiatric evaluation must be made on an individual basis by taking into account both the patient's clinical findings, including any previous history and immediate needs, and the clinician's own experience and expertise in assessing and managing the disorder (Table 404-16).

HEADACHES AND OTHER HEAD PAIN

KATHLEEN B. DIGRE

DEFINITION

Headache, which is a very common symptom, can be caused by a serious underlying abnormality but is usually a primary headache disorder, such as migraine headache, tension-type headache, cluster headache, and paroxysmal hemicrania.

EPIDEMIOLOGY

About 90% of all adults experience headache at some time in their lives, and more than 75% of children have reported significant headaches by the age of 15 years. In the United States, the cost associated with migraine is almost $17 billion annually in both direct and indirect costs. Patients at most risk for lost days of employment are those with transformed migraine and daily headache.

In large population-based studies, the relative risk of having migraine, tension-type headaches, or cluster headaches increases up to four times if a first-degree relative has the same kind of headaches. Studies of twins, especially identical twins, also show a similar susceptibility.

PATHOBIOLOGY

Headache pain is initiated by primary trigeminal afferents that innervate the blood vessels, mucosa, muscles, and tissues. Fibers from these sources coalesce in the trigeminal ganglion, especially the first division. The trigeminal afferents terminate in the primary sensory nucleus of cranial nerve V and its spinal nucleus, which has several small subnuclei, the most important of which is the subnucleus caudalis. This subnucleus receives afferents from meningeal vessels, dura-sensitive neurons, and even the upper cervical cord and then projects them to the lateral and medial thalamus by way of the spinothalamic tract and to diencephalic and brain stem regions that are involved in the regulation of autonomic functions. Thalamic nociceptive information ascends to the sensory cortex, as well as to other areas of the brain.

Although secondary headaches may stimulate the pathway by way of processes such as inflammation and compression, primary headache disorders occur spontaneously by means of chemical mediators. The sequence of events commences with peripheral activation caused by neurogenic plasma extravasation activated spontaneously or by cortical spreading depression. The trigeminocervical complex, especially the nucleus caudalis, is then activated, and patients can experience allodynia, a condition in which a nonnoxious stimulus is sensed as painful.

Aura is defined as a focal visual, sensory, or motor neurologic disturbance that may occur with or without headache. Aura is thought to occur when cortical spreading depression causes depolarization of membranes. Both neurons and glia can cause both constriction and dilation of blood vessels.

Migraine headache clearly has a genetic component. Familial hemiplegic migraine can be caused by mutations in the *CACNA1A* gene, which is located on chromosome 19p13.2-p13.1 and encodes for voltage-gated neuronal calcium channels. Many mutations are found in the *CACNA1A* gene, and other phenotypes include episodic ataxia and epilepsy. Another mutation is on *ATP1A2*, also called the familial hemiplegia migraine 2 (*FHM2*) gene, which is located on chromosome 1q21-q23 and encodes for the sodium-potassium adenosine triphosphatase (Na^+,K^+-ATPase) transport protein. A third genetic locus is the *SCN1A* gene on chromosome 2q24.3, which is a voltage-gated sodium channel. Although there are linkages to many genetic loci for more common forms of migraine, migraine and other headaches probably have multiple gene interactions with environmental factors.

CLINICAL MANIFESTATIONS

Patients with headache may describe the pain as throbbing, bandlike, or aching, but it is invariably moderate to severe and interferes with activities. The pain is frequently unilateral but can be bilateral. Migraine headache is often associated with nausea, vomiting, photophobia, and phonophobia. Other autonomic manifestations that can accompany migraine, cluster, and other headache variants include ptosis, rhinorrhea, Horner's syndrome, and facial edema. Secondary headaches may appear to be similar to tension-type or migraine headaches, but there may be "red flags" suggesting a secondary rather than a primary headache disorder (Table 405-1).

TABLE 405-1 REASONS FOR FURTHER EVALUATION TO LOOK FOR SECONDARY HEADACHES

Beginning of headaches at an older age without a previous history or a positive family history
Unexplainable and abnormal worsening of previously existing migraines
Dramatic or unusual change in character of the prodrome or the headache previously present
Headaches awakening the patient in the middle of the night (except for a cluster headache)
Headaches much worse when recumbent or with coughing, sneezing, or the Valsalva maneuver
Unusually severe headache of sudden onset ("worst headache of my life")
Focal deficits that do not disappear after the headache is over
Any abnormal neurologic finding on examination
A new headache in a patient with human immunodeficiency virus infection, malignancy, or pregnancy

DIAGNOSIS

Evaluation of an individual's headache is almost entirely based on five elements of the history. The family history helps determine whether a person has a genetic predisposition to headache. The life history of headache determines whether the headache is new or has evolved over the course of a lifetime. The attack history provides the clinical features of the headache or headaches. The medical and psychiatric history determines whether there are comorbid conditions that can cause or worsen the headache. The medication and drug history determines whether the headache could be caused by or worsened by medications or drugs that the person has ingested.

Diagnosis of the type of headache is based on the type of pain, the duration of headache, and accompanying features (Table 405-2). Secondary headaches are usually due to an underlying condition, such as a brain tumor (Chapter 195), increasing intracranial pressure, sinus disease (Chapter 434), or a vascular malformation (Chapter 415); on removing the cause, the headache generally improves. Headaches that occur at a frequency of less than 15 days a month are called episodic, whereas headaches that occur more than 15 days a month are considered chronic.

The diagnostic evaluation for headache depends on the clinical findings. If there is a typical history without any reason for further evaluation and if the findings on neurologic examination are completely normal, no further evaluation is needed. The features of the history that are most likely to predict migraine headache without a secondary disorder include a pulsating quality, duration of 4 to 72 hours, unilateral headache, nausea, and disabling headache. However, if there are atypical features of the history or any abnormality on neurologic examination, further evaluation is indicated. Patients with cluster headache types and headaches of undetermined cause need imaging to exclude secondary causes.

In patients with acute headache, computed tomography (CT) is best for assessing acute hemorrhage as the cause of the headache, whereas magnetic resonance imaging (MRI) is best for assessing most persistent headaches to look for mass lesions, evidence of intracranial hypertension or hypotension, hemosiderin (old hemorrhage), and congenital abnormalities (e.g., Chiari malformation). In individuals older than 60 years with an unexplained new or unusual headache, the erythrocyte sedimentation rate (ESR) needs to be determined to evaluate for giant cell arteritis (Chapter 78). Cerebrospinal fluid (CSF) analysis, including opening pressure, protein, glucose, cells, culture, and cytology, is indicated in patients with suspected intracranial hypertension or meningitis.

TREATMENT

Rx

Treatment of acute headache depends on the type and severity of the headache. For mild headaches, simple analgesics such as acetaminophen (500 to 1000 mg), aspirin (250 to 1000 mg), and nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., ibuprofen, 400 to 800 mg; naproxen sodium, 220 to 500 mg) will suffice. If the migraine headaches are moderate to severe, patients benefit from migraine-specific therapies (Table 405-3) such as triptans (sumatriptan, zolmitriptan, rizatriptan, almotriptan, naratriptan, frovatriptan, and eletriptan), ergotamine (dihydroergotamine, ergotamine tartrate), or isometheptene, and the combination of naproxen plus sumatriptan is better than either alone.

TABLE 405-2 DIFFERENTIAL DIAGNOSIS OF HEADACHE

HEADACHE TYPE	GENETICS	EPIDEMIOLOGY	CHARACTERISTIC FEATURES	LENGTH	ACCOMPANYING SYMPTOMS
Migraine headache	Complex genetics but usually a family history	More frequent in women	Unilateral, bilateral; throbbing; moderate to severe; worsens with activity	Hours to days	Photophobia, phonophobia, nausea and/or vomiting
Tension-type headache	Usually a family history	Equal frequency in men and women	Tight band–like pain; bilateral; pain may be mild to moderate; improves with activity	Hours to days	No nausea or vomiting; small amount of light or sound sensitivity, but not both
Cluster headache	May have a family history	More frequent in men	Unilateral, severe pain in the face	Minutes to hour	Ipsilateral ptosis, miosis, rhinorrhea, eyelid edema, tearing
Paroxysmal hemicrania	Usually no family history	More frequent in women	Unilateral pain in the face	Minutes	Ipsilateral ptosis, miosis, rhinorrhea, eyelid edema, tearing; responds to indomethacin
Hemicrania continua	No family history	More frequent in women	Unilateral, continuous headache with episodic stabbing pains	Continuous	Ipsilateral autonomic features: ptosis, miosis, rhinorrhea, eyelid edema, tearing

TABLE 405-3 ACUTE MIGRAINE-SPECIFIC TRIPTAN MEDICATIONS FOR THE TREATMENT OF MIGRAINE

	SUMATRIPTAN	ZOLMITRIPTAN	NARATRIPTAN	RIZATRIPTAN	ALMOTRIPTAN	FROVATRIPTAN	ELETRIPTAN
Trade Name	Imitrex	Zomig	Amerge	Maxalt	Axert	Frova	Relpax
Forms	SQ, nasal (NS), oral	Oral: tablet/ZMT, NS	Oral	Oral: tablet/MLT	Oral	Oral	Oral
Dose	Oral: 50-100 mg (200 mg/24 hr max.) SQ: 4-6 mg (12 mg/24 hr max.) NS: 5-20 mg (40 mg/24 hr max.)	2.5-5 mg (10 mg/24 hr max.) 5 mg (10 mg/24 hr max.)	1-2.5 mg (5 mg/24 hr max.)	5-10 mg (30 mg/24 hr max.)	6.25-12.5 mg (25 mg/24 hr max.)	2.5 mg (7.5 mg/24 hr max.)	20-40 mg (80 mg/24 hr max.)
Half-life	2-3 hr	3-4 hr	6-8 hr	2-3 hr	3-4 hr	26 hr	4-6 hr
Crosses blood-brain barrier	–	+	+	+	+	+	+
Use with monoamine oxidase inhibitor (MAOI)	–	–	+	–	+	+	–
Good for recurrences	–	–	+	–	–	+	–
Rapid response	SQ, 10-15 min NS, 15-20 min Oral, 30 min	30 min	1-4 hr	30 min	60 min	1-4 hr	20-30 min
Menstrual migraine	+	+	+	+	+	+	+
Other	Now in combination with naproxen (Treximet)			Decrease dose by ½ with propranolol			Do not use with CYP3A4 drugs (ketoconazole and some macrolide antibiotics)

NS = nasal spray; SQ = subcutaneous.

PREVENTION

Preventive medications are recommended when headaches are frequent or severe enough to interfere with quality of life. The choice of medications should be based on the type of headache (migraine, tension type), their side effect profiles, and the patient's comorbid conditions (Table 405-4).■

PROGNOSIS

The natural history of headache depends on many factors, including the type of headache, the comorbid conditions that accompany the headache, and the success of treatment. Risk factors for chronic headache include female gender, migraine-type headaches, frequent headaches, obesity, low education and socioeconomic level, overuse of medication, stressful events, and sleep apnea.

MIGRAINE HEADACHE

DEFINITION

Migraine is an inherited headache disorder that is typically unilateral but sometimes bilateral, moderate to severe, worsened by routine physical activity, associated with nausea and vomiting, and accompanied by photophobia and phonophobia. The headache occurs anytime and persists from 4 to 72 hours. It may occur with an aura (a focal neurologic symptom that may be visual, sensory, or motor) or without an aura. Visual auras may have positive (photopsias) and negative (scotomas) features.

EPIDEMIOLOGY

The prevalence of migraine is 15 to 20% in women and 4 to 7% in men. In children the prevalence may be as high as 17% and is equal in boys and girls. At puberty, the prevalence rises in girls and remains higher throughout their lifespan. The highest prevalence occurs between the ages of 25 and 55. Migraine with aura affects 5% of the adult population, and 90% of auras are visual. Migraine is more prevalent in white persons and in those with a lower socioeconomic status or income.

Comorbid conditions that may be associated with migraine headache include epilepsy, stroke, depression, anxiety, myocardial infarction, patent foramen ovale, Raynaud's syndrome, irritable bowel syndrome, and pain disorders such as fibromyalgia. Menstruation and ovulation may increase the frequency of headache.

PATHOBIOLOGY

The aura of a migraine headache is thought to be due in part to cortical spreading depression, which is associated with a brief reduction in flow followed by hyperemia. These changes do not seem to correlate with the phase of the headache. Pain occurs when trigeminal afferents of the dura are stimulated.

TABLE 405-4 PREVENTIVE MEDICATIONS FOR HEADACHE

DRUG	RATIONAL USE	DOSAGE	SIDE EFFECTS	CONTRAINDICATIONS/ CAUTION	LEVEL OF EVIDENCE
β-Blockers: e.g., propranolol, nadolol, timolol	Migraine, anyone with elevated blood pressure	20-80 mg; may increase	Lethargy, depression	Asthma, low blood pressure	A
Calcium-channel antagonists: verapamil, amlodipine	Cluster headache, elevated blood pressure	Verapamil, 120 to 480 mg/day	Low blood pressure		B
Nonsteroidal anti-inflammatory drugs: naproxen sodium, ibuprofen	Migraine, tension-type, and menstrual migraine	Naproxen, 200-600 mg/day; ibuprofen, 600-800 mg bid-tid	Gastrointestinal	Ulcers, sensitivity, allergy	A
Indomethacin	Paroxysmal hemicrania, hemicrania continua	25 mg tid	Gastrointestinal	Ulcers	A
Tricyclic antidepressants: amitriptyline, nortriptyline, imipramine	Migraine, tension-type headache, anyone with poor sleep	10-25 mg qhs	Dry mouth, orthostatic hypotension	Sensitivity	A—amitriptyline
Anticonvulsants: topiramate valproate	Migraine, cluster headache	Topiramate, 25-50 mg bid; valproate, 250-500 mg bid	Topiramate: weight loss, kidney stones, intra-ocular hypertension Valproate: weight gain	Pregnancy	A

CLINICAL MANIFESTATIONS

Migraine headache often begins with a prodrome, which may persist for hours to days, when patients note difficulty concentrating or fatigue without headache. An aura may or may not occur but is generally present before the headache begins. The headache may be unilateral or bilateral, throbbing, moderate to severe, and worsened with activity. Accompanying clinical features include nausea, vomiting, and sensitivity to light and sound. Other clinical features include neck pain, occasionally dizziness, osmophobia, and difficulty thinking.

The migraine aura is generally visual but can be sensory or can include aphasia or vertigo. Migraine aura without headache begins with a neurologic disturbance, such as a visual phenomenon, but without a subsequent headache.

DIAGNOSIS

The diagnosis of migraine is based on the history. The differential diagnosis includes tension-type headache, but most moderate to severe headaches are migraine. In patients with a history suggestive of a secondary headache, further evaluation with MRI should be considered (see Table 405-2). However, if the headache is typical of migraine and the findings on neurologic examination are normal, no further studies are needed.

TREATMENT

Rx

Treatment of migraine is divided into treatment of the acute headache and prevention of subsequent migraine attacks. Acute treatment is most effectively accomplished with migraine-specific stepped care: a nonspecific analgesic agent, combination analgesic therapy, opioids, and aggressive migraine-specific therapy (see Table 405-3). For example, *mild attacks* can generally be treated successfully with over-the-counter analgesics such as acetaminophen (suggested dose, 650 to 1000 mg[1]) or NSAIDs (aspirin, 900 to 1000 mg[2]; ibuprofen, 1000 to 1200 mg; naproxen, 500 to 825 mg; or ketoprofen, 75 mg). During pregnancy, mild to moderate attacks can be treated with acetaminophen. Moderate headaches may respond to the combination of acetaminophen, isometheptene mucate (a mild vasoconstrictor, 65 mg), and dichloralphenazone (a mild sedative, 100 mg). Antinausea agents include prochlorperazine (10 to 25 mg) and metoclopramide (2.5 to 10 mg).

Stratification of care, including tailoring the treatment according to the type of headache, results in fewer days of disability and use of medications.[3] Which migraine-specific drug will work for any individual patient depends on the patient. It is important to avoid overuse of analgesic and other medications because overuse can cause chronic daily headache in susceptible individuals. Prompt treatment improves the outcome of headache when compared with late treatment. Contraindications to use of the triptans (Table 405-3) include uncontrolled hypertension, clinical evidence of ischemic heart disease, and Prinzmetal's angina.

Opioids such as *N*-acetyl-*p*-aminophenol (APAP) with codeine, or butorphanol, benefit some patients, but meperidine is not effective. Oral opiates should not be used for chronic recurrent, primary headaches, although sometimes opiates (e.g., acetaminophen, 325 mg, with codeine, 30 mg) are the only option during pregnancy or in patients with severe vascular disease. When opiates are used, caution is required, and the associated risks of rebound headache and dependency must be recognized by both the patient and physician. Barbiturates (e.g. APAP, caffeine, and butalbital or aspirin) have not been efficacious in controlled trials but may be helpful in individual patients in whom other migraine-specific drugs cannot be used.

For *moderate to severe attacks*, options include dihydroergotamine (1 to 2 mg intranasally); oral, intranasal, or subcutaneous administration of sumatriptan (25 to 100 mg orally, 20 mg intranasally, or 4 to 6 mg subcutaneously); or sumatriptan-like drugs (e.g., naratriptan, 2.5 mg; zolmitriptan, 5 mg; rizatriptan, 10 mg; eletriptan, 40 mg; frovatriptan, 2.5 mg; or almotriptan, 12.5 mg).[4] Ergotamine (2 mg sublingually or 1 to 2 mg orally), when given early in the migraine attack, can be effective if the associated nausea and peripheral vasoconstriction are tolerable. Telcagepant (300 mg), a calcitonin gene–related peptide antagonist, may be as effective as zolmitriptan (5 mg), with fewer side effects.[5]

For *very severe attacks*, dihydroergotamine (1 mg subcutaneously or 0.5 to 1 mg intravenously) is usually effective but generally requires an antiemetic (e.g., promethazine, 25 mg) before intravenous use. Intramuscular injections of ketorolac (60 mg) or prochlorperazine (10 to 25 mg) may be helpful. For patients who are nonresponsive or have contraindications to vasoactive abortive agents, 10 mg of intravenous prochlorperazine (10 mg delivered over a 5-minute period) is another alternative.[6]

PREVENTION

Preventive treatment (see Table 405-4) is often recommended when the headaches interfere with activities on 3 or more days per month, the headaches are severe or prolonged, or migraine is complicated by events such as cerebral infarction. Prophylactic options include β-adrenergic blockers, calcium-channel antagonists, NSAIDs, tricyclic antidepressants, and anticonvulsants. Other alternatives include the serotonergic drug cyproheptadine (4 to 20 mg) or the monoamine oxidase inhibitor phenelzine (30 to 60 mg). Acupuncture and biofeedback have been used successfully.[7,8] OnabotulinumtoxinA injection is also effective for prophylaxis.[9]

PROGNOSIS

The prognosis for patients with migraine is variable. In many patients, headaches decrease in severity with age, but migraine aura without headache becomes more frequent with older age. Modification of inciting factors such as avoiding dietary triggers (tyramine, phenylethylamine, ethanol), ameliorating or preventing insomnia, and averting environmental triggers (light, sound, odor) may improve outcome. Migraines may become chronic, defined as more than 15 days per month, especially when associated with obesity and low socioeconomic status.

TENSION-TYPE HEADACHE

DEFINITION

Tension-type headache is defined as a holocranial headache without nausea or vomiting. Patients may have either photophobia or phonophobia but not both, and the headache does not worsen with activity.

EPIDEMIOLOGY

The 1-year prevalence is 14 to 93 per 100,000 individuals for episodic tension-type headache and 8.1 per 100,000 for chronic tension-type headache. Tension-type headaches are more common in women than in men, regardless of age, race, and educational level. Tension-type headaches are more common in Western countries and less frequent in Asian countries, and they are more common in white persons than in African Americans.

PATHOBIOLOGY

The pathophysiology of tension-type headache is less well understood than that of the other types of headache. Myofascial tenderness is increased, especially in chronic tension-type headache. Genetic factors are uncertain. Migraine and tension-type headache often coexist. Although tension-type headaches are not due to emotion or muscle contraction, triggers of a tension-type headache are similar to those associated with migraine: stress, fatigue, and lack of sleep. Comorbid conditions in patients with tension-type headache include depression and anxiety in more than 50% of individuals.

CLINICAL MANIFESTATIONS

Tension-type headaches are usually mild to moderate in severity, and most individuals do not seek care. Tension-type headache can be episodic, occurring less than 15 days per month, or chronic, occurring more than 15 days per month. In many patients headaches remain episodic, but about 25% progress to chronic headache. Of the patients with chronic tension-type headache, about a quarter to a third continue as chronic, half can improve to episodic, and in about a quarter medication overuse headache can develop. Episodic tension-type headaches can last minutes, hours, or days.

DIAGNOSIS

Headaches that can be misdiagnosed as tension-type headache include migraine, hemicrania continua, new daily persistent headache, and headaches caused by brain tumors, elevated or low intracranial pressure, or giant cell arteritis. A careful history is the best way to distinguish other types of headaches.

TREATMENT Rx

Episodic tension-type headaches are generally treated successfully with acetaminophen (650 to 1000 mg) or NSAIDs (aspirin, 900 to 1000 mg; naproxen, 250 to 500 mg; ibuprofen, 200 to 800 mg; or ketoprofen, 12.5 to 75 mg). However, analgesic use for more than 3 days per week can worsen headaches.

PREVENTION

Chronic tension-type headaches may benefit from prophylactic treatment with amitriptyline (starting with 10 mg at bedtime and increased slowly up to 100 mg until the patient improves or intolerable side effects develop), nortriptyline (25 to 100 mg each evening), doxepin (25 to 75 mg/day), maprotiline (10 to 25/mg/day), or fluoxetine (10 to 20 mg/day). Muscle relaxants, physical therapy, and acupuncture are also useful.

PROGNOSIS

Tension-type headache has a variable prognosis. Adolescents with tension-type headache and two or more psychiatric factors (e.g., depression and anxiety) have a worse prognosis.

CLUSTER HEADACHE AND OTHER TRIGEMINAL AUTONOMIC CEPHALALGIAS

DEFINITION

Trigeminal autonomic cephalalgias, including cluster headaches, are unilateral headaches associated with ipsilateral autonomic features. Other trigeminal autonomic cephalalgias include paroxysmal hemicrania, which is characterized by bouts of headache that persist for 5 to 30 minutes, is generally unilateral, and usually occurs in women; they typically respond to indomethacin. Hemicrania continua, another indomethacin-responsive headache that is seen in both men and women, is characterized by continuous unilateral pain and mild associated autonomic features; it is frequently observed in conjunction with chronic daily headache but not with trigeminal autonomic cephalalgia. Short unilateral neuralgiform headache with conjunctival injection and tearing is a rare trigeminal autonomic cephalalgia that occurs in men, and the individual headache attack persists for only a very short time.

EPIDEMIOLOGY

Cluster headache occurs in 56 to 401 per 100,000 persons and is more frequent in men (3:1 to 7:1). Attacks usually begin between 20 and 30 years of age. Paroxysmal hemicrania occurs in 56 to 381 per 100,000 persons; it affects women more often (2:1) and can begin at any age but usually commences at 34 to 41 years. Short unilateral neuralgiform headache with conjunctival injection and tearing is rare, with a slight male preponderance (2:1).

PATHOBIOLOGY

There appears to be a genetic predisposition for cluster headache. Imaging studies such as positron emission tomography and functional MRI show inferior posterior hypothalamic activation at the onset of cluster headache and other trigeminal autonomic cephalalgias. In addition, the trigeminovascular complex and the cranial autonomic system are activated. The pathophysiology of hemicrania continua is unknown, and there is debate whether it is associated with hypothalamic involvement or whether it resembles migraine.

CLINICAL MANIFESTATIONS

Cluster headaches are almost always unilateral, rarely bilateral, and have characteristic ipsilateral autonomic features, commonly including lacrimation and conjunctival injection and sometimes including nasal congestion, rhinorrhea, ptosis, miosis, flushing, and eyelid edema (Table 405-5). The location of the pain is usually behind or above the eye or in the temple, but other areas of pain can include the forehead, cheek, teeth, or jaw. The pain reaches its maximum intensity in about 9 minutes and tends to end abruptly. Attacks occur one to eight times a day and are usually described as "boring" or "stabbing" excruciating pain that persists for 15 minutes to 2 hours. Migraine symptoms may coexist, including unilateral photophobia, phonophobia, and rarely, an aura. Unlike migraine patients, who usually try to rest, patients with cluster headaches pace and are unable to sit or lie down. Cluster headaches, when precipitated by alcohol, histamine, or nitroglycerin, have a daily periodicity and may also have a seasonal periodicity. For example, episodic cluster headache may occur annually or every 2 years, often in the same season each time. Chronic cluster headache may occur without a remission.

Paroxysmal hemicrania is pain of short duration, usually 2 to 30 minutes, and occurs unilaterally around the eye, temple, or maxillary region, sometimes precipitated by head movements. Autonomic features similar to cluster headache can occur. The usual attack rate is up to 40 episodes each day. Bouts of pain may be episodic, separated by a remission, but most patients have daily chronic paroxysmal hemicrania without a remission.

Short unilateral neuralgiform headache with conjunctival injection and tearing attacks are unilateral and consistently on the same side. Although the pain is excruciating, the attack is brief, usually seconds; most patients are free of pain between attacks, although a dull ache can be present. Associated autonomic features include ipsilateral conjunctival injection and tearing.

DIAGNOSIS

The diagnostic criteria for *cluster headache* include severe unilateral orbital, supraorbital, or temporal pain persisting for 15 to 180 minutes with at least one of the following: ipsilateral conjunctival injection or lacrimation, nasal congestion or rhinorrhea, eyelid edema, forehead and facial sweating, miosis with or without ptosis, and restlessness or agitation. Attacks occur between once and as often as eight times each day. There is no other cause of the disorder.

Paroxysmal hemicrania is defined by unilateral pain persisting for 2 to 30 minutes, about 5 times each day, with one or more autonomic features such as conjunctival injection, nasal congestion, eyelid edema, forehead and facial sweating, and miosis or ptosis (or both). Complete prevention may be achieved with indomethacin.

Hemicrania continua is a unilateral headache that occurs daily and continuously without pain-free periods; its intensity is moderate with exacerbations of severe pain. During the exacerbations, at least one autonomic feature is present and is ipsilateral to the pain: conjunctival redness, lacrimation, nasal congestion, ptosis, or miosis.

Short unilateral neuralgiform headache with conjunctival injection and tearing is diagnosed by unilateral orbital, supraorbital, temporal stabbing pain persisting for 5 to 240 seconds at a frequency of 3 to 200 per day. It is associated with conjunctival injection and tearing.

TABLE 405-5 DISTINGUISHING CHARACTERISTICS OF THE TRIGEMINAL AUTONOMIC CEPHALALGIAS

CHARACTERISTIC	CLUSTER	PAROXYSMAL HEMICRANIA	HEMICRANIA CONTINUA	SHORT UNILATERAL NEURALGIFORM HEADACHE WITH CONJUNCTIVAL INJECTION AND TEARING
Sex—F:M	1:3-7	2:1	2:1	1:2
Unilateral	+	+	+	+
Attack frequency	1-8/day	1-40/day		3-200/day
Attack duration	15-80 min	2-30 min	Continuous with episodic exacerbations	5-240 sec
Autonomic features	+	+	+ with exacerbations	+
Indomethacin effect	–	+++	+++	–
Acute treatment at onset	Oxygen, sumatriptan SQ, DHE nasal spray; sumatriptan or zolmitriptan nasal spray (A level evidence)	None	None	None
Preventive medications	Verapamil, lithium, corticosteroids, anticonvulsants (A level)	Indomethacin (A level)	Indomethacin (A level)	Lamotrigine, topiramate, gabapentin (B level)

DHE = dihydroergotamine.

An imaging procedure such as MRI is indicated for all patients with cluster headaches or the other trigeminal autonomic cephalalgias because they can be caused by a primary lesion such as an infection (Chapters 420 through 422), vascular malformation (Chapter 415), or neoplasm, especially a pituitary tumor (Chapter 195). Other possibilities in the differential diagnosis include migraine, hypnic headache (rare, short-lasting headaches exclusively during sleep in the elderly), and trigeminal neuralgia.

TREATMENT

Rx

Because the course of the headache is brief, oral medications take too long to work to be effective. The use of 100% oxygen at 7 to 10 L/min for 15 to 30 minutes benefits some patients.[14] Sumatriptan or zolmitriptan nasal spray or sumatriptan subcutaneously (4 to 6 mg) can be helpful. Dihydroergotamine can be helpful when given nasally, intramuscularly, or even intravenously. Refractory cases may respond to occipital nerve stimulation. Short unilateral neuralgiform headache with conjunctival injection and tearing attacks is so short that there are no medications to treat it acutely.

PREVENTION

Preventive medications should be started at the beginning of a cluster bout. Verapamil, 240 to 480 mg, is the drug of choice. Lithium (300 mg twice daily) is another alternative. Corticosteroids (e.g., prednisone, 40 mg/day, or dexamethasone, 4 mg twice daily for 2 weeks) act rapidly to prevent cluster headache and can be used acutely while other preventive medications are started. Valproic acid (500 to 1500 mg/day in divided doses), topiramate (50 to 100 mg/day), melatonin (4 mg at bedtime), and gabapentin (300 mg three times daily) are sometimes beneficial. Surgical approaches, including occipital nerve stimulators, hypothalamic stimulation, and destructive procedures, are sometimes necessary for this disabling headache.

Paroxysmal hemicrania and hemicrania continua respond to daily indomethacin (25 to 50 mg three times daily). If the patient cannot tolerate indomethacin, calcium-channel blockers (e.g., verapamil, 240 to 480 mg/day) may be helpful. Preventive treatment of short unilateral neuralgiform headache with conjunctival injection and tearing includes lamotrigine (100 to 400 mg/day), topiramate (50 to 100 mg), gabapentin (300 to 900 mg), or intravenous lidocaine (starting at 2 mg/min with cardiac monitoring).

PROGNOSIS

Cluster headache is often a lifelong problem, but remissions may persist for longer periods as the patient ages. The other trigeminal autonomic cephalalgias are probably lifelong; nevertheless, symptomatic treatment combined with preventive medications is helpful.

CHRONIC DAILY HEADACHE

DEFINITION

Though not a specific disorder, chronic daily headache, defined as a headache that is present on more than 15 days per month, is challenging for both patients and physicians. These headaches may be chronic migraine, chronic tension-type headache, new daily persistent headache, or chronic cluster headache, with or without overuse of medications.

EPIDEMIOLOGY

About 4 to 5% of the population suffers from chronic daily headache, most commonly chronic tension type. Trigger factors such as a previous infection, mild head injury, or stressful life event can be present in 40 to 60% of patients with new daily persistent headache. Risk factors for chronic daily headache include medication overuse, history of migraine headache, depression, female gender, obesity, snoring, stressful life events, and low educational level.

PATHOBIOLOGY

The pathophysiology of chronic daily headache is probably related to migraine, with both central and peripheral abnormalities. Once migraine has been prolonged and headache occurs on a daily basis, allodynia, a sense that a usually nonpainful stimulus is becoming painful, often develops. Central sensitization associated with painful structures around the head increases.

CLINICAL MANIFESTATIONS

New daily persistent headache is characterized by daily occurrence and an unrelenting course. It is generally bilateral, nonpulsating, mild to moderate, and associated with no more than one of the following: photophobia, phonophobia, or nausea. Severe nausea or vomiting is rare. New daily persistent headache can be disabling.

Chronic daily headache is often associated with profound psychiatric comorbidity, especially depression and anxiety, and psychiatric comorbidity predicts intractability.

Use of an opiate for more than 8 days per month, especially in men, use of barbiturates for more than 5 days per month, especially in women, or use of triptans for more than 10 to 14 days per month can often lead to chronic migraine headache or at least worsening of headaches.

DIAGNOSIS

Diagnosis of chronic daily headache is based on the history. It is important to identify the underlying type of primary chronic daily headache: chronic migraine, chronic tension-type headache, new daily persistent headache, or hemicrania continua. Of note is that headaches of less than 4 hours' duration can also be chronic and daily: cluster headache; paroxysmal hemicrania; hypnic headaches, occurring every night, usually in the elderly; and episodic stabbing headache. It is most important to exclude secondary headaches, including post-traumatic headache, headaches associated with vascular disorders (e.g., giant cell arteritis, arteriovenous malformations, carotid and vertebral artery dissections), and headaches associated with nonvascular disorders (e.g., intracranial hypertension, intracranial hypotension, infections). MRI and laboratory studies (e.g., ESR in an elderly individual) are commonly recommended. Lumbar puncture to assess intracranial pressure may also be indicated in selected patients.

TREATMENT

Rx

The most common cause of chronic daily headache is overuse of medications, so patients must be weaned off the overused symptomatic medication. Treatment of underlying depression, anxiety, and pain may also be helpful. Occasionally, hospital admission is necessary to break the headache cycle. Acute migraine–specific treatments (see earlier), especially intravenous dihydroergotamine (0.5 to 2 mg), are helpful in terminating migrainous attacks.

PREVENTION

Medications that are helpful in preventing chronic daily headache include tricyclic antidepressants, selective serotonin re-uptake inhibitors if patients are depressed, anticonvulsants, β-blockers, and calcium-channel blockers (see Tables 405-3 and 405-4). For hemicrania continua, indomethacin (25 to 50 mg three times daily) is the preferred treatment.

PROGNOSIS

The prognosis depends on the underlying headache diagnosis. If medication overuse is the cause but the patient is successfully detoxified, about 75% of patients improve when treated with preventive medications. Treatment may fail if the diagnosis is incorrect or because of continued overuse of medications, overuse of caffeine, lack of sleep, dietary or other life triggers, hormonal factors, or psychiatric factors.

SINUS HEADACHE

Rhinosinusitis (Chapter 434) is characterized by inflammation or infection of the nasal mucosa and sinuses. The sinuses themselves are relatively insensate, but ducts, turbinates, and ostia are the painful structures.

Headaches attributed to rhinosinusitis are frontal headaches with pain in the face, ears, or teeth. The onset of pain is simultaneous with the rhinosinusitis, and the headache and face pain resolve within 7 days after successful treatment. The diagnosis requires imaging (see Fig. 434-4) and clinical evidence that support the diagnosis of acute or chronic rhinosinusitis, and most headaches that are initially thought to result from sinus disease are found to be migraine or tension-type headache.

Treatment of acute sinusitis (Chapter 434) should resolve the headache. If it does not, an underlying primary headache disorder is likely.

SECONDARY CAUSES OF HEADACHES

Temporal (Giant Cell) Arteritis

Temporal arteritis (Chapter 279) is an inflammatory process seen mainly in elderly individuals. Headache is one of the most common features. Its incidence is approximately 12 per 100,000 and increases with age to 51 per 100,000 in individuals over 80 years of age. It affects women more often than men (3:1) and is more common in white individuals, especially those of Scandinavian and British descent. It is associated with polymyalgia rheumatica.

The headache has no specific feature, but the pain is usually continuous, generalized, and occasionally throbbing. The temples are generally painful, and patients complain of pain when performing certain activities of daily living, such as chewing food or combing their hair. Transient monocular blindness and diplopia can occur.

Elevation of the ESR and C-reactive protein occurs almost invariably. The diagnosis is made by finding giant cells in a temporal artery biopsy specimen. Immediate treatment with corticosteroids, sometimes before the biopsy result is available, is necessary in doses between 40 and 80 mg daily, with the dose then titrated downward while monitoring the ESR. Used early enough, corticosteroids generally prevent the complications of temporal arteritis, including blindness. The disorder can be long lasting.

Intracranial Hypertension

Intracranial hypertension can be primary and idiopathic in obese women of childbearing age. Secondary intracranial hypertension can be seen with cerebral venous thrombosis (Chapters 414 and 421), masses in the brain (Chapter 195), hydrocephalus, or other intracranial processes.

Idiopathic increased intracranial pressure occurs in 20 per 100,000 individuals (15 to 55 years of age) who are obese. Women are affected more frequently than men. Onset is usually in young adulthood. The cause of the increased pressure is either poor CSF absorption, as is thought to be the problem in idiopathic intracranial hypertension, venous hypertension, as is seen in venous thrombosis, or a mass that causes an increase in pressure.

CLINICAL MANIFESTATIONS

Idiopathic intracranial hypertension is characterized by headache in more than 90% of individuals, about 90% of whom are obese. Other symptoms include pulsatile tinnitus, transient visual obscurations, and double vision.

On examination, papilledema (see Fig. 431-27) may be found. The remainder of the general and neurologic examination is usually normal in patients with idiopathic intracranial hypertension, but abnormalities on examination may point to a secondary cause, such as underlying venous sinus thrombosis (Chapter 414), ischemic stroke, central nervous system infection (Chapter 420), or brain tumor (Chapter 195). Although some individuals have idiopathic intracranial hypertension for years, the condition can be self-limited. In about a third of patients, permanent visual sequelae related to the effect of papilledema develop.

DIAGNOSIS

The diagnosis of intracranial pressure is made by the presence of clinical features, as well as by signs such as papilledema (see Fig. 431-27). MRI is necessary to exclude secondary causes of increased intracranial pressure. MR or CT venography is often needed to exclude venous sinus thrombosis (Chapter 414). Lumbar puncture must be performed unless patients have a contraindication such as an intracranial mass lesion, and CSF pressure should be measured. The diagnosis can be made if the pressure is elevated (CSF > 200 mm H_2O), but the fluid itself is normal. Visual fields must be examined formally because visual acuity is not affected until late in the course of the disorder.

TREATMENT AND PROGNOSIS Rx

Although no controlled trials of treatment of intracranial hypertension have been conducted, acetazolamide in doses of 500 to 1000 mg/day appears to be useful for the treatment of idiopathic intracranial hypertension. Any underlying secondary cause should also be treated. Weight loss may be beneficial in obese subjects. The prognosis of patients with idiopathic intracranial hypertension is good with treatment, but up to a third of inadequately treated patients can experience permanent loss of visual fields or visual acuity.

Intracranial Hypotension

Intracranial hypotension causes a headache that is characteristically better when the patient is supine and worse when the patient is upright. It can be primary (spontaneous) or secondary to another underlying cause, most commonly a previous lumbar puncture.

Intracranial hypotension was once considered rare, but modern imaging techniques suggest an incidence of about 5 per 100,000 per year.

PATHOBIOLOGY

The cause of primary intracranial hypotension is thought to be a small leak or tear in the dura, usually in the lumbar region around cystic structures called Tarlov's cysts. The cause of intracranial hypotension may not be not the tear itself, but low epidural venous pressure that assists in development of the lower pressure and hence the leak.

CLINICAL MANIFESTATIONS

Intracranial hypotension is characterized clinically by a positional headache. The location of the pain is variable, and the most constant characteristic is the orthostatic change in the pain. Double vision can develop if hindbrain herniation occurs.

DIAGNOSIS

The diagnosis of intracranial hypotension is made by MRI showing pachymeningeal enhancement and thickening, along with herniation of the hindbrain. Lumbar puncture may also show low (<50 mm H_2O) CSF pressure. The differential diagnosis includes chronic daily headache, migraine, or a secondary headache. The diagnosis is confirmed if a CSF leak is demonstrated by isotope studies or CT myelography.

TREATMENT AND PROGNOSIS Rx

Treatment of CSF leaks includes bedrest, caffeine, and fluids. For post–dural puncture headache, an epidural blood patch improves the symptoms.[1,5] Surgical repair is rarely required. With treatment, the symptoms and MRI findings should resolve completely.

Trigeminal Neuralgia

Trigeminal neuralgia is a distinct, excruciatingly painful condition provoked by sensory stimuli in the distribution of the trigeminal nerve. Trigeminal neuralgia occurs in 4 per 100,000 individuals, most commonly in persons

between 50 and 70 years of age and in women slightly more than in men (1.5:1).

In younger individuals, multiple sclerosis (Chapter 419) can be associated with the condition. In older individuals, an ectatic artery in the vertebrobasilar system can cause the syndrome. The trigeminal nerve root entry zone is thought to be the site of pathology. Either demyelination or compression of this region increases the firing of trigeminal afferents. When a specific cause can be defined, the term "symptomatic trigeminal neuralgia" is often used.

CLINICAL MANIFESTATIONS

Trigeminal neuralgia pain is characteristically sharp, shooting, and electric shock–like in the distribution of the trigeminal nerve: cheek (V2), chin or lower teeth (V3), and around the eye (V1). A combination of V2 and V3 is the most common. The paroxysms are brief—seconds to up to 2 minutes. Some patients have a dull and continuous interictal pain, whereas most have only staccato-like volleys of pain. Pain is usually triggered by stimuli such as touching the face, brushing the teeth, air moving across the face, or masticating food. Once a volley of pain is triggered, there is usually a refractory period in which pain will not occur.

DIAGNOSIS

Diagnostic criteria include paroxysmal attacks of pain persisting for a second to 2 minutes and affecting one or more divisions of the trigeminal nerve. To make the diagnosis, the pain must be intensely sharp, stabbing, or precipitated by a trigger. Each attack is stereotypical, and there are usually no other neurologic defects. Idiopathic trigeminal neuralgia by definition has no causative lesion, whereas symptomatic trigeminal neuralgia has a cause, such as vascular compression of the trigeminal nerve root exit zone. The differential diagnosis includes trigeminal autonomic cephalgia, which has autonomic accompaniments that are not associated with trigeminal neuralgia. Atypical facial pain and Tolosa-Hunt syndrome, an inflammatory syndrome of the anterior cavernous sinus, are also included in the differential.

TREATMENT

Rx

Trigeminal neuralgia is treated with medications or surgery. Carbamazepine (400 to 1200 mg) is considered the first-line agent for the neuralgia.[1,4] Phenytoin (200 to 300 mg), baclofen (40 to 80 mg), clonazepam (2 to 6 mg), valproic acid (500 to 1500 mg), lamotrigine (100 to 400 mg), gabapentin (900 to 1800 mg), oxcarbazepine (300 to 1800 mg), and topiramate (50 to 200 mg) are also used. Surgical treatments include microvascular decompression, which may alleviate the symptoms and preserve sensory function. Other treatments include partial destruction of the trigeminal nerve with heat (radio frequency lesions) or with glycerol (chemical destruction).

PROGNOSIS

Patients with trigeminal neuralgia can have spontaneous or medication-induced remissions. Microvascular decompression is often curative.

Glossopharyngeal Neuralgia

Less common than trigeminal neuralgia, glossopharyngeal neuralgia is unilateral pain in the distribution of the glossopharyngeal and vagal nerves in the ear, jaw, throat, and tongue. The cause is thought to be compression of the glossopharyngeal nerve by blood vessels, tumor, aneurysm, or infection. The pains are paroxysmal and persist for less than seconds to 2 minutes, but patients can experience 30 to 40 attacks in a day. Like trigeminal neuralgia, the pain is triggered by chewing, swallowing, or talking. Pharmacologic therapy is similar to that for trigeminal neuralgia. Rarely, surgical therapy and microvascular decompression are required.

TRAUMATIC BRAIN INJURY AND SPINAL CORD INJURY

GEOFFREY S. F. LING

EPIDEMIOLOGY

Traumatic brain injury and traumatic spinal cord injury are all too common preventable diseases. Traumatic brain injury is the leading cause of traumatic death and disability (Chapter 112). Approximately 1.4 million cases per year result directly in about 52,000 deaths in the United States annually—almost a third of all injury-related deaths. The majority of traumatic brain injuries are due to falls (Chapters 24), motor vehicle accidents, and assaults. An additional approximately 11,000 cases of severe spinal cord injury occur each year in the United States, primarily the result of motor vehicle accidents, falls, sports-related injuries, and work-related accidents (Chapter 112). The majority of patients with traumatic brain and spinal cord injuries are young adult men.

During the past 20 years, the marked improvement in overall mortality associated with traumatic brain and spinal cord injuries can largely be ascribed to improved care in intensive care units, early aggressive neurosurgical intervention, and prevention of long-term conditions such as deep vein thrombosis and decubitus ulcers. The almost 5.5 million survivors of traumatic brain and spinal cord injuries in the United States often require extended rehabilitation. Because the majority of these patients are young and otherwise in good physical health at the time of injury, many need chronic care for decades. Even minor injury can lead to major disability; approximately 75% of patients who are classified as having mild to moderate traumatic brain injury continue

to have residual symptoms months later, and many of these patients are unable to return to gainful employment.

PATHOBIOLOGY

Traumatic injury to the central nervous system has two phases. The first, neuronal injury, is a direct result of the initiating traumatic event. The second or late phase, which is caused by multiple neuropathologic processes, can continue for days to weeks after the initial insult.

Primary Injury Phase

The primary injury phase is immediate, and its damage, which can cause death almost instantaneously, is often complete by the time that medical care can be instituted. In closed compartment injury to the head or spine, the direct impact of neuronal tissue against the bony vault and shearing of neurovascular structures result in wounding. Because the neuronal structures reside in a fluid-filled compartment, these structures often lag behind the bony structure as it moves during sudden stopping of the body in motion. Thus, the structures will strike both anteriorly and posteriorly against the inner bony table, and a coup-contrecoup lesion will result. If a rotational component is present, the structures will torque, twist, and shear, thereby causing diffuse axonal injury. Motor vehicle accidents are particularly injurious because of the sudden deceleration. In penetrating lesions, the moving projectile will tear neural, vascular, and support structures as it traverses through the brain or spinal cord. If the projectile is moving at high velocity, such as a bullet, the vacuum created by its wake will give rise to tissue cavitation. The temporary cavity, which will ultimately collapse, may be many-fold larger than that of the projectile itself; the transient expansion of surrounding tissue will be sufficient to cause substantial irreversible damage.

Secondary Injury Phase

The delayed secondary phase of injury, which begins quickly after the primary phase and can continue for a prolonged period, involves both neurons and glia. Most neurologic injury is thought to be related to this secondary injury, when "neuron suicide" is caused by processes such as hypoxia, ischemia, and inflammation and the effects of free radicals, excitatory amino acids, and certain ions (e.g., calcium).

The injured brain is more susceptible to hypoxic-ischemic states. The most commonly affected areas are the hippocampus and "watershed" areas. It has been hypothesized that delayed neurologic compromise can be attributed to delayed ischemia.

Diffuse microvascular damage is due to early loss of cerebral vascular autoregulation and loss of integrity of the blood-brain barrier, with resulting endothelial changes such as the formation of intraluminal microvilli. Although the clinical significance of this injury is uncertain, it may play a role in the development of cerebral edema.

Diffuse axonal injury, which consists of shearing of axons in cerebral white matter, causes neurologic deficits such as nonfocal encephalopathy. The consequences of this type of injury can be delayed for up to 12 hours after the initial trauma.

CLINICAL MANIFESTATIONS

Traumatic Brain Injury

The signs and symptoms of traumatic brain injury vary with its severity. Patients suffering from mild traumatic brain injury often experience headache, difficulty concentrating, anxiety, and disrupted sleep; findings on clinical examination are normal, but detailed neuropsychological testing may reveal mild cognitive abnormalities. With moderate traumatic brain injury, patients may have an abnormal sensorium, motor and sensory involvement, and impaired language; the results of neurologic examination will be abnormal. In very severe traumatic brain injury, patients are comatose; at best, they may exhibit some eye opening and decorticate or decerebrate posturing to stimulation.

Focal injuries cause neurologic deficits related to the site of impact. The orbitofrontal and anterior temporal lobes are most commonly affected. Extreme vigilance is needed to recognize the development of delayed hematomas and edema, which can be manifested days later.

Traumatic brain injury may be accompanied by a transient increase in systemic arterial pressure. Apnea or cerebral dysfunction may develop. Depending on the degree of injury, spontaneous resolution may be delayed, and laceration of the microvasculature will exacerbate this injury.

Traumatic Spinal Cord Injury

Spinal Cord Syndromes

There are three main spinal cord syndromes: Brown-Séquard, central cord, and anterior cord syndrome. In Brown-Séquard syndrome, the deficits are referable to a lesion of a lateral half of the cord; findings consist of loss of ipsilateral motor, touch, proprioception, and vibration sensation as well as contralateral pain and temperature sensation. Central cord or "man in a barrel" syndrome is manifested as bilateral loss of motor function involving the upper extremities but sparing the lower extremities. Proximal weakness is greater than distal weakness. Pain and temperature sensation is generally reduced, whereas proprioception and vibration are usually spared. Anterior cord syndrome is manifested by deficits referable to bilateral anterior and lateral spinal cord columns or funiculi. There is loss of touch, pain, and temperature sensation and motor function below the level of the lesion, but the posterior column functions of proprioception and vibratory sensation remain intact.

Spinal Shock

After acute traumatic spinal cord injury, patients may suffer from spinal shock, or temporary loss of spinal reflexes below the level of injury. Clinically, there is loss of deep tendon reflexes, the bulbocavernosus reflex, and the anal wink. In high cervical injuries, the lower reflexes (bulbocavernosus and anal wink) may be preserved. Some patients demonstrate the Schiff-Sherrington phenomenon, in which reflexes are affected above the level of injury. Loss of autonomic reflexes can lead to neurogenic shock, ileus, and urinary retention.

DIAGNOSIS

Traumatic Brain Injury

The Glasgow Coma Scale score (Table 406-1) should be calculated promptly, and a detailed neurologic examination should be performed to determine the extent of injury and the severity of impairment. Important clinical signs of occult injury may be revealed on a general physical examination. For example, a scalp laceration should be palpated for evidence of an underlying skull fracture. Periorbital ecchymosis ("raccoon eyes") and postauricular ecchymosis ("Battle's sign") are concerning for a basal skull fracture. A clear or blood-tinged watery discharge from the nose or ear may be a cerebrospinal fluid leak.

Intracranial bleeding caused by traumatic brain injury includes subdural hematoma, epidural hematoma, intraparenchymal hemorrhage, contusion, and traumatic subarachnoid hemorrhage (Chapter 415). The most common is subdural hematoma, which is the basis of approximately 50% of admissions for head injury. Epidural hematoma accounts for about 3%. An associated skull fracture, especially at the temporoparietal junction, increases the incidence of epidural hematoma, usually by disrupting the middle meningeal artery.

Imaging

A computed tomography (CT) scan without contrast should be obtained as soon as possible after the initial clinical assessment. The need for neuroimaging is best determined by use of the Glasgow Coma Scale score and a validated clinical prediction instrument such as the Canadian CT Head Rule (Table 406-2). In any patient thought to have suffered a head injury, the

TABLE 406-1 GLASGOW COMA SCALE SCORE

BEST EYE RESPONSE	BEST VERBAL RESPONSE	BEST MOTOR RESPONSE
1 = No eye opening	1 = No verbal response	1 = No motor response
2 = Eye opening to pain	2 = Incomprehensible sounds	2 = Extension to pain
3 = Eye opening to verbal command	3 = Inappropriate words	3 = Flexion to pain
4 = Eyes open spontaneously	4 = Confused 5 = Oriented	4 = Withdrawal from pain 5 = Localizing pain 6 = Obeys commands

To calculate the score, sum the numbers from each of the three columns.

TABLE 406-2 DECISION RULES TO DETERMINE INDICATIONS FOR CT SCAN IN PATIENTS WITH MINOR HEAD INJURY

STUDY	POPULATION OF PATIENTS	INDICATIONS FOR CT SCAN	Reported Validity (%)* SENSITIVITY	SPECIFICITY
Canadian CT Head Rule[†]	GCS score of 13-15, loss of consciousness, no neurologic deficit, age ≥16 yr	High-risk patients: GCS score <15 at 2 hr after injury, suspected skull fracture, any sign of basal skull fracture, vomiting (≥2 times), age ≥65 yr[‡] Medium-risk patients: retrograde amnesia >30 min, dangerous mechanism (pedestrian vs. motor vehicle, ejection from motor vehicle, fall from height >1 m or 5 stairs)[§]	100	24.5
New Orleans Criteria[¶]	GCS score of 15, loss of consciousness, no neurologic deficit, no seizure, no anticoagulation, age >3 yr	Headache, vomiting, seizure, intoxication, short-term memory deficit, age ≥ 60 yr, or injury above the clavicles	98.4	49.6

*Validity for identification of patients with traumatic CT findings.

TABLE 406-3 AMERICAN ACADEMY OF NEUROLOGY: DIAGNOSIS AND MANAGEMENT OF CONCUSSION

GRADE 1 (MILD)*	GRADE 2 (MODERATE)[†]	GRADE 3 (SEVERE)[‡]
Remove from duty/work/play	Remove from duty for the rest of the day	Take to the emergency department
Examine immediately and at 5-minute intervals	Examine frequently for signs of CNS deterioration Physician's neurologic examination as soon as possible (within 24 hours)	Neurologic evaluation, including appropriate neuroimaging
May return to duty/work if clear within 15 minutes	Return to duty after 1 full asymptomatic week (after being cleared by the physician)	Consider hospital admission

GRADE OF CONCUSSION	RETURN TO PLAY/WORK
Grade 1 (first)	15 minutes
Grade 1 (second)	1 week
Grade 2 (first)	1 week
Grade 2 (second)	2 weeks
Grade 3 (first) (brief loss of consciousness)	1 week
Grade 3 (first) (long loss of consciousness)	2 weeks
Grade 3 (second)	1 month
Grade 3 (third)	Consult a neurologist

*Mild: transient confusion, no loss of consciousness, symptoms associated with concussion (such as amnesia) or mental status changes lasting less than 15 minutes.
[†]Moderate: transient confusion, no loss of consciousness, symptoms lasting longer than 15 minutes.
[‡]Severe: any loss of consciousness.

FIGURE 406-1. Subdural hematoma.

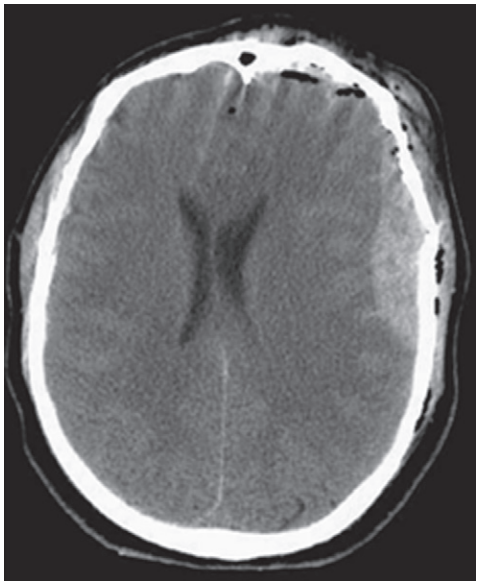

FIGURE 406-2. Epidural hematoma.

severity of the concussion should be assessed (Table 406-3). A subdural hematoma (Fig. 406-1) is blood that accumulates above the brain but below the dura; on CT imaging, it appears as a crescentic or concave opacity overlying the brain. An epidural hematoma (Fig. 406-2) is blood that accumulates below the skull but above the dura; it appears as a convex or lenticular opacity on CT imaging. Skull fractures are best diagnosed with the use of CT bone windows.

Traumatic Spinal Cord Injury

A detailed neurologic examination is needed to identify the level of the injury and the severity of any deficits as well as to document the degree of neurologic dysfunction at the earliest time possible. The level of the injury is the lowest spinal cord segment with intact motor and sensory function. Normal neurologic findings in patients with a clear sensorium obviate the need for

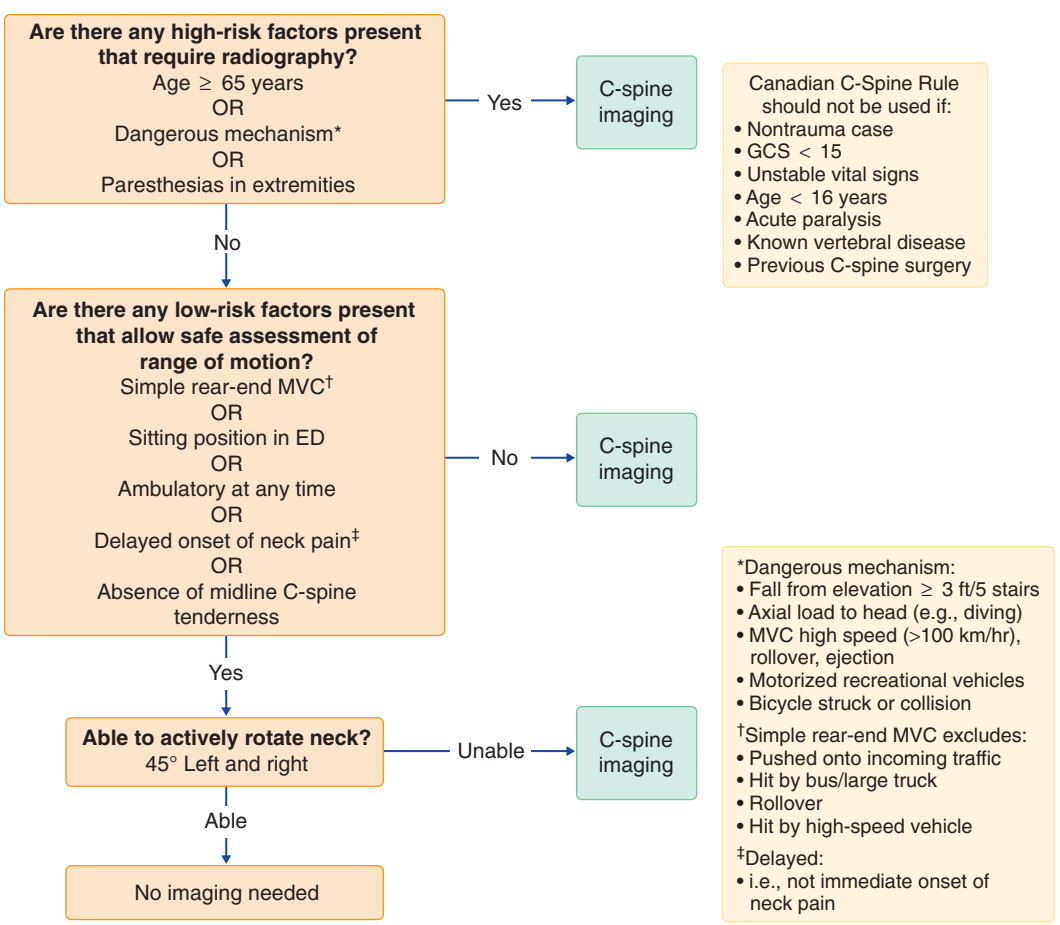

FIGURE 406-3. Canadian C-Spine Rule. For alert (Glasgow Come Scale ≥ 15) and stable trauma patients in whom cervical spine injury is a concern. ED = emergency department; GCS = Glasgow Coma Scale (see Table 406-1); MVC = motor vehicle collision. (Modified from Stiell IG, Clement CM, McKnight RD, et al. Comparative validation of the Canadian C-Spine Rule and the NEXUS low-risk criteria in alert and stable patients. *N Engl J Med.* 2003;349:2510-2518; and Stiell IG, Wells GA, Vandemheen KL, et al. The Canadian C-Spine Rule for radiography in alert and stable trauma patients. *JAMA.* 2001; 286:1841-1848).

imaging studies. However, any complaints of pain over the spine, numbness, tingling, or weakness should raise suspicion of spinal cord injury. In particular, a complaint of "burning hands" suggests traumatic spinal cord injury.

The time of injury should be recorded as accurately as possible. The prognosis for neurologic improvement is better if the lesion is incomplete as opposed to complete. During the acute period, serial examinations must be performed frequently.

If spinal cord injury is suspected, the patient should be appropriately immobilized, such as with a rigid collar and back board. In patients who are able to cooperate with a neurologic examination, are not intoxicated, and do not have painful distracting injuries (such as a femoral fracture, which would interfere with the leg motor and sensory examination), normal neurologic findings effectively rule out cervical spine disease.

Imaging

In patients in whom a cervical injury cannot be excluded, the radiologic evaluation should begin with plain radiographs of the bony spine, with further neuroimaging of any abnormalities that are found. In patients who are alert and stable, the Canadian C-Spine Rule (Fig. 406-3) can be used to reduce unnecessary imaging without any adverse effect on patients' outcomes.■ Bony vertebrae should be examined with CT and the spinal cord with magnetic resonance imaging. Intervertebral and paravertebral soft tissues are best studied with magnetic resonance imaging. A chest radiograph is usually indicated to provide images of the lower cervical and thoracic vertebrae; the presence of a pleural effusion in the setting of a possible thoracic spine injury suggests a hemothorax.

Ligamentous Injury Versus Spinal Cord Injury

If plain radiographs of the cervical spine are normal but the patient still complains of neck pain, a ligamentous injury should be considered. Ligamentous injury can be evaluated by flexion-extension radiographs of the cervical spine. If pain prevents an adequate study, patients should be kept in a rigid cervical collar for 3 to 5 days until the pain and muscle spasm resolve. If studies at that time are normal, the patient will no longer require the collar. Conversely, abnormal results warrant surgical evaluation to determine whether further immobilization or surgical correction is necessary.

TREATMENT

The immediate goals of therapy are to arrest ongoing injury, to preserve and if possible to restore neurologic function, and to avoid secondary medical complications. To achieve these goals, an organized team approach is essential. Despite major research efforts, current clinical treatment is largely confined to supportive measures: maintaining perfusion pressure, minimizing intracompartment hypertension (e.g., increased intracranial pressure [ICP]), and indirectly treating edema.

Traumatic Brain Injury

Initial Management

It is crucial that prehospital providers optimize perfusion and oxygenation because the duration and severity of hypoxia and hypotension in this critical early period have dramatic consequences on clinical outcome. Treatment begins with immediate attention to airway and cardiopulmonary function, early identification of the potential for traumatic brain injury, and minimization of secondary insults such as hypoxia and ischemia.

Patients with mild or moderate traumatic brain injury often have returned to normal or are rapidly recovering by the time that they reach an emergency department. The critical element is the duration of amnesia or loss of consciousness (see Table 406-3). Longer periods of abnormal sensorium are associated with higher grades of concussion, and higher grades of concussion necessitate longer periods of convalescence.

Severe Traumatic Brain Injury

Patients with Glasgow Coma Scale scores of 8 or lower are considered to have severe traumatic brain injury. With this level of impaired consciousness, even with an intact gag reflex, patients are unable to protect the airway adequately. Intubation should be performed with either an endotracheal or a nasotracheal tube, depending on clinical circumstances. The patient should be in a rigid neck collar with the head elevated 30 degrees. The neck collar is used not only to protect the cervical spine until appropriate imaging can be performed but also to keep the head midline to avoid compromising venous drainage.

If intracranial hypertension is suspected, a 30-mL intravenous dose of 23% hypertonic saline through a central venous catheter■ may be better than mannitol (intravenously at a dose of 0.5 to 1.0 g/kg) to reduce it. Continuous infusion of 3% hypertonic saline through a central venous catheter may be started at a rate of 75 to 100 mL/hr with the goal of a serum sodium level of 150 to 155 mM/L to maintain ICP below 20 mm Hg. Intravenous

steroids are of no benefit acutely and increase mortality at 2 weeks after the injury.[■] Hyperventilation may also be tried but has the potential to exacerbate ischemia; if it is used, the goal should be hyperventilation to a P_{CO_2} of 34 to 36 mm Hg. Induced hypothermia reduces ICP in patients with traumatic brain injury. However, its use is not currently recommended,[■] and a large study found no benefit and potential harm in children.[■]

In addition to ICP control, cerebral perfusion must be maintained. The goal is to maintain cerebral perfusion pressure, which is the difference between mean arterial pressure and ICP, higher than 60 mm Hg. Volume resuscitation is the first therapeutic intervention, with the aim of achieving euvolemia or only slight hypervolemia to a central venous pressure (CVP) goal of 4 to 6 mm Hg. For fluid resuscitation, saline is preferred to albumin.[■] Furthermore, for treatment of elevated ICP, an osmolar gradient between the systemic vasculature and the brain is needed. Thus, intravenous hyperosmolar solutions may be used, including normal saline and hypertonic saline (e.g., 3% sodium solutions). The initial goal is 310 mOsm or a serum sodium level of 150 to 155 mM/L. If a cerebral perfusion pressure above 60 mm Hg cannot be achieved with intravenous fluids alone, vasoactive pharmacologic agents such as norepinephrine (beginning at 2 µg/min by continuous intravenous infusion) and phenylephrine (100 µg/min) may be required. Invasive hemodynamic monitoring with an arterial pressure line and CVP catheter may be needed.

Types of Injury

Certain lesions require prompt surgical intervention, whereas others do not. Penetrating wounds, intracerebral hemorrhage with a mass effect (including subdural and epidural blood), and bone injury (such as a displaced fracture and vertebral subluxation) require emergency surgical evaluation for intervention. However, focal, hypoxic-anoxic, diffuse axonal, and diffuse microvascular injuries do not warrant surgical intervention; treatment remains primarily with the critical care clinician. Skull fractures and intracranial hemorrhages require neurosurgical evaluation. In general, if a fracture is displaced more than the thickness of the skull, it needs to be elevated.

If a surgical lesion is not identified, the patient should be admitted to an intensive care unit. If the patient is still at a Glasgow Coma Scale score of 8 or lower, an ICP-monitoring device should be used. An intraventricular catheter provides the most reliable data. It is also a treatment option because it allows drainage of cerebrospinal fluid. However, a subdural bolt and fiberoptic catheter are less invasive alternatives.

Pharmacologic Coma and Surgical Decompression

If ICP remains poorly controlled after the aforementioned efforts, pharmacologic coma or surgical decompression is considered. The postulated effect of pharmacologic coma on ICP is through reduction of cerebral metabolism. If the decision to use pharmacologic coma is made, pentobarbital can be administered at a loading dose of 5 mg/kg intravenously, followed by an infusion of 1 to 3 mg/kg/hr. Another option is propofol (loading dose of 2 mg/kg intravenously, followed by an infusion of up to 100 µg/kg/hr). Continuous electroencephalographic monitoring is helpful because the target response is burst suppression. Barbiturates and propofol are myocardial depressants, so aggressive cardiovascular management is often necessary to achieve the desired cerebral perfusion pressure. Recalcitrant elevated ICP despite these interventions is an ominous sign; serious consideration should be given to frontal or temporal lobe decompression and hemicraniectomy.

Complications

If the patient is agitated, an evaluation should be made to determine whether the patient is in pain or poorly tolerating mechanical ventilation. If pain is a concern, a narcotic analgesic such as fentanyl (50 to 100 µg intravenously) or morphine (1 to 2 mg intravenously) should be administered. Because these agents are easily reversed by naloxone, periodic reassessment of neurologic status can be performed. If agitation alone is the issue, haloperidol (0.5 to 2 mg intravenously), a nonsedating agent that still maintains the ability for a neurologic examination to be performed, should be considered.

The P_{O_2} level should be maintained at approximately 100 mm Hg. Phenytoin (loading dose of 1000 mg intravenously followed by a maintenance dose of 300 mg/day intravenously) reduces seizures during the first week after traumatic brain injury, but its later usefulness is less clear. Fever greatly increases cerebral metabolism; antipyretic interventions such as acetaminophen and cooling blankets should be used as needed. Gastric stress ulcers may be prevented with H_2-antagonists such as ranitidine (50 mg intravenously four times daily) or proton pump inhibitors such as omeprazole (20 mg/day orally). Low-dose heparin (5000 units subcutaneously twice daily) or a low-molecular-weight heparin such as enoxaparin (40 mg/day subcutaneously) and pneumatic stockings should be instituted to avoid deep vein thrombosis. A nasogastric or orogastric tube should be placed for nutrition. Feeding should be initiated as soon as practical, usually on the second day after injury. Because cerebral edema is a concern, hyperosmotic feeding should be instituted. If ileus is present, total parenteral nutrition (TPN; Chapter 224) should be given.

After the first 6 to 12 hours, effort should be made to reduce hyperventilation. Otherwise, the metabolic compensation to chronic hyperventilation negates the ameliorative effects of the respiratory alkalosis.

Regular neurologic examinations and monitoring of ICP and cerebral perfusion pressure are useful to guide ongoing therapy. In general, the peak period of cerebral edema is 48 to 96 hours after traumatic brain injury. Thereafter, cerebral edema spontaneously resolves, often in association with clinical improvement.

Recovery

Recovering patients may experience "postconcussive syndrome," which is primarily manifested as headache. Other symptoms may include difficulty concentrating, changes in appetite, sleep abnormalities, and irritability. In general, postconcussive syndrome lasts a few weeks after injury, but it can persist beyond a year or more. Therapies are based on the patient's symptoms. For headache, nonsteroidal anti-inflammatory agents (such as ibuprofen at an oral dose of 400 to 600 mg), migraine drugs (such as sumatriptan at an oral dose of 25 to 50 mg), and biofeedback may be considered. For cognitive dysfunction, neuropsychological testing may be helpful in determining appropriate intervention.

Traumatic Spinal Cord Injury

Initial Management

Emergency management of traumatic injury to the spinal cord begins with the basics of airway, breathing, and circulation. A secure airway is essential. For patients suffering from high cervical lesions, spontaneous ventilation will be lost. Cervical lesions below C5 may also be associated with impaired ventilatory capability. If there is any concern that the airway or ventilatory effort is compromised, emergency intubation is required. In a patient in whom the cervical spine has not been imaged, the preferred method is nasotracheal intubation under fiberoptic guidance. Other approaches are nasotracheal (blind) or orotracheal intubation, provided that in-line traction is applied.

Other immediate concerns are bleeding and circulation. Hypotension (systolic blood pressure < 90 mm Hg) may be due to either neurogenic shock or hypovolemia and should be avoided. For neurogenic shock, vasopressive pharmacologic agents such as phenylephrine (beginning as a continuous intravenous infusion at 100 µg/min with titration to clinical effect) may be needed. If tachycardia is present, hypovolemia is more likely, so fluid resuscitation would be more appropriate.

Targeted Therapy

If closed compartment spinal cord injury is identified, immediate pharmacologic therapy with methylprednisolone may be instituted,[■] but treatment must be started within 8 hours of injury. The initial dose is an intravenous bolus of 30 mg/kg administered during 15 minutes, followed 45 minutes later by a continuous infusion of 5.4 mg/kg/hr for 23 hours; longer durations of therapy are significantly more toxic. The utility of methylprednisolone in penetrating traumatic spinal cord injury has not been demonstrated, and it should not be used.

At this time, the decision for surgical intervention should be based on the stability of the anterior, middle, and posterior vertebral columns. The anterior column consists of the anterior half of the vertebral body and the vertebral disc. The middle column is the posterior half of the body and the disc. The posterior column is composed of the arch, facets, and ligaments. In general, if two of the three columns are damaged, surgical stabilization is needed. If immediate surgery is not indicated, the patient should be admitted to the intensive care unit for further management.

Acute and Subacute Management

Patients with severe spinal cord injuries require close cardiovascular and ventilatory care, supportive care for bladder and bowel function, approaches to avoid pressure ulcers (Chapter 24), and general measures similar to those used for patients with traumatic brain injury.

Neurogenic Shock and Dysautonomia

After traumatic spinal cord injury, patients are at risk for neurogenic shock and dysautonomia. Lesions of the cervical and thoracic spine disrupt the descending sympathetic pathways to the intermediolateral cell column of the thoracolumbar spinal cord, thereby leading to peripheral vasodilation and hypotension. If the lesion is at T3 or above, sympathetic tone to the heart is compromised. In this setting, hypotension is accompanied by bradycardia, thus producing the neurogenic shock triad of bradycardia, hypotension, and peripheral vasodilation.

Initial therapy for dysautonomia should be fluid administration to restore an adequate circulating volume with a target CVP of 4 to 6 mm Hg. A hematocrit of 30 is optimal for perfusion of the central nervous system, so blood can be used if the patient is anemic. If blood is not required, either colloid (e.g., albumin solutions) or crystalloid (e.g., normal saline) may be used. If there is a suspicion of cardiac or pulmonary disease, a pulmonary artery catheter may be needed briefly to assess fluid status and the relationship between pulmonary pressure and CVP.

Once adequate circulating volume has been achieved, hypotension should be managed with vasopressive agents such as phenylephrine (see earlier), norepinephrine (see earlier), or dopamine (beginning at 1 µg/kg/min by continuous intravenous infusion; Chapter 106), with the goal of a mean arterial pressure of 85 to 90 mm Hg that should be maintained for 7 days

after injury. Symptomatic bradycardia can be treated with atropine (1 mg intravenously).

Ventilatory Compromise

An injury at C5 or higher results in diaphragmatic denervation and requires complete ventilatory assistance. Proper management requires endotracheal or nasotracheal intubation and mechanical ventilation, with an appropriate tidal volume (6 to 10 mL/kg), an FIO_2 to achieve a PO_2 between 80 and 100 mm Hg, and a rate to give a PCO_2 of 40 mm Hg. Positive end-expiratory pressure should also be given to minimize atelectasis (Chapter 105). If the patient does not show signs of ventilatory recovery within 2 weeks of intubation, a tracheostomy should be considered.

Lesions below C5 may also be associated with inadequate spontaneous ventilation. Midcervical lesions may be associated with intact but compromised diaphragm function. If this is suspected, a "sniff" test under fluoroscopy can be performed to determine whether both hemidiaphragms are functioning properly. If they are not, intubation or tracheostomy with volume-controlled ventilation may be needed. If function is intact, pressure support ventilation may be sufficient (Chapter 105) to achieve an appropriate tidal volume.

Cervical lesions at C6 and below spare the phrenic nerves but may disrupt innervation of the intercostal muscles. The primary finding is decreased cough and an inability to increase ventilation when needed, thereby leading to atelectasis and pneumonia; assisted elimination of tracheal secretions is essential.

Thromboembolic Disease

Thromboembolic disease (Chapters 81 and 98) is a leading cause of morbidity and mortality after traumatic spinal cord injury. Prolonged immobility of the lower extremities leads to deep vein thrombosis in up to 70% of spinal cord–injured patients. Patients should receive prophylaxis with heparin alone or in combination with intermittent compression devices (e.g., pneumatic stockings) or graduated compression stockings. Anticoagulation therapy with warfarin to a therapeutic goal of an international normalized ratio of 2 to 3 should begin during rehabilitation. An inferior vena cava filter may be placed if anticoagulation and mechanical therapies are contraindicated.

Visceral Function

The abdominal wall musculature is innervated by T7 to T12. The stomach, small bowel, liver, pancreas, and proximal two thirds of the colon receive innervation from T5 to L2. Spinal cord injury at these levels or above may impair visceral function. For ileus, a nasogastric tube should be placed to decompress the stomach. Parenteral nutrition should be started as soon as possible. Enteral feeding should be delayed until gastrointestinal motility returns, usually within 2 to 3 weeks. In comparison with conservative bowel management, transanal irrigation improves constipation, fecal incontinence, and symptom-related quality of life in patients with spinal cord injuries.[8]

Stress-induced peptic ulcer disease occurs in nearly a third of patients without prophylaxis. An H_2-receptor antagonist such as ranitidine (50 mg intravenously four times daily) or a proton pump inhibitor such as omeprazole (20 mg/day orally) reduces the incidence of ulcers.

Bladder tone may be lost because of spinal shock. A Foley catheter should be placed for a minimum of 5 to 7 days to drain the bladder and to evaluate volume and renal status. After spinal shock has resolved, autonomic dysreflexia may occur as a result of bladder distention. Clinical signs such as sweating, skin flushing, and hypertension may be present. Clinical examination with palpation and percussion will reveal a distended bladder, which can be treated by bladder training or intermittent catheterization.

Nutrition

Until enteral feeding can begin, parenteral nutrition should be used. Ideally, TPN should be started. However, if TPN is not possible, peripheral parenteral nutrition should be used until TPN (Chapter 224) can begin. Energy expenditures of 19 kcal/kg/day for high cervical injuries to 35.8 kcal/kg/day for injuries at T10 and below have been reported. A calorie level of 80% of the Harris-Benedict prediction should be used for quadriplegic patients. The full Harris-Benedict predicted amount should be used in patients with thoracic spine injuries and below.

Other Therapy

Patients with traumatic spinal cord injury have a propensity for the development of decubitus ulcers and pressure sores (Chapter 24). Mechanical kinetic beds, regular log rolling (every 2 hours), and padded orthotics are useful in minimizing this complication. Orthotics, physical therapy, and occupational therapy (for cervical cord injury) are also important to minimize contractures and to begin the rehabilitation process.

PROGNOSIS

Traumatic Brain Injury

The most useful prognostic indicator after traumatic brain injury is the neurologic examination at initial evaluation. For patients with severe traumatic brain injury, the initial Glasgow Coma Scale score is the most reliable prognostic indicator. The lower the initial Glasgow Coma Scale score, the less likely a patient will have meaningful neurologic or functional recovery. After traumatic brain injury, 40% of patients with a score of 8 have a good recovery versus only 7% when the score is 3. Furthermore, only 27% of patients with a score of 3 survive versus 88% of patients with a score of 8. Patients in whom the Glasgow Coma Scale score remains the same or worsens during a period of 6 hours do worse clinically than those whose score improves. Further prognostic stratification at 24 hours can be based on pupillary responses, motor responses, and age (see Chapter 411).

A subsequent head injury before full recovery from even a mild traumatic brain injury may occasionally result in "second impact syndrome," which can worsen the clinical outcome. When seen (mostly in children and adolescents), coma develops rapidly after the second injury, often within minutes. There is decreased autoregulation, diffuse cerebral edema, and intracranial hypertension. Second impact syndrome is associated with high mortality.

TABLE 406-4 AMERICAN SPINAL INJURY ASSOCIATION IMPAIRMENT SCALE

GRADE	INJURY TYPE	DEFINITION	LIKELIHOOD OF RECOVERY*
A	Complete	No motor or sensory function below the lesion	15.5% (cervical) and 7% (thoracic)
B	Incomplete	Sensory but no motor function	47%
C	Incomplete	Some motor strength (<3)	84%
D	Incomplete	Motor strength > 3	84%
E	None	Sensory and motor function normal	100%

*Data from Coleman WP, Geisler FH. Injury severity as primary predictor of outcome in acute spinal cord injury: retrospective results from a large multicenter clinical trial. *Spine J.* 2004;4:373-378.

Traumatic Spinal Cord Injury

For traumatic spinal cord injury, the completeness of the injury is the most useful predictor (Table 406-4). A grade "A" or complete motor and sensory deficit below the lesion has a poor prognosis. If such a lesion persists for 24 hours, there is little likelihood of meaningful recovery. On the other hand, even severe partial injuries have a higher probability of recovery.

407 MECHANICAL AND OTHER LESIONS OF THE SPINE, NERVE ROOTS, AND SPINAL CORD

RICHARD L. BARBANO

DEFINITION

Disorders of the spine, nerve roots, and spinal cord together are frequent reasons for a patient to visit a physician. Many of these disorders either initially or eventually involve more than one element of the vertebra–spinal cord–nerve root unit, so there is much overlap in the pathobiology and clinical manifestations of these diseases.

The spine consists of 30 vertebrae: 7 cervical (C), 12 thoracic (T), 5 lumbar (L), 5 sacral (S), and the coccyx (Fig. 407-1). The ring shape of the bony vertebrae forms a protective circle around the spinal cord while leaving ample room to allow the cord to move within this canal during flexion and extension of the spine. The vertebral bodies help bear the compressive weight of the body and provide the surface area to support the intervertebral discs, which act to cushion the axial force along the spine. The overlapping facet joints and multiple sets of longitudinal ligaments give the spine stability during its many ranges of motion. The posteriorly placed foramina allow the exit of spinal nerves.

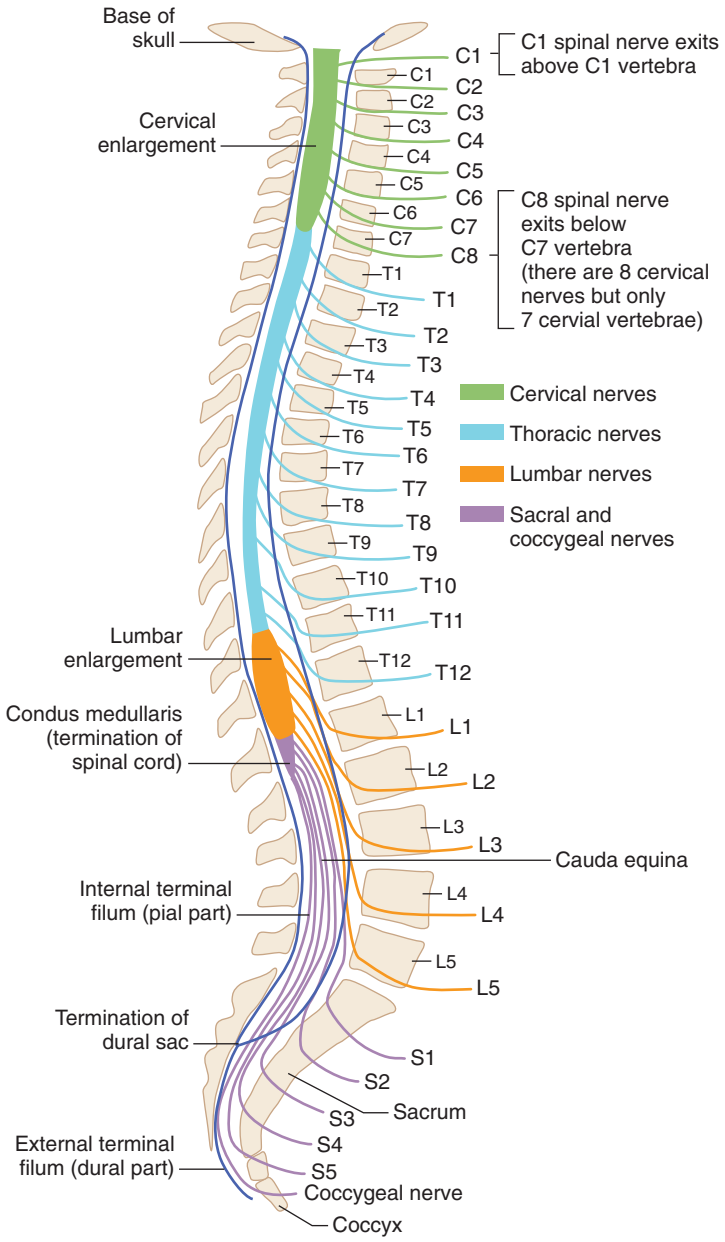

FIGURE 407-1. Anatomy of the spinal cord.

The spinal cord consists of 31 spinal segments, with one more cervical cord segment (8) than vertebrae; each gives rise to a bilateral pair of spinal nerves. Spinal nerves C1 to C7 exit the canal above their corresponding vertebral body, the C8 nerve exits below the C7 vertebra, and subsequent inferior nerves also exit below the numbered vertebrae. The spinal segments of the cord itself, however, lie progressively superior to the vertebrae, so that the end of the spinal cord, the conus medullaris, in adults is approximately adjacent to the L1 vertebra. The more caudal spinal nerves travel as the cauda equina in the subarachnoid space within the spinal canal before exiting their respective foramina. The spinal cord does not have a uniform diameter; the cervical and lumbar segments are wider compared with the thoracic and lower sacral areas because the increased motor and sensory neurons supplying the arms and legs enlarge the cord.

Spinal nerves are formed by the joining of the anterior and posterior spinal roots, which directly exit and enter the spinal cord. The anterior root derives from axons of the anterior horn cells and lateral columns, and it serves motor and autonomic efferent pathways; the posterior root mostly derives from the axons from the dorsal root ganglion and carries afferent sensory signals (Fig. 407-2). The sensory root is twice the thickness of the motor root and lies in a more anterior and inferior location as it crosses the foramen.

CLINICAL MANIFESTATIONS

Disorders of the spinal nerve root produce signs and symptoms referable to the corresponding dermatome or myotome. By far the most frequent complaint is localized neck or back pain, but compromise of the nerve roots or spinal cord will cause symptoms such as abnormal or painful sensations (paresthesias or dysesthesias), loss of sensation, weakness, and autonomic dysfunction (most commonly bladder or bowel incontinence).

When it affects a myotome (the group of muscles served by motor neurons of a spinal cord segment; Fig. 407-3), the motor deficit associated with a spinal root disorder is of the *lower motor neuron* type. Typical findings are weakness, hypotonia, depressed or absent reflexes, and, if the syndrome has persisted for at least several weeks, atrophy with or without fasciculations. Sensation at the root level is diminished or absent for all modalities, but sensation below the affected root level is intact.

Conversely, disorders of the spinal cord produce a "level" below which sensation is abnormal and motor deficits are of the *upper motor neuron* type, with weakness without atrophy (unless complicated by disuse), hypertonia, and increased reflexes. At the level of a spinal cord lesion, the motor deficits can be of the lower motor neuron type as the anterior horn cell bodies or exiting fibers are affected; below this level, an upper motor neuron syndrome will predominate. With strokes (Chapter 414) and other central nervous system disorders (Chapter 195), the full upper motor neuron syndrome may not be present in the acute phase of cord injury and can take time to appear.

DIAGNOSIS

The clinical history can help localize the patient's symptoms, especially complaints of pain and sensory alterations that may exist in the absence of objective sensory loss on probing with light touch, pinprick, and vibration stimuli. The neurologic examination should include evaluation of the sensory, motor (Table 407-1), and reflex (Table 407-2) functions. Careful side-to-side comparisons can help assess subtle deficits. For example, elderly patients often have decreased or absent ankle jerks, so contralateral comparison is necessary. However, all muscles receive innervation from more than one root/spinal cord level, and all roots send fibers to multiple muscles. The clinical implication of this anatomic pattern is that individual muscles are rarely profoundly weak, and patients rarely report isolated muscle weakness in single root involvement syndromes. Likewise, overlap of the sensory dermatomes (see Fig. 407-3) explains why sharp demarcations in the sensory examination rarely occur.

DISORDERS OF THE SPINE

Neck and Back Pain

DEFINITION

Most neck and back pain is *mechanical,* that is, theoretically emanating from the spine's structural elements, which are the vertebrae, discs, ligaments,

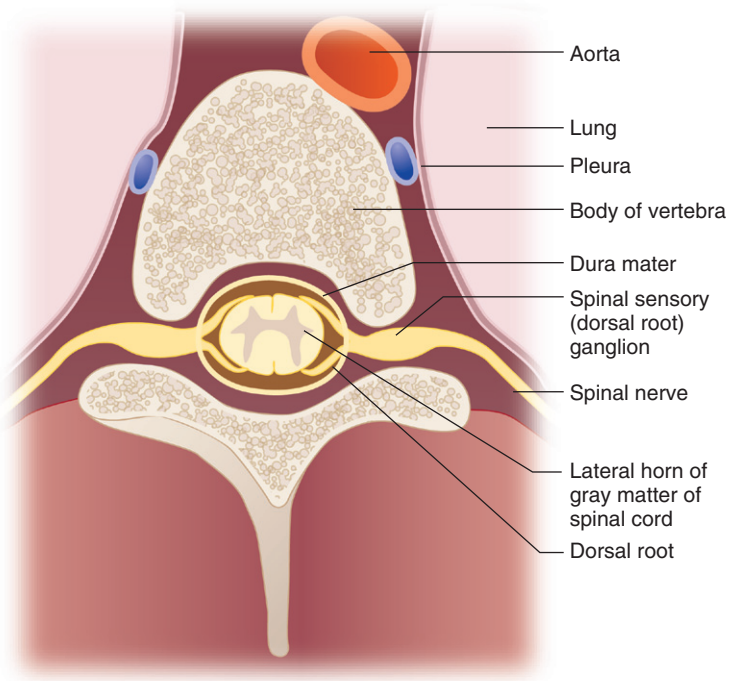

FIGURE 407-2. Anatomy of the spinal cord: section through a thoracic vertebra.

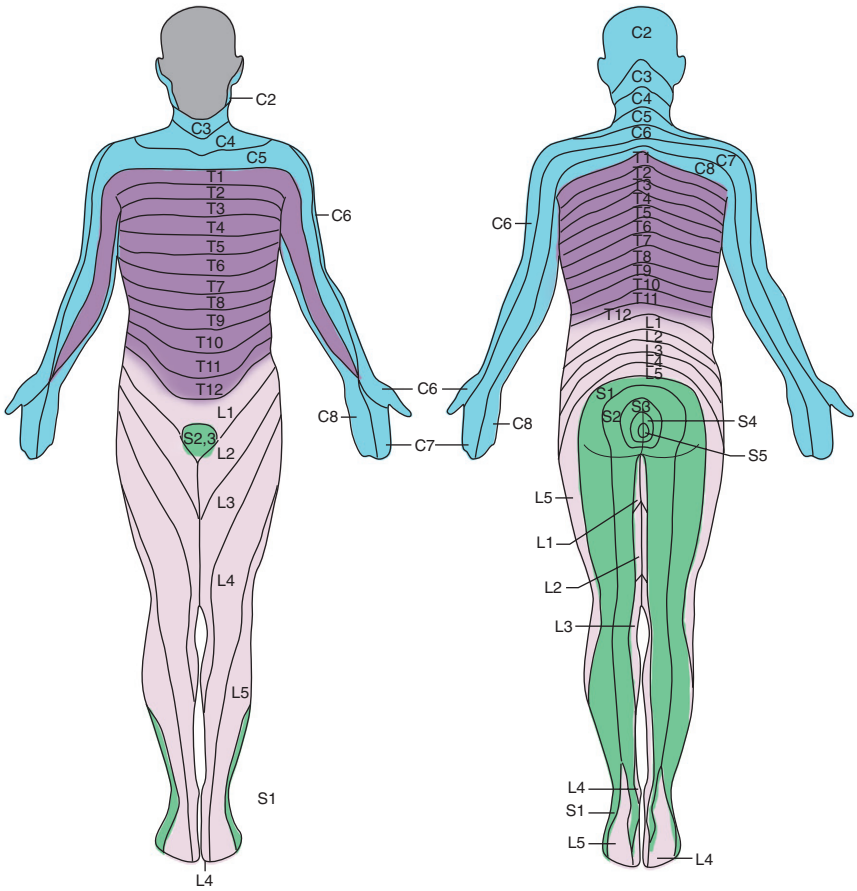
tendons, and muscles. The location of pain is either *axial,* which means it is located along the spine itself, or *referred;* the term *perceived pain* is sometimes used when the pain from a spinal lesion is felt elsewhere by the patient, whereas *referred pain* is often used to describe pain caused by nonspinal structures that is experienced by the patient in the spinal area. If the pain follows a dermatomal (nerve root) distribution, it is referred to as *radicular pain,* which is likely to involve the nerve root.

EPIDEMIOLOGY

Neck and back pain is a frequent reason for visits to a primary care physician. Low back pain is more common than neck pain, but both are common. The thoracic spine, possibly because of rib attachments and limited range of motion, is an uncommon location for back pain.

In the general population, the incidence of self-reported neck pain is 213 per 1000; the 12-month prevalence of any pain is typically between 30 and 50%, and pain severe enough to limit activity is between 1.7 and 11.5%. The prevalence is higher among women. Risk factors for neck pain include inherited factors, poor psychological health, and tobacco use; the presence of disc degeneration is not a significant factor.

More than 70% of people will experience low back pain significant enough to inhibit their participation in daily activities at some time in their life. The highest prevalence is in the 45- to 64-year age group. There is less of a gender difference than with neck pain, although tobacco use is an associated risk factor. Physical work–related factors, such as heavy lifting, prolonged sitting, and repetitive twisting, increase risk; prospective studies show that psychosocial issues, such as work monotony and job dissatisfaction, also are major predisposing factors.



Levels of principal dermatomes

C5	Clavicles
C5,6,7	Lateral parts of upper limbs
C8, T1	Medial sides of upper limbs
C6	Thumb
C6,7,8	Hand
C8	Ring and little fingers
T4	Level of nipples
T10	Level of umbilicus
T12	Inguinal or groin regions
L1,2,3,4	Anterior and inner surfaces of lower limbs
L4,5 S1	Foot
L4	Medial side of great toe
S1,2, L5	Posterior and outer surfaces of lower limbs
S1	Lateral margin of foot and little toe
S2,3,4	Perineum

FIGURE 407-3. Schematic demarcation of levels of principal dermatomes shown as distinct segments. There is actually considerable overlap between any two adjacent dermatomes.

TABLE 407-1 ESSENTIAL MUSCLE TESTING

ROOT	MUSCLES	ACTION/TESTING
ARM		
C5	Deltoid Infraspinatus	Abducts arm Externally rotates arm with elbow flexed
C6	Brachioradialis	Flexes elbow (along with biceps [C5-6])
C7	Triceps Extensor digitorum	Extends elbow Extends fingers
C8	Flexor digitorum Flexor pollicis longus	Flexes fingers (both superficialis and profundus) Flexes distal phalanx of thumb
T1	Interossei	Spread fingers
LEG		
L1-2	Iliacus	Flexes hip
L2-3	Adductor magnus	Adducts thigh (as part of adductor group)
L3-4	Quadriceps	Extends knee
L4	Tibialis anterior	Dorsiflexes foot
L5	Extensor hallucis longus Extensor digitorum longus	Great toe extension Toe extension
S1	Hamstrings Flexor hallucis longus	Flex knee Flexes great toe (along with S2)

TABLE 407-2 ESSENTIAL REFLEX EXAMINATION

REFLEX	EFFECT	ROOT/IMPLICATION
Jaw jerk	Jaw closes with tap on slightly opened jaw	Cranial nerve V; implies lesion above cervical cord
Biceps	Tap tendon: elbow flexion	C5-6; musculocutaneous nerve
Brachioradialis	Tap tendon over distal radius with elbow flexed and mid pronation: elbow flexion	C5-6; radial nerve
Triceps	Tap tendon: elbow extension	C6 < C7
Finger flexion	Tap partially flexed fingertips: finger flexion	C6-T1; when hyperactive, may imply lesion above midcervical spinal cord
Patella	Tap patella: quadriceps contraction (knee extension)	L2-4
Achilles	Tap Achilles tendon: foot plantar flexion	S1-2
Babinski	Scratch sole: great toe flexion	Great toe extension implies lesion of cord (or brain) above L4
Anal wink	Scratch perineum: external anal sphincter contraction	Absence of contraction implies S2-4 lesion

PATHOBIOLOGY

Although the popular impression is that the disc is the source of most spine pain, it is estimated that disc disease such as protrusion accounts for only 5% of all low back problems. Degenerative changes are a much more common cause of both acute and chronic spine pain. There is a genetic predisposition to intervertebral disc degeneration, with heritability estimates in the range of 34 to 61%.

Degenerative changes can result in *spondylosis,* a condition that includes degenerative disc disease with bulging and occasionally herniation. The condition is often accompanied by the formation of osteophytes, ligamentous hypertrophy, and sometimes facet fracture and vertebral subluxation. Spondylosis, which is a consequence of age-related disc disease, is exemplified by the fact that almost everybody has at least anterior osteophytes by the age of 40 years, and it is not necessarily painful. Spondylosis probably starts with age-related disc desiccation and loss of elasticity of the annulus fibrosus. Tension of the longitudinal ligaments results in the formation of hypertrophic osteophytes. Compromise of microvascular supply may also contribute. Eventually, the facet joints can ride over one another, thereby leading to instability, the formation of more osteophytes, and inflammation of the synovial joints. If there is fracture of the pars interarticularis, the term *spondylolysis* is used. Further instability between the intervertebral segments leads to *spondylolisthesis,* in which one vertebral body shifts sagittally in relation to its adjacent vertebra. Spondylolisthesis is graded by the amount of shift as measured with flexion and extension lateral spine films.

Whiplash, an acute flexion-extension injury of the cervical spine, is common after motor vehicle accidents and other situations of rapid deceleration. Although specific acute and chronic manifestations are controversial, the acute syndrome is generally accepted to be a result of mechanical irritation of pain-sensitive structures in the cervical spine with or without nerve root injury. More severe trauma can cause fracture and vertebral instability, both of which require rapid surgical evaluation.

CLINICAL MANIFESTATIONS

Acute neck pain and low back pain are commonly limited to the axial region, although radicular signs and symptoms can occur in the presence of nerve root irritation. The most common radicular pain occurs in the distribution of a dermatome. Other radicular signs and symptoms can include dysesthesias or sensory loss in the affected dermatome, decreased strength in muscles of the affected myotome, and decreased reflex. Cranial nerve findings, diffuse weakness throughout a limb or in more than one limb, hemisensory symptoms, autonomic symptoms, and increased reflexes are not manifestations of spine disease and should prompt more extensive evaluation for other conditions that affect the brain or brain stem. Bowel and bladder symptoms should prompt urgent evaluation of a cauda equina or myelopathy syndrome (see later).

Acute spine problems can also cause referred or perceived pain at sites other than their anatomic source. For example, mechanical low back pain may include aching in the buttocks or thigh, most often posteriorly and occasionally the hip region but rarely below the knee. More commonly, however, the term *referred pain* denotes the situation in which other structures, usually internal organs, refer pain to the spine or back. Areas of referred pain usually share the same embryologic origin and, during development, the same sensory pathways. Differentiation of referred pain from localized back pain depends on the history and examination. Mechanical pain is often exacerbated by movement, such as twisting, bending, extension, or flexion, whereas referred pain tends to be independent of such activities.

Chronic spine disorders lead to chronic back pain directly and as a secondary complication. For example, chronic degenerative arthropathy can lead to degenerative lumbar scoliosis with secondary involvement of neural structures. Back pain and radiculopathy are the most prominent symptoms, present in upward of 80% of patients, but symptoms of neurogenic claudication also develop in about 50% of patients.

DIAGNOSIS

History and Clinical Examination

The history and examination are essential for the initial evaluation and triage of patients with neck and back pain. Patients with so-called red flags (Table 407-3) merit special attention, as does any patient who awakens from sleep because of pain or has pain that is constant and unchanged by position, is unremitting and progressive, or is accompanied by any systemic signs or symptoms.

As part of the history in the setting of acute neck trauma, well-established screening protocols such as the Canadian C-Spine Rule and the NEXUS Low-Risk Criteria (Fig. 407-4) are validated ways to detect cervical spine fracture and to direct appropriate radiographic evaluation. In such a setting, a computed tomographic (CT) scan of the cervical spine would be the imaging test of choice.

On clinical examination, inspection should assess evidence of trauma, muscle wasting, fasciculations, erythema, rashes, and scars. Palpation is directed to areas of point tenderness during evaluation for more diffusely tender regions, muscle spasm, and masses. If light percussion of the spinous process evokes significant pain, a focal process, such as fracture, malignant neoplasm (Chapter 195), or infection (Chapter 421), should be considered because such a finding is unusual in typical mechanical spine pain. Finally, the active and passive range of motion for flexion, extension, rotation, and tilt should be noted. Many provocative tests have been described for the evaluation of neck and back pain, but few have undergone formal evaluation of their diagnostic accuracy. For neck pain, contralateral rotation of the neck with extension of the arm and fingers (Video 407-1) suggests cervical root involvement, particularly in combination with other provocative tests, such as the Spurling maneuver, in which the patient's head is rotated 45 degrees to the contralateral side with the neck in slight extension to minimize the

TABLE 407-3 "RED FLAGS" IN THE EVALUATION OF SPINE PAIN

Recent significant trauma or minor trauma at age >50 years
Unexplained weight loss
Unexplained fever
Immunosuppression
History of cancer
History of prior local surgery
Systemic disorder, bone or arthritic disorder
Intravenous drug use
Prolonged use of corticosteroids or osteoporosis
Age >70 years
Focal neurologic deficit with progressive symptoms
Duration >6 weeks
Thoracic spine pain

Modified from Davis PC, Wippold FJ, Brunberg JA, et al. ACR Appropriateness Criteria on low back pain. *J Am Coll Radiol.* 2009;6:401-407.

The NEXUS Low Risk Criteria (NLC) Algorithm for screening of neck injuries

- No posterior midline cervical spine tenderness—Midline posterior bony cervical-spine tenderness is present if the patient reports pain on palpation of the posterior midline neck from the nuchal ridge to the prominence of the first thoracic vertebrae, or if the patient evinces pain with direct palpation of any cervical spinous process.
- No evidence of intoxication—Patients should be considered intoxicated if they have either of the following: a recent history provided by the patient, or an observer of intoxication or intoxicating ingestion, or evidence of intoxication on physical examination such as an odor of alcohol, slurred speech, ataxia, dysmetria, or other cerebellar findings, or any behavior consistent with intoxication. Patients may also be considered to be intoxicated if tests of bodily secretions are positive for alcohol or drugs that affect level of alertness.
- A normal level of alertness—An altered level of alertness can include the following: a Glasgow Coma Scale score of 14 or less; disorientation to person, place, time, or events; an inability to remember three objects at five minutes; a delayed or inappropriate response to external stimuli; or other findings.
- No focal neurological deficit—A focal neurological deficit is any focal neurological finding on motor or sensory examination.
- No painful distracting injuries—No precise definition of painful distracting injury is possible. This category includes any condition thought by the clinician to be producing pain sufficient to distract the patient from a second (neck) injury. Such injuries may include, but are not limited to, any long-bone fracture; a visceral injury requiring surgical consultation; a large laceration, degloving injury, or crush injury; large burns; or any other injury causing acute functional impairment. Physicians may also classify any injury as distracting if it is thought to have the potential to impair the patient's ability to appreciate other injuries.

FIGURE 407-4. The NEXUS Low-Risk Criteria (NLC) algorithm for screening of neck injuries. (Reproduced from Hoffman JR, Mower WR, Wolfson AB, et al. Validity of a set of clinical criteria to rule out injury to the cervical spine in patients with blunt trauma. National Emergency X-Radiography Utilization Study Group. *N Engl J Med.* 2000;343:94-99.)

foraminal opening. Downward pressure on the top of the head by the examiner will reproduce arm dysesthesias (Video 407-2). Provocative tests also can diminish symptoms. For example, in the cervical distraction test, the examiner's hands are placed under the jaw and occiput; gentle upward pulling of the head will temporarily reduce or alleviate the symptoms (Video 407-3).

For low back pain, the straight leg raise (Video 407-4) has sensitivity of 0.85 to 0.91 but a specificity of only 0.26 to 0.52 for the diagnosis of sciatica due to a herniated disc. The crossed straight leg raise test (Video 407-5) has a lower sensitivity of 0.23 to 0.34 but a much higher specificity of 0.86 to 0.90. The seated straight leg raise (Video 407-6) can be used for confirmation of root irritation as the spine-leg angle is increased to 90 degrees. A negative result of the seated straight leg raise in the setting of a positive result of the straight leg raise suggests the possibility of a nonorganic component, although a mechanical alteration of the root exit zone in this position should also be considered.

Ancillary Testing

For neck pain (Fig. 407-5), plain radiography and CT scanning, which are the mainstays of cervical spine imaging, allow adequate view of the bony structures. Magnetic resonance imaging (MRI) has largely replaced myelography, which is still used occasionally to provide information about the spinal cord and nerve roots. However, magnetic resonance abnormalities are common and can have a high false-positive rate; for example, 12 to 17% of patients younger than 30 years and 86 to 89% of patients 60 years of age have disc degeneration as evidenced by loss of signal intensity, disc protrusion, narrowing of the disc space, or foraminal stenosis. Cervical discography also has a high false-positive rate and cannot be recommended as a diagnostic test in the assessment of neck pain.

Uncomplicated acute low back pain, with or without radiculopathy, is generally self-limited, and imaging studies are unnecessary unless any of the red flags (see Table 407-3) are present. ■ For trauma, osteoporosis, or patients older than 70 years, plain radiography *may* suffice if the results are normal and no other abnormalities are present. Otherwise, with few exceptions, MRI is the test of choice given its superiority in evaluating soft tissue structures and its lack of radiation exposure. Care must be taken, however, to ensure correlation with the clinical syndrome because 28% of asymptomatic volunteers with a mean age of 42 years have herniated discs, 52% have bulging discs, and 14% have annular tears. The percentage of imaging abnormalities increases even more in asymptomatic volunteers older than 60 years; 57% have significantly abnormal scans, with 36% showing herniated discs and close to 98% showing disc degeneration. Abnormalities of the Modic end plate, anterolisthesis, and disc extrusion are more strongly associated with low back pain than is disc degeneration without end plate changes. Situations in which alternative imaging should be considered include spondylosis and stress fracture, for which bone scintigraphy with single-photon emission computed tomography is more sensitive than MRI. CT can also be useful when MRI is contraindicated or to evaluate scoliosis, bone graft integrity, surgical fusion, and instrumentation. For back and neck pain that persists for 6 weeks, electrodiagnostic testing can demonstrate compromise of spinal root function but is not usually helpful in axial spine pain without neurologic symptoms.

Differential Diagnosis

Mechanical or idiopathic pain explains up to 97% of cases of neck pain (Table 407-4) and low back pain (Table 407-5); the remaining 3% is nonmechanical in origin and includes referred pain and other conditions. Acute mechanical neck pain is most often caused by a neck strain, a herniated nucleus pulposus, or whiplash; for pain of insidious onset, osteoarthritis and myelopathy are the leading causes. For back pain, muscle strain and a herniated nucleus pulposus are acute causes; insidious causes include osteoarthritis, spinal stenosis, spondylolisthesis, and scoliosis. Queries regarding the red flags will identify serious and nonmechanical causes of neck and back pain (Table 407-6).

Abdominal and pelvic structures can refer pain *to* the low back (referred pain). Abdominal aortic aneurysms (Chapter 78) can present with a mid to low back ache that may radiate to the hips or anterior thighs. Cholecystitis (Chapter 158) can cause pain in the midthoracic area; pancreatic disease (Chapter 146) can cause pain in the L1 region; and diverticulitis (Chapter 144) in the left lower quadrant can cause diffuse low back pain. Genitourinary disorders (Chapter 128) can cause colicky referred pain to the flanks and costovertebral angle. Bladder disorders (Chapter 125) may occasionally refer pain to the sacral area, as can prostate problems (Chapter 131). Pelvic disorders in women that can cause referred low back pain include endometriosis (Chapter 244), ectopic pregnancy, and pelvic inflammatory disease (Chapters 307 and 326). Most of these disorders have additional signs and symptoms to aid in the diagnosis.

Myocardial ischemia (Chapter 71) can be associated with anterior neck pain, although less commonly than with left arm or jaw pain. Arterial dissections (Chapter 78) are more commonly associated with neck pain; for example, up to 20% of patients with carotid dissections complain of anterolateral pain, and about 80% of patients with vertebral dissections have posterior or occipital pain. Patients with arterial dissections frequently but not necessarily have signs and symptoms of stroke (Chapter 414). Disorders of the esophagus (Chapter 140) and mass lesions of the throat (Chapters 196 and 437) can also present as neck pain.

Acute spine pain can precede the rash in herpes zoster (Chapter 383) or can be seen in the vaso-occlusive crisis of sickle cell anemia (Chapter 166).

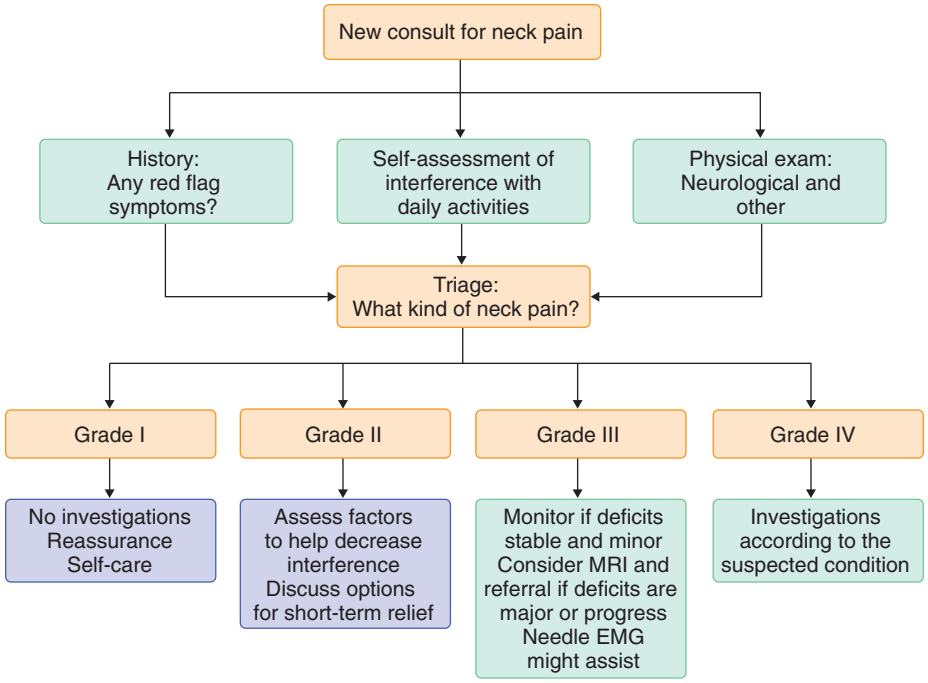


FIGURE 407-5. Approach to new-onset neck pain. (Modified from Guzman J, Haldeman S, Carroll LJ, et al. Clinical practice implications of the Bone and Joint Decade 2000-2010 Task Force on Neck Pain and Its Associated Disorders. Infections of the disc (Chapter 421) cause sharp back pain worsened by movement. Arachnoiditis (Chapter 420), an inflammatory process of the arachnoid space, can cause diffuse, chronic back pain, often after the introduction of foreign substances or manipulation of the intrathecal space. Finally, 20 to 50% of patients with depression (Chapter 404) will complain of back pain that often is diffuse and described in emotionally laden terms. Complaints of low back pain are also common in malingering patients.

TREATMENT

Rx

Treatment options vary according to the severity of pain, presence of radicular signs or symptoms, and any underlying disease. *Acute nontraumatic neck pain* is common and usually benign. Beneficial treatments include nonsteroidal anti-inflammatory drugs (NSAIDs, e.g., ibuprofen 600 mg three times daily for 2 weeks), exercise, and physical therapy. The low risk of myocardial

TABLE 407-6 DIFFERENTIAL DIAGNOSIS OF ORGANIC CAUSES OF LOW BACK PAIN*

MECHANICAL LOW BACK OR LEG PAIN (97%)†	NONMECHANICAL SPINAL CONDITIONS (~1%)‡	VISCERAL DISEASE (2%)
Lumbar strain, sprain (70%)§	Neoplasia (0.7%)	Disease of pelvic organs
Degenerative processes of discs and facets, usually age related (10%)	Multiple myeloma	Prostatitis
Herniated disc (4%)	Metastatic carcinoma	Endometriosis
Spinal stenosis (3%)	Lymphoma and leukemia	Chronic pelvic inflammatory disease
Osteoporotic compression fracture (4%)	Spinal cord tumors	Renal disease
Spondylolisthesis (2%)	Retroperitoneal tumors	Nephrolithiasis

Spondylolysis‖	Epidural or subdural abscess	Cholecystitis
Internal disc disruption or discogenic low back pain¶	Shingles	Penetrating ulcer
Presumed instability**	Inflammatory arthritis (often associated with HLA-B27) (0.3%)	Cardiac or pericardial disease
Other structural anomalies	Ankylosing spondylitis	Pulmonary or pleural disease
	Rheumatoid arthritis	
	Psoriatic spondylitis	
	Reiter's syndrome	
	Inflammatory bowel disease	
	Arachnoiditis	
	Scheuermann's disease (osteochondrosis)	
	Paget's disease of bone	

*Values in parentheses indicate the estimated percentages of patients with these conditions among all adult patients with low back pain in primary care, excluding nonorganic causes such as conversion reaction, psychosis, litigation-related disorders, malingering, and substance abuse. Diagnoses in italics are often associated with neurogenic leg pain. Percentages may vary substantially according to demographic characteristics or referral patterns in a practice. For example, spinal stenosis and osteoporosis will be more common in geriatric patients, spinal infections in injection drug users, and so forth.
†The term *mechanical* is used to designate an anatomic or functional abnormality without an underlying malignant, neoplastic, or inflammatory disease. Approximately 2% of cases of mechanical low back pain or leg pain are accounted for by spondylolysis, internal disc disruption, or discogenic low back pain and presumed instability.
‡Scheuermann's disease and Paget's disease of bone probably account for less than 0.1% of nonmechanical spinal conditions.
§Strain and sprain are nonspecific terms with no pathoanatomic confirmation. Idiopathic low back pain may be a preferable term.
‖Spondylolysis is as common in asymptomatic persons as in those with low back pain, and its role in causing low back pain remains ambiguous.
¶Internal disc disruption is diagnosed by provocative discography (injection of contrast material into a degenerated disc, with assessment of pain at the time of injection). However, discography often causes pain in symptomatic adults, and the condition of many patients with positive discograms improves spontaneously. The clinical importance and appropriate management of this condition remain unclear. Discogenic low back pain is used more or less synonymously with internal disc disruption.
**Presumed instability is loosely defined as more than 10 degrees of angulation or 4 mm of vertical displacement on lateral flexion and extension radiographs. However, the diagnostic criteria, natural history, and surgical indications remain controversial.
From Deyo RA, Weinstein JN. Low back pain. *N Engl J Med.* 2001;344:363-370.

infarction or upper gastrointestinal bleed from NSAIDs must be weighed against pain relief and the relative benignity of the condition. Chiropractic manipulation is of benefit but has the rare complication of posterior circulation stroke from arterial dissection, especially in patients younger than 45 years. Low-level laser therapy[3] and acupuncture[4] are also of short-term benefit. Cervical collars and traction are not of established benefit. Even in the absence of radicular pain, surgical intervention for neck pain is indicated in cases of vertebral instability, such as caused by fracture or dislocation. Surgery, including fusion, may be needed for stabilization after surgery for lesions such as tumors, infections, or hemorrhages. For neck pain that is accompanied by signs or symptoms of radiculopathy, surgery should be considered but is not usually the initial therapy (see later). If a cervical spine lesion is causing spinal cord compression, emergent evaluation for possible surgery is indicated (see later).

Because *acute low back pain* is generally benign, invasive therapy should be avoided in the first 3 months. Conservative treatment includes NSAIDs (e.g., ibuprofen 600 mg three times daily as needed) and controlled physical activity; strict bed rest for longer than 2 days is no better than restricted physical activity.[5] Other options include local heat and massage. Spinal manipulation, exercise therapy, yoga, acupuncture, and cognitive-behavioral therapy are moderately effective.[6]

For *persistent, nonradicular low back pain*, exercise and cognitive-behavioral therapy are recommended. Prolotherapy, in which a mild irritant is injected into a tendon or ligament to increase blood flow and to promote healing, and facet joint injections can be helpful, but intradiscal steroid injections and percutaneous intradiscal radiofrequency thermocoagulation are not effective.[7] When persistent nonradicular low back pain is accompanied by associated degenerative spine changes, surgical fusion is of benefit but not superior to interdisciplinary rehabilitation.

Surgery is indicated for spine instability, progressive neurologic deficits, or severe radicular pain that persists for more than 3 months despite conservative therapy,[8] especially in patients with spinal stenosis and herniated discs. When degenerative changes lead to lumbar scoliosis with or without neurologic signs, decompressive surgery with or without fusion appears effective for at least 5 years for the majority of patients. In more focal disorders, surgery to remove disc material pressure from pain-sensitive structures can be considered; techniques include open, laser, and microdiskectomy approaches, with little evidence to favor one option over the other.

PROGNOSIS

Between 50 and 85% of patients who have neck pain that persists for more than 1 day report recurrence of symptoms in 1- and 5-year follow-up. Patients younger than 45 years have less recurrence, and patients aged 45 to 59 years have the highest risk. Prior neck injury or pain, coexistent low back pain, and self-perceived poor general health are risk factors for recurrence.

Mechanical spine pain, even with radicular symptoms, resolves without specific intervention within 30 days in many patients and within 3 months in 90% of patients. Recurrence is frequent, however, especially in patients with spondylosis, because the underlying process persists and further degeneration of the spinal elements can be expected.

Long-term disability is more common with obesity, low education level, tobacco use, high levels of pain at the onset, tendency to somatization, job dissatisfaction, lack of availability of light-duty employment, and need to perform significant lifting at work. The strongest factors affecting outcome are psychological, especially worrying, fear avoidance, anger, and frustration.

Spinal Stenosis

DEFINITION

Spinal stenosis, which is a narrowing of the spinal canal, results in compression of neural structures in the cervical and lumbar regions, where the

diameter of the spinal cord is largest. Signs and symptoms of spinal stenosis are referable to these levels. In the lumbar region, L4-5 is the most common level of stenosis, followed by L3-4 and L5-S1.

EPIDEMIOLOGY

The annual incidence of spinal stenosis in the United States is about 1 to 2 per l00,000 for the cervical region and 5 per 100,000 for the lumbar region. Spinal stenosis often coexists in the cervical and lumbar regions, and the incidence is higher in patients with more complex degenerative anatomy.

PATHOBIOLOGY

Primary spinal stenosis is due to a congenital narrowing of the spinal canal. Causes of secondary stenosis include chronic degenerative conditions, such as spondylosis and thickening of the ligamenta flava and longitudinale posterius neoplasia, osteomyelitis, and rheumatoid arthritis. In patients receiving corticosteroids long term, epidural lipomatosis is a cause predominantly at the thoracic level.

In spinal stenosis, myelopathy results from compression of the veins that drain the canal, thereby leading to capillary stasis and edema, which result in further compromise of the spinal cord. If the anterior spinal artery is also occluded intermittently or chronically, ischemic gliosis develops. The cord itself can be compressing, and dynamic injury can occur during flexion and extension, especially in chronic degenerative conditions associated with thickening and buckling of the ligamentum flavum. Superimposed trauma, such as severe flexion-extension from whiplash injury or falls, can cause the central cord syndrome (see later, Disorders of the Spinal Cord).

CLINICAL MANIFESTATIONS

Cervical stenosis, which usually results from spondylosis (cervical spondylotic myelopathy) and degenerative spine changes superimposed on congenital stenosis, can be manifested in a number of ways. At the C5-8 level, both the cord and roots are involved, and patients develop lower motor neuron findings in the arms and upper motor neuron signs in the legs; the result is the slow onset of painless atrophy of the weakened hand muscles, accompanied by gait abnormalities. Above the C5 level, the arms may become numb and clumsy, but there is little atrophy. Gait problems are frequently described as leg stiffness, heaviness, or incoordination, and patients may complain of falls or fear of falling, difficulty walking on uneven surfaces, and needing to watch where they are walking. In general, neck pain is not as prominent a complaint as is low back pain in lumbar spinal stenosis, but radicular pain occurs in about one third of patients. On examination, a Lhermitte sign, which is a shocklike tingling traveling down the spine with neck flexion or less commonly with extension, may be elicited. Sensation to pinprick examination will often be decreased in the hands, but this finding may be patchy and not well demarcated. Increased muscle tone will predominate in the legs, and reflexes will likely be increased; the Babinski sign is often present. The stance and gait may be wide based, with slow, short steps. A Romberg sign may be present.

Lumbar spinal stenosis can present with intermittent or persistent signs and symptoms referable to both cord and roots; axial neck or back pain is almost always present. The pain can also radiate in a pseudoradicular pattern from the lumbar region into the gluteal region, groin, and one or both upper legs, but pain rarely radiates distal to the knee unless spinal root involvement occurs. Lumbar neurogenic claudication is perhaps the most specific; symptoms are precipitated by compressive effects on the spinal cord and exiting roots and are characterized by increasing leg paresthesias and weakness as the patient remains standing and gravity pulls the lumbar cord enlargement into the narrowed spinal segment. As opposed to vascular claudication (Chapter 79), symptoms occur even at rest and can be relieved only by bending at the waist or sitting; the patient will characteristically report improved ability to walk if bent at the waist. Other features that suggest neurogenic claudication rather than vascular claudication include back pain, paresthesias, numbness, weakness, and prolonged presence of symptoms after changing of position (seconds to 1 to 2 minutes in vascular claudication but 2 to 20 minutes in neurogenic claudication).

DIAGNOSIS

MRI can localize and quantify the severity of the stenosis. The normal diameter of the lumbar canal is approximately 22 to 25 mm, relative lumbar stenosis is 10 to 12 mm diameter, and a diameter of less than 10 mm is considered absolute stenosis. MRI also can identify any comorbid spinal disease, such as degenerative changes and spondylolisthesis. However, CT myelography, which provides the details needed for surgical treatment, is another alternative. Electromyography (EMG) is not generally useful in the diagnosis of spinal stenosis except in assessment of comorbid conditions, such as localized radiculopathy, which might be important for surgical planning, as well as for detection of other potentially significant disorders, such as polyneuropathy.

The differential diagnosis of lumbar spinal stenosis includes vascular claudication from peripheral vascular disease (Chapter 79) and abdominal aortic aneurysm (Chapter 78). The symptoms of vascular claudication are activity dependent, unlike the positional dependency of the spinal stenosis. Other conditions that can mimic lumbar stenosis include radiculopathy or disc prolapse, polyneuropathy, tethered cord, and spina bifida. Because cervical stenosis can cause both arm and leg symptoms, the differential diagnosis also includes multiple sclerosis (Chapter 419), syringomyelia (Chapter 426), Arnold-Chiari malformation (Chapter 426), cerebrovascular disease (Chapters 414 and 415), normal-pressure hydrocephalus (Chapter 195), and motor neuron disorders (Chapter 418).

TREATMENT

Rx

Spinal stenosis is not necessarily an indication for surgery. Conservative therapy with NSAIDs (e.g., ibuprofen or acetaminophen 600 mg three times daily or acetaminophen 650 mg every 6 hours as needed), muscle relaxants, physical therapy, and a hard cervical collar can help many patients. However, surgery should be considered in patients with severe symptoms and signs of progressive myelopathy. Decompressive laminectomy, with or without fusion, is superior to nonsurgical therapy for improvement of pain and function for at least a year in patients with lumbar spinal stenosis.

PROGNOSIS

Because spinal stenosis is usually degenerative, it is a slowly progressive condition. After symptoms develop and the condition is affecting quality of life, decompressive surgery should be considered. Because the underlying condition itself is progressive, however, surgery is not a permanent cure, and symptoms often recur.

DISORDERS OF THE NERVE ROOTS

DEFINITION

Disorders of the nerve root, termed radiculopathy, lead to symptoms referable to a dermatome or myotome. Either the ventral (anterior, motor) or posterior (dorsal, sensory) root can be involved independently or after they join to form the spinal nerve. Symptoms will follow the anatomic location. Because the root must traverse the vertebral foramen, it is prone to disorders of the spine at these locations. *Sciatica,* which is a commonly used but poorly defined term, often connotes low back pain with radiation into the ipsilateral leg, thereby implying pain radiating along the sciatic nerve, which anatomically contains fibers originating in the L4-S2 roots. The *cauda equina syndrome* results from disease involving the roots of the lower lumbar and sacral spinal cord levels as they traverse inside the spinal canal on their way to exit below their respective vertebral bodies.

PATHOBIOLOGY

Irritation of the spinal sensory nerve root or dorsal root ganglion causes symptoms referable to that dermatome. Spontaneous dysesthesias are hypothesized to result from ectopic discharges from the injured nerve; sensitization of the injured nerve leads to tactile evoked dysesthesias in the same distribution. Mechanical compression of the nerve contributes to the syndrome. In addition, inflammatory cytokines leak from the nucleus pulposus into the epidural space, where they result in endoneurial edema and pain. The pro-inflammatory cytokine tumor necrosis factor-α is a likely main contributor. Rupture of the nucleus pulposus releases phospholipase A_2, which also plays an important role in the inflammatory process. The inflammatory process itself can cause pain even in the absence of frank root compression.

The nerve root exits through the intervertebral foramen, where it is subject to compression and injury. The proximal portion of the nerve root has a small region of decreased vascular supply, where it is especially prone to edema, which can exacerbate the effect of the original injury. Treatment of this edema is one of the potential therapeutic effects of corticosteroid injections. The S1 root is the most susceptible to injury at the foramen because it is the largest

diameter spinal nerve and exits through the narrowest lumbar foramen. In addition, because it is traveling inferiorly from the S1 spinal cord level to pass out of the foramen under the S1 vertebral body, it passes through the superior, most narrow part of the foramen. The superior location of the sensory root on these nerves may account for the early predominance of sensory symptoms versus motor symptoms.

CLINICAL MANIFESTATIONS

The symptoms of radiculopathy depend on the affected root. Root involvement is likely if pain radiates beyond the shoulder or the knee. In the thoracic region, root involvement often produces symptoms that "wrap around" the trunk. Radicular pain is often worsened by activities that increase intraspinal pressure, such as coughing, sneezing, straining, and other Valsalva maneuvers. The characteristics of the pain vary, but when they are exacerbated by such provocation, they are often described as sharp, shooting, electrical, and tingling. When reporting the symptoms, patients may point to or rub the distal dermatome where they are experiencing the discomfort (perceived pain). Patients also may report specific positions that increase or decrease pain; for example, sitting will often worsen the pain of acute lumbar disc herniation, and neck extension can produce radiating pain in cervical disc herniation or other processes that narrow the foramen.

It is uncommon for patients to spontaneously note anesthesia, but they often note dysesthesias in radiculopathy, even in the absence of spine pain. The localization of these dysesthesias often follows the dermatome but also may be described diffusely by the patient. Likewise, complaints of weakness may be difficult to isolate to a particular muscle; however, exceptions exist, such as when the patient complains of a weak grip or a foot drop.

On examination, side-by-side strength testing of specific muscles (see Table 401-1) can help identify slight weakness. Slight weakness may also be identified by evaluating for pronator drift in the arms or asking patients to walk on their toes, walk on their heels, and do shallow knee bends on each leg independently. Sensory examination should test all potential root distributions; pinprick is often sufficient, and it is helpful to ask the patient to report any abnormalities, not just frank hypesthesia. Hyperreflexia in the arms is not expected in a spinal nerve disorder and, if unexplained, should be further investigated for an injury to the spinal cord or brain (Chapter 406). Patients who are older than 65 years or who have a peripheral neuropathy (Chapter 428) might have reduced or even absent ankle jerks.

The cauda equina syndrome is manifested as unilateral or bilateral leg weakness, saddle anesthesia, urinary dysfunction with hesitancy or retention, and, less commonly, bowel dysfunction. Depending on the cause, it is frequently accompanied by low back pain. The syndrome can be accompanied by severe sciatica, which can be unilateral or bilateral but also involve perineal pain. The weakness of the legs, which may be asymmetrical, is of the lower motor neuron type. The major causes of the cauda equina syndrome include lumbar disc herniation, neoplasm, and lumbar spinal stenosis.

DIAGNOSIS

The history and physical examination are similar to the evaluation of neck and back pain (see earlier), with special emphasis on finding evidence of nerve root involvement.

The patient should be queried about bowel and bladder dysfunction. Frank incontinence needs to be investigated for either the cauda equina syndrome or a myelopathy. If the patient has any loss of perineal sensation, such as might be noted during or after voiding or bowel movement, the examination should test perianal sensation, anal sphincter tone, and anal wink reflex. Because the cauda equina syndrome involves nerve roots, reflexes should be normal or decreased; hyperactive reflexes or a Babinski sign would indicate a myelopathy (see later).

Ancillary Testing

Imaging to evaluate a potential radiculopathy is similar to the evaluation for neck and back pain (see earlier). EMG can localize radicular abnormalities and their severity as well as assess possible comorbid neurologic diseases, such as diffuse peripheral or entrapment neuropathies. EMG electrodiagnostic localization can be extremely helpful in determining whether a finding on MRI is truly associated with neurologic impairment, and it has a high sensitivity and specificity for identification of acute and chronic denervation when the motor (anterior) aspect of the root is involved. However, EMG is less sensitive (about 30 to 70%) if only the sensory (posterior) limb of the root is involved by the lesion. MRI with its high sensitivity and EMG with its high specificity should be considered complementary tests.

Differential Diagnosis

Many mechanical processes can injure the spinal nerve root (see earlier, Neck and Back Pain), and most of the causes of spine pain can cause root disorders. Spinal cord compression may accompany radiculopathy.

In addition to conditions that can affect the nerve root as it leaves the spinal column, intra-column abnormalities below the level of the conus medullaris can affect the lumbar and sacral roots before they exit, thereby resulting in the cauda equina syndrome. Most commonly, the cauda equina syndrome is caused by extrinsic compression of the caudal sac by a mass, such as a large and centrally herniated lumbar disc, metastatic tumor, abscess, or epidural hematoma, but arachnoiditis or chronic meningitis must be considered.

Disorders of the brachial or lumbosacral plexus can cause pain radiating down a limb in a radicular or polyradicular pattern. Painful peripheral neuropathies (Chapter 428) can also resemble a radiculopathy. Non-neurologic disorders, such as fibromyalgia (Chapter 282) and polymyalgia rheumatica (Chapter 279), can cause axial pain that mimics a radiculopathy. Cervical radiculopathy also can be mimicked by acromioclavicular joint arthropathy, shoulder bursitis, and the shoulder impingement syndrome; lumbar radiculopathy can be mimicked by hip arthritis, trochanteric bursitis, iliotibial band syndrome, and hamstring tendinitis (Chapter 264).

TREATMENT Rx

Acute neck and back pain, even with radicular symptoms, is usually self-limited and resolves. If radiculopathy is associated with an underlying non-structural lesion, such as infection or tumor, treatment should be directed toward that underlying lesion (see also later, Metastatic Spinal Cord Compression). If symptoms or neurologic dysfunction progresses or persists for more than 6 weeks, interventional options should be considered.

In *cervical radiculopathy,* either foraminal or epidural corticosteroid injection may be of benefit.[10] A series of injections, usually between one and three, provides short-term relief of radicular symptoms, with an acceptable adverse event profile. Although minor events, such as increased neck pain, headache, and vasovagal reactions, are relatively frequent (5 to 20%), serious events, such as epidural hematoma or abscess, are uncommon (<1%). In cervical spondylopathy with radiculopathy, surgery provides more rapid pain relief than does physiotherapy but little additional benefit in the long term.[11] Anterior cervical discectomy, with or without fusion, is beneficial.[3] Cervical anterior discectomy and arthroplasty result in a lower risk of postoperative dysphagia compared with discectomy and fusion,[12] but more complicated surgeries are not of established benefit.

In *lumbar radiculopathy,* transforaminal epidural steroid injections provide short-term symptom relief,[13] but there are no clear guidelines on how many injections or on the indications for continuing the series. Chemonucleolysis of a lumbar disc is moderately superior to placebo but inferior to surgery.

For symptomatic radiculopathy associated with a herniated disc, either open surgical discectomy or microdiskectomy is superior to nonsurgical therapy for at least 3 months.[3] If the condition is isolated to a single disc and no significant degenerative changes are present, longer periods of benefit are more likely. Systematic reviews suggest that conservative discectomy allows a quicker return to work and has less long-term back pain than does more aggressive surgery, but with the downside of an increased risk of recurrent disc herniation. Video 407-7 demonstrates a right L4-5 hemilaminectomy with removal of a herniated disc fragment. The presurgical magnetic resonance images show the position and extent of the disc herniation.

DISORDERS OF THE SPINAL CORD

DEFINITION AND GENERAL OVERVIEW

A disorder of the spinal cord itself is termed a myelopathy. A myelopathy can be intramedullary, as the result of a disorder intrinsic to the cord, or extramedullary, as the result of an abnormality that is extrinsic to the cord but compressing it.

EPIDEMIOLOGY AND PATHOBIOLOGY

Spinal cord disorders can be caused by a wide range of conditions (Table 407-7).

The functional elements of the spinal cord (Fig. 407-6) include descending tracts largely to motor and autonomic neurons, motor neurons, autonomic neurons, and sensory ascending tracts. The anterior horn cell motor neuron is the cell body for the axon that will become the anterior nerve root and

continue directly to innervate the muscle. The cell bodies for the primary sensory neurons reside in the dorsal root ganglion outside the spinal cord itself.

CLINICAL MANIFESTATIONS

The clinical manifestations of myelopathy result from the spinal level of the lesion. The majority of signs will be bilateral, but asymmetry, or even unilaterality, does not exclude a spinal cord lesion.

In general, the three major functions affected are motor, sensory, and autonomic, especially bowel, bladder, and erectile function. If anterior horn cells are involved at the lesion level, the corresponding myotome will exhibit lower motor neuron function (hypotonic weakness), and reflexes may be decreased at that level. Below the lesion, however, patients will have hypertonic weakness that can progress to spastic paralysis, hyperreflexion, and Babinski sign. Sensation will be decreased from the level of the lesion and distally. Because increased tone and spasticity often develop over time, they may not be dramatic at the initial clinical presentation. If the posterior columns are compromised, patients may lose joint position sense and develop ataxia, especially of gait. If the posterior columns of the cervical cord are impaired, patients may have *pseudoathetosis* of the fingers, manifested as unconscious athetotic movements of the fingers of the outstretched arm when the eyes are closed.

The *anterior cord syndrome* is manifested as lower motor neuron weakness at the level of the lesion (anterior horn); upper motor neuron weakness and spasticity below the lesion (corticospinal tracts); autonomic dysfunction below the level of the lesion (lateral horn), most often bowel and bladder dysfunction; and loss of pain and temperature sensation below the level of the lesion (spinothalamic tract). Vibration and joint position sense remain intact (posterior columns). The major causes of this syndrome are vascular, such as an anterior spinal artery, or an anteriorly impinging mass lesion, such as disc or vertebral body mass.

The *central cord syndrome* is manifested as lower motor neuron signs and symptoms at the level of the lesion (anterior horn cells) and upper motor neuron signs and symptoms below the lesion (corticospinal tracts), urinary retention, and a band of loss of temperature and pain sensation at the level of the lesion (anterior white commissure decussation of these fibers). In the midcervical level, this syndrome is typical of syringomyelia (Chapter 426). Other major causes include intramedullary tumors (Chapter 195) and post-traumatic cervical injury (Chapter 406) in patients with disc herniation or preexisting cervical spondylosis.

The *posterior cord syndrome* is manifested as complaints of imbalance, especially in the dark or with eyes closed, and an examination notable for ataxia, presence of Romberg sign, and loss of vibration sense and proprioception below the level of the lesion (posterior columns), with preservation of pain and temperature sensation. Patients are seldom weak. Posterior compression may be caused by spondylotic disease, but other major causes include deficiencies of vitamin B_{12} or vitamin E (Chapters 225 and 425), syphilis (Chapter 327), AIDS-associated vacuolar myelopathy (Chapter 401), and nitrous oxide inhalation (Chapter 425).

The *Brown-Séquard (cord hemisection) syndrome* combines features of these syndromes. At the level of the lesion, patients exhibit *ipsilateral* lower motor weakness (anterior horn) and loss of all sensation (posterior root entry zone). Below the level of the lesion, patients have *ipsilateral* upper motor weakness and spasticity (corticospinal tract) and *ipsilateral* loss of vibration sense and proprioception (posterior columns), with *contralateral* loss of pain and temperature (spinothalamic tract, the fibers of which have crossed from the opposite side through the anterior white commissure). The Brown-Séquard syndrome is often caused by trauma (Chapter 406) or eccentric compression.

TABLE 407-7 CAUSES OF MYELOPATHY

Trauma/compression	Neoplastic
Direct ± vertebral spine disease	Metastatic cord compression
Spondylotic myelopathy/stenosis	Spinal tumors
Post-traumatic syrinx	Paraneoplastic
Arachnoid cyst	Infectious
Vascular	Epidural abscess
Cord infarction	Syphilis
Dural arteriovenous malformation	Lyme disease
Inflammatory/autoimmune	Tuberculosis
Multiple sclerosis	HIV infection
Devic's disease	Tropical spastic paraparesis
Acute disseminating encephalomyelitis	Herpes zoster
Adrenomyeloneuropathy	Toxic/metabolic
Systemic lupus erythematosus	Post-radiation myelopathy
Sjögren's syndrome	Vitamin B_{12} deficiency
Mixed connective tissue disease	Vitamin E deficiency
Postinfectious/postvaccination	Heroin
Arachnoiditis	Epidural lipomatosis
	Congenital/hereditary
	Chiari malformation
	Syringomyelia

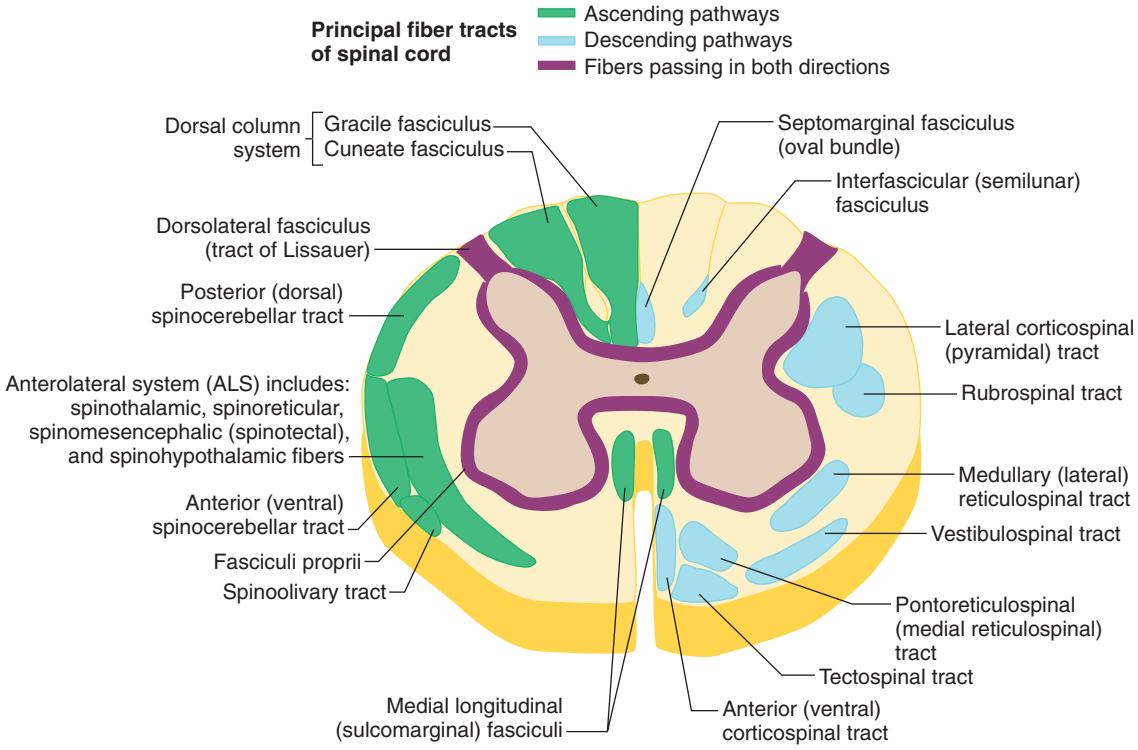

FIGURE 407-6. Principal fiber tracts of spinal cord.

The *conus medullaris syndrome* refers to dysfunction of the distal-most tapered portion of the spinal cord, which anatomically lies at approximately the T12-L1 vertebral spine level. The arms are normal; weakness in the legs is variable but often symmetrical when it is present. The main signs and symptoms are sexual dysfunction, loss of bowel and bladder control, and perianal anesthesia with loss of the anal wink reflex. The major causes are disc herniation, lumbar stenosis, and neoplasm.

DIAGNOSIS

Symptoms of bilateral involvement of the arms or legs suggest a myelopathy, although bilateral leg involvement can be seen in lumbar spinal stenosis and the cauda equina syndrome. Complaints of leg stiffness or incoordination suggest spasticity from myelopathy. Other symptoms include a recent change in bowel or bladder function, erectile dysfunction, imbalance (especially in the dark or with eyes closed), and catching of feet when walking. These central symptoms can also reflect lesions of the brain stem and higher, so the patient should be queried about cortical and brain stem symptoms (e.g., cognitive function, vision, facial strength, sensation, and swallowing). Focal back pain supports a myelopathy.

Examination for a potential myelopathy must include an evaluation of anal tone and perineal sensation. The patient should be examined in a gown to allow inspection of the spine as well as the overlying skin. A *sensory level,* which represents a point where distal (inferior) sensation is altered, should also be sought, but a spinal cord lesion rarely causes a sharp line of sensory demarcation. Joint position sense can be diminished if the posterior columns are involved. A tandem gait will assess possible gait ataxia. Finally, the patient should be examined for distal hypertonicity, if not frank spasticity, by assessment for hyperreflexia and Babinski signs. *In acute spinal cord lesions, however, a state of "spinal shock" can cause hyporeflexia or even a flaccid paralysis.*

Ancillary Testing

MRI is the test of choice because it provides anatomic detail of the spine and subarachnoid space as well as the spinal cord. MRI may also show evidence of demyelinating or metastatic disease. Plain films are not adequate to evaluate the spinal cord. If the MRI is normal, lumbar puncture is sometimes useful for evaluation of conditions that resemble myelopathy: Guillain-Barré syndrome (Chapter 428), infectious or carcinomatous meningitis (Chapter 420), arachnoiditis, and transverse myelitis.

Differential Diagnosis

The many causes of myelopathy (see Table 407-7) can typically occur at any spinal level, but certain conditions predominate at specific spinal levels.

Any lesion that has an upper *cervical* location must be evaluated for disorders of the craniocervical junction, especially disorders that can produce atlantoaxial instability, such as rheumatoid arthritis (Chapter 272); after trauma, cervical or odontoid fracture must be excluded. Disorders at the base of the skull, such as Chiari I and other congenital malformations (Chapter 426), can sometimes affect the upper cervical cord. Syringomyelia (Chapter 426), which may or may not be associated with Chiari malformation, also has a predilection for the cervical cord.

The *thoracic* cord is relatively protected from all but direct trauma, but it is the most common site for metastatic cord compression. Transverse myelitis is most commonly thoracic, and the thoracic cord also is particularly vulnerable to a watershed ischemic myelopathy due to severe hypotension. Epidural lipomatosis often is most symptomatic at the thoracic level.

The *lumbar-conus* region is the most common site for disc herniations. In addition, ependymomas are relatively more common in this region, as are metastases from more caudal locations and compression from arachnoiditis.

The rapidity of onset helps in diagnosis. *Acute or relatively acute myelopathy* suggests vascular causes, trauma, demyelinating lesions, or sudden decompensation of a preexisting lesion, such as a pathologic fracture. In a young person, with no other comorbid illnesses, a demyelinating illness, such as multiple sclerosis (Chapter 419) or acute disseminated encephalomyelitis (Chapter 422), is suggested; other central nervous system lesions separated in space with white matter signal abnormalities on MRI would increase the likelihood of this diagnosis. In older persons or patients with known vascular risk factors, hypotension, or an onset in the immediate postoperative period, a spinal cord infarction is possible. Sudden, sharp back pain suggests mechanical disorders (e.g., pathologic fracture, sudden worsening spondylolisthesis) or spinal cord infarction, whereas demyelinating lesions are often painless.

Myelopathy developing *subacutely,* especially accompanied by back pain, can be caused by metastatic disease (Chapter 195) and abscesses (Chapter 421). Both of these conditions must be evaluated and treated as true emergencies to prevent permanent paralysis. *Subacute* or *chronic* myelopathies include vitamin B_{12} deficiency (Chapter 425), although nitrous oxide inhalation may cause an acute expression of the disorder; syringomyelia (Chapter 426); and more slowly growing tumors, such as meningiomas (Chapter 195), lipomas, and neurofibromas (Chapter 426).

In the setting of known malignant disease or unexplained weight loss, metastatic cord compression (Chapter 195) must be considered. Weight loss, back pain, and fever can be seen in infection (Chapter 421) and occasionally spondyloarthropathies (Chapter 273). Infectious causes also include tropical spastic paraparesis (HTLV-1, Chapter 386). Syphilis (Chapter 327) is the cause of tabes dorsalis; patients may have other signs and symptoms, such as lancinating pains, ataxia, depressed leg reflexes, and Argyll Robertson pupils. Myelopathies that follow an infectious illness include acute disseminated encephalomyelitis and progressive necrotizing myelopathy. Transverse myelitis can follow viral infections, such as herpes zoster (Chapter 383). Myelopathy accompanied by evidence of multifocal cortical dysfunction would likely be multiple sclerosis or acute disseminated encephalomyelitis (Chapter 419). An accompanied peripheral neuropathy is seen in vitamin B_{12} deficiency myelopathy (Chapter 425), which tends to cause gait ataxia. Rheumatoid arthritis (Chapter 272) causes progressive loss of cartilage and bone destruction, potentially leading to atlantoaxial instability and cervical subluxation. Other systemic illnesses, such as systemic lupus erythematosus (Chapter 274), Behçet's syndrome (Chapter 278), and sarcoidosis (Chapter 95), can also cause myelopathies. In patients with exogenous or endogenous hypercortisolemia (Chapter 234), epidural deposition of unencapsulated fat can cause epidural lipomatosis that compresses the spinal column. Patients with a distant history of trauma might be evaluated for post-traumatic syringomyelia. Patients with a history of lumbar puncture, surgery, or intrathecal injections can develop arachnoiditis.

Younger patients are more likely to be symptomatic from congenital disorders, ankylosing spondylitis, or multiple sclerosis. In patients older than 55 years, cervical spondylytic myelopathy is the most common cause of myelopathic symptoms.

TREATMENT AND PROGNOSIS

Rx

Acute traumatic spinal cord lesions are treated with high-dose steroids (Chapter 34). Steroids should also be used in cord compression from metastatic tumors (Chapter 195). Steroids are also frequently used in transverse myelitis, although no controlled trials have been performed.

Patients with spinal cord lesions must be assessed emergently for any potential complications. With high cervical spine lesions, paresis or paralysis of the diaphragm and respiratory depression can occur. Although not emergent, higher cervical or medulla extension of inflammatory myelopathies can cause distressing hiccups and nausea. In lesions at the thoracic level or above, interruption of the lateral column autonomic pathways can lead to autonomic instability, including altered blood pressure responses. At almost any level, but especially at the conus and cauda equina, acute urinary retention may require catheterization. Long-term complications of spinal cord injury include osteoporosis (Chapter 251), orthostatic hypotension (Chapters 50 and 62), and chronic neuropathic pain (Chapter 428), all of which may require specific therapy. Other aspects of treatment and prognosis depend on the specific cause.

Specific Causes of Myelopathy

VASCULAR MYELOPATHIES

The central nervous system tissue of the spinal cord is as intolerant of ischemia as the brain is. Vascular myelopathy occurs when there is loss of blood flow to the spinal cord, whether it is acute or chronic and whether the cause is ischemic or hemorrhagic.

The blood supply to the spinal cord comes from the anterior and posterior spinal arteries that run longitudinally along the length of the spinal cord (Fig. 407-7). The paired posterior spinal arteries are derived in their most rostral origin as branches of the vertebral arteries at the level of the medulla and then run inferiorly along the posterolateral surface of the spinal cord. Along their course, they are fed by a series of small arteries that enter the spinal canal through the intervertebral foramina. Inside the canal, they anastomose extensively to provide redundancy. The anterior spinal artery is formed superiorly when branches of the vertebral artery join to form a single anterior spinal artery, which then runs down the midline of the anterior surface of the spinal

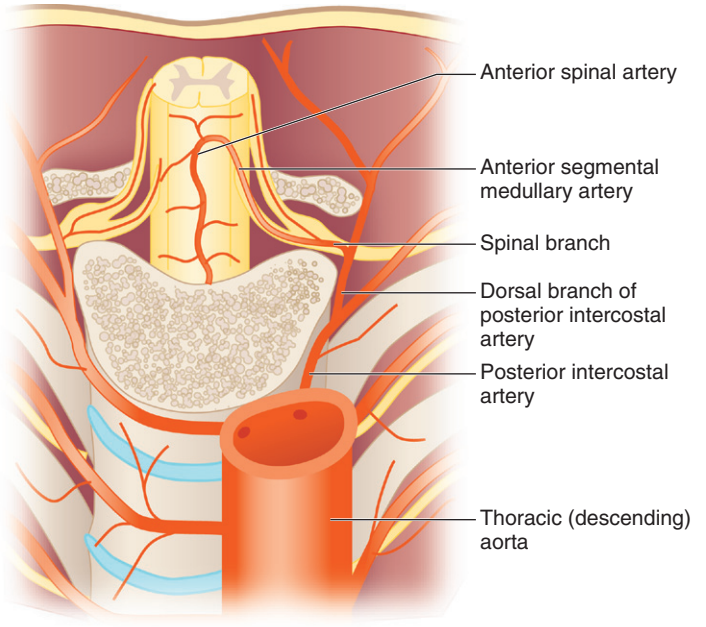

FIGURE 407-7. Blood supply of the spinal cord: section through thoracic level, antero-superior view.

cord. It also receives feeders along its length, but not to the same extent as the posterior segmental branches do. A large anterior radicular artery at C5-6 supplies the cervical enlargement. The main caudal anterior blood supply, however, is from the large artery of Adamkiewicz that enters the spinal canal between the cord levels of T9 and L2 and serves as the main blood supply to the anterior spinal artery, which supplies the lumbar enlargement, the lower thoracic cord, and the conus medullaris.

Compromise of the microvascular supply to the cord underlies the gliotic changes in many slowly progressive myelopathies, such as spondylotic myelopathy. Ischemic causes include general hypotension, atherosclerotic disease, embolic events, vasculitis, and vascular steal; hemorrhagic events usually result from rupture of abnormal vascular malformations.

Severe global hypotension or aortic dissection or surgery can cause ischemic myelopathy, especially in watershed areas of the spinal cord, notably the thoracic region. Atherosclerosis, especially of the artery of Adamkiewicz, can lead to ischemic infarction of the cord by either decreased perfusion or thromboembolic events. Ischemia has also been reported to be a result of compression of the anterior spinal artery by a centrally herniated T12-L1 disc.

Embolic events and local thrombosis can occur in pregnancy and sickle cell disease (Chapter 166). During decompression sickness (Chapter 94), nitrogen bubbles cause microvascular emboli and ischemia. Vasculitis affecting the spinal cord is rare, but granulomatous angiitis of the central nervous system and polyarteritis nodosa (Chapter 278) can lead to infarction.

Spinal dural arteriovenous fistulas are the most common type of vascular malformation of the spinal cord. Arteriovenous malformations are most common in the thoracic cord, especially in patients older than 30 years. Vascular malformations can cause myelopathy by being mass lesions that compress local structures, by interfering with normal venous drainage, by diverting blood as part of a vascular steal with exercise of muscles that compete for blood flow, or by hemorrhage.

Spinal cord hemorrhage, which is rare, can occur intramedullary in the cord itself or in subarachnoid, subdural, or epidural locations. Intramedullary hemorrhage is most often caused by trauma, although bleeding can also occur into a tumor or from an intramedullary vascular malformation. Bleeding from a malformation that enters the subarachnoid space can cause back pain and headache. Epidural hematomas, which cause extramedullary cord compression, can occur as a complication of surgery, myelography, or lumbar puncture, particularly in patients with bleeding diatheses.

CLINICAL MANIFESTATIONS

Occlusion of the artery of Adamkiewicz usually presents with signs of thoracic watershed ischemia—paraplegia with relative sparing of the sacral roots. Infarction in the anterior spinal artery distribution results in dysfunction of the anterior two thirds of the cord, including the anterior horns, the spinothalamic tracts, and the corticospinal tracts; patients usually present with acute paraparesis and impaired bowel and bladder function. Sharp and sometimes circumferential pain at the level of the infarct is often described. Below the level of the lesion, temperature and pain sensation are lost, but vibration and position sense (posterior columns) are preserved.

Infarction of the posterior arteries is less common because of their better collateral circulation. Clinical manifestations, which are less dramatic, include loss of vibratory and position sense, ataxia, gait coordination problems, and Romberg sign; reflexes may be depressed at the level of the infarction.

The central cord vasculature syndrome is similar clinically to a traumatic central cord syndrome (Chapter 406). It may occur as a watershed lesion between the territories of the anterior and posterior spinal circulation and is most common in the cervical cord in older patients with preexisting cervical spondylotic disease.

Vascular malformations most often have a chronic progressive clinical course. Pain is common. Arteriovenous fistulas, commonly in the thoracic cord, present as progressive paraplegia. Patients may have exacerbations of symptoms with exercise and certain postures, and sudden worsening usually indicates hemorrhage.

DIAGNOSIS

Vascular malformations are initially evaluated by MRI, which also can assess the health of the surrounding tissue. When the vascular malformation is connected to the dura (arteriovenous fistula), myelography can occasionally detect lesions that are not seen or are poorly defined by MRI. If embolization or surgery is being considered, spinal angiography is needed to identify feeding and draining vessels, although the test carries a small risk of infarction. Intramedullary arteriovenous malformations are more commonly found in the cervical and thoracic levels and may require angiography to be visualized.

TREATMENT AND PROGNOSIS

Rx

Prognosis for most cases of spinal cord infarct is poor unless blood flow is restored rapidly. Treatment options are limited and include reversal of the cause of ischemia, for example, by correcting hypotension (Chapter 106) or treating for emergent sickle crisis (Chapter 166).

Arteriovenous fistulas are treated by occluding the shunt with embolization or surgery. Successful treatment may arrest and occasionally improve symptoms. Patients with suspected epidural hematomas (Chapter 406) require emergency treatment and surgery if there is progressive neurologic dysfunction.

INFLAMMATORY AND METABOLIC MYELOPATHIES

Transverse myelitis, multiple sclerosis, and other demyelinating diseases are considered in Chapter 419. Metabolic myelopathies can be caused by vitamin B_{12}, vitamin E, and copper deficiencies (Chapter 225).

Acute disseminated encephalomyelitis is mostly a monophasic disorder of demyelination of the spinal cord and brain. If it is isolated to the spinal cord, it might best be termed transverse myelitis. Parainfectious or postvaccination causes account for at least 75% of cases. Postvaccination acute disseminated encephalomyelitis is associated with measles-mumps-rubella vaccinations and diphtheria-tetanus-polio vaccinations as well as with vaccinations for influenza, hepatitis B, pertussis, and Japanese B encephalitis.

Connective tissue diseases can infrequently be a cause of myelopathy. Systemic lupus erythematosus (Chapter 274), with or without antiphospholipid antibody, can include myelitis in 1 to 3% of patients. Sjögren's syndrome (Chapter 276), Behçet's syndrome (Chapter 278), sarcoidosis (Chapter 95), ankylosing spondylitis (Chapter 273), mixed connective tissue disease (Chapter 278), and systemic sclerosis (Chapter 275) can be associated with inflammatory myelitis.

Human T lymphotropic virus type 1 (HTLV-1)–associated myelopathy/tropical spastic paraparesis (Chapter 386) is a chronic progressive myelopathy that causes leg weakness, spasticity, loss of vibratory sense, and bladder dysfunction. More than 90% of infected people remain asymptomatic, with transformation to a symptomatic condition thought to be largely related to the host's inflammatory response. Other neurologic dysfunctions associated with HTLV-1 infection include mild cognitive impairment, sensory neuropathy, and erectile dysfunction. There is no effective therapy.

DIAGNOSIS

In general, diagnosis of the inflammatory myelopathies is based on the clinical examination. MRI often shows a high T2 signal focal enlargement of the cord.

TREATMENT AND SECONDARY PREVENTION

Rx

Intravenous corticosteroid infusions (e.g., methylprednisolone, 1 g intravenously daily for 5 days) are usually the mainstay for treatment of acute attacks of inflammatory myelopathies.

In patients who do not respond to corticosteroids, plasma exchange is effective in the acute treatment of central nervous system demyelinating disorders[14]; about 60% of patients show improvement at 6 months. Factors predicting improvement are initiation of treatment within 15 days of the onset of symptoms and evidence of early improvement.

METASTATIC SPINAL CORD COMPRESSION

When metastatic cancer invades the spine or epidural space, the resultant destruction and growth compress the spinal cord and lead to a myelopathy. The prevalence of metastatic spinal cord compression may be as high as 5% in patients with cancer, depending on the type of malignant neoplasm and its tendency to metastasize to bone. Prostate (Chapter 207), breast (Chapter 204), and lung (Chapter 197) cancers each account for approximately 15 to 20% of cases, and non-Hodgkin's lymphoma (Chapter 191), renal cell cancer (Chapter 203), and multiple myeloma (Chapter 193) account for about 5 to 10% each.

Most metastatic disease causes compression as a result of an extradural lesion, although a smaller number of metastatic lesions can be intradural-extramedullary disease. Intramedullary metastases are rare. Symptoms can be caused by direct compression of the cord and roots in the epidural space as the result of direct extension from hematogenous metastasis to the vertebral body. However, some tumors, such as lymphomas, may grow through the intervertebral foramen without causing significant bone destruction; the accompanying edema can compromise the local vasculature and cause ischemic damage in addition to direct compression. Vertebral destruction can make the spine unstable and cause pathologic fractures, which can lead to cord and root damage.

CLINICAL MANIFESTATIONS

About 90% of patients present with pain that is classically worse on lying down and increases with the Valsalva maneuver. If the nerve root is involved, the pain will have a radicular component; if there is bone collapse, pain can be made worse by movement. Muscle weakness is present in 35 to 75% of patients at the time of diagnosis; sensory deficits are present in 50 to 70% of patients and autonomic dysfunction in 50 to 60% of patients. The range of signs will depend on the level of compression.

DIAGNOSIS

Spinal cord compression, which must be suspected when any patient with cancer complains of spine pain even in the absence of neurologic signs or symptoms, is a neurologic emergency. MRI is the test of choice because plain films, which might recognize bone metastases and vertebral collapse, will miss soft tissue tumors that are in the epidural space and yield no information about the spinal cord itself. Conventional myelography should be used if MRI cannot be performed because of availability or the presence of metallic implants in the patient. Because up to 35% of patients have more than one site of metastasis, care should be taken to image the entire spine by MRI, myelography, or isotope bone scanning.

Differential Diagnosis

For extradural lesions, the differential diagnosis includes lipomas, fibromas, meningiomas, and chordomas as well as vascular malformations and abscesses. Intradural-extramedullary lesions include neurofibromas (Chapter 426), neurinomas, meningiomas, vascular malformations, and, less often, metastases. Arachnoid cysts, although benign, can cause compression through pressure effect. Finally, intramedullary lesions that can present as myelopathy and must be considered in the differential of metastatic cord compression include intramedullary vascular malformations, ependymomas, astrocytomas, and syringomyelia.

TREATMENT

Rx

Prompt initiation of corticosteroids (e.g., dexamethasone, loading dose of 10-16 mg followed by tapering over 10 to 14 days) and radiation therapy are the mainstays of initial therapy. Surgical decompressive surgery plus radiation therapy is better than radiation therapy alone for maintaining ambulation[15] in patients who have a radioinsensitive tumor, have displacement of the spinal cord on MRI, have a single site of cord compression, and have not been totally paraplegic for more than 48 hours.

PROGNOSIS

Metastatic spinal cord compression usually occurs in the setting of metastases to multiple locations, and the expected survival prognosis is generally less than 6 months. Prognosis is improved in patients with malignant neoplasms that are sensitive to steroid therapy (especially lymphoma and leukemia) or are radiosensitive (e.g., multiple myeloma, small cell lung cancer). Patients who are ambulatory at the time of diagnosis, have a single site of compression, and had a less rapid onset of symptoms also generally have a better prognosis.

408 REGIONAL CEREBRAL DYSFUNCTION: HIGHER MENTAL FUNCTIONS

DAVID S. KNOPMAN

DEFINITION

Higher mental function is at the core of what defines competent, independent individuals. Impairment of higher mental function can be broadly classified into four categories. Mental retardation is a form of cognitive impairment that is present from infancy. Acquired forms of cognitive impairment are delirium, dementia, and focal cognitive disorders. Delirium (Chapter 27) is defined by its acute or subacute onset and coexistent alterations in alertness. Dementia (Chapter 409) represents an acquired cognitive impairment that is usually gradual in onset and not associated with alterations in alertness. Focal cognitive disorders involve only one aspect of cognition: memory, language, visuospatial cognition, or executive cognitive functioning, each of which is supported by a different cerebral region.

For the majority of patients in a non-neurology practice, a global description such as "normal mental function" or "cognitively impaired" will suffice. "Cognitive impairment" then becomes a diagnosis that subsumes all forms of altered higher mental function regardless of which domains are affected or how severely they are affected.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

An informal conversation with a patient lacks sensitivity for detecting cognitive impairment. If cognitive impairment is suspected from the patient's history, formal assessments such as the Mini-Cog Test (see Table 26-4) should be performed. Bedside evaluations of orientation, memory, language, reasoning, and visuospatial function can be used to derive an overall view of cognitive function but do not automatically translate into diagnoses because alertness, cooperation, education, native language, sensorimotor function, and mood must be taken into account. Although scores on bedside mental status examinations correlate strongly with severity and prognosis, they provide only rough guides to cognitive ability and cannot localize a cognitive deficit anatomically in the brain. If cognitive dysfunction is discovered in the course of the bedside examination, further exploration of individual cognitive domains must be undertaken.

MEMORY FUNCTION AND AMNESIC DISORDERS

DEFINITION

Human memory operates over a wide time range, from seconds to decades, and with quantities of information ranging from a single word to a lifetime's experience. Each neural system that achieves this monumental dynamic range has its own brain localization (Table 408-1).

Declarative memory describes the type of learning and retrieval of facts and information that occur with conscious attention and intent; examples include remembering conversations, events, and intentions. Declarative memory has semantic and episodic components. Semantic memory refers to the brain's storehouse of knowledge, words, and facts. Episodic memory refers to learning and recall of specific events. Retention of information for more than a few seconds, in the face of exposure to additional facts, details, or events, requires declarative episodic memory to store and organize the information suitable for later recall. It is this declarative, episodic memory system that is assessed as "memory" in the clinical setting. Anterograde amnesia is the clinical manifestation of disturbances in declarative episodic memory. "Anterograde" refers to failure to learn and hence recall new information on an ongoing basis. Most disorders of memory also exhibit retrograde amnesia, a disturbance of the ability to retrieve information from the past.

Immediate recall of information with zero delay and zero intervening information is a very short-term declarative memory function. Immediate memory is capable of storing an image of an auditory message in exact form, but only a small amount and for a short period. The fidelity of immediate memory recall accuracy drops off dramatically over seconds, particularly if intervening sensory stimuli attract attention. A comparable system exists in the visual modality in that the memory acts like a photograph that fades rapidly. From a clinical perspective, immediate memory is separate from declarative episodic memory. Immediate recall is generally used as a marker of attention and alertness and not memory per se. Loss of immediate recall is not usually indicative of memory loss.

PATHOBIOLOGY

The hippocampal formations are the anatomic structures of importance for the declarative episodic memory system. The hippocampal formations are imaged well with magnetic resonance imaging (MRI) (Fig. 408-1). The principal input to the hippocampus comes through the entorhinal cortex from multimodal association areas in the frontal, parietal, and temporal neocortex. A second important input is a cholinergic pathway that originates in the septum of the medial-orbital frontal lobe. There are two principal output circuits of the hippocampal formations. One is via the subiculum back to multimodal association areas. The other hippocampal efferent pathway projects via the fornix to the mammillary bodies. The projection from the mammillary bodies passes through the medial thalamus to the ventral anterior nucleus of the thalamus, then to the posterior cingulate, and then back to the entorhinal cortex. The hippocampal circuit is believed to facilitate the formation of memory in association neocortices. The hippocampus does not store a particular learned fact, but rather it enables the appropriate region in a multimodal association cortical region to do so.

Lesions in one hippocampal formation will not generally have as devastating an impact on episodic memory as bilateral lesions will. However, in older people who may have subclinical bilateral hippocampal pathology, a unilateral lesion, particularly in the dominant hemisphere, may produce a dense

TABLE 408-1 DESCRIPTION OF MEMORY SYSTEMS

TYPE OF MEMORY FUNCTION	REGIONAL LOCALIZATION	LEARNING EFFICIENCY	TIME SPAN UNTIL EFFECTIVE RETRIEVAL	CAPACITY	CLINICAL TESTING TECHNIQUES	EXAMPLES IN DAILY LIFE
Declarative episodic memory	Hippocampus, medial thalamus	Single exposure	Decades	Very large, with rehearsal and elaboration	Recall of 3-4 words after 5 minutes	Recall of recent events and conversations
Declarative semantic memory	Temporal-parietal association cortices	Capable of single exposure; enhanced with repetition	Decades	Very large, perhaps limitless	Confrontation naming, general knowledge	Vocabulary, knowledge of life events from remote past
Attention span, "immediate memory"	Primary auditory or visual cortex	Single exposure only	Seconds	Very small: 7 ± 2 digits (auditory)	Digit span	Dialing a telephone number after hearing it or reading it
Working memory	Lateral frontal cortex	Single exposure only	Seconds	Small	Digits backward	Supporting many mental activities, such as mental arithmetic, abstract reasoning
Procedural memory	Basal ganglia, probably association neocortices	Requires extensive training	Decades	Moderate	Experimental laboratory methods only	Retention of motor skills, e.g., riding a bicycle or typing

(Courtesy Maria Shiung and Clifford Jack, MD.)

anterograde amnesia. Lesions in the columns of the fornix, mammillary bodies, and medial thalamus have also been linked to anterograde amnesia.

CLINICAL MANIFESTATIONS

Patients with anterograde amnesia have poor or no recollection of events, conversations, or observations. Family members report that patients repeat themselves in conversation or re-ask the same questions over the course of a few minutes to hours. Patients will generally forget important events and conversations, even when they were fully engaged in them. They will lose track of the date and time of day. They will forget appointments, even with reminders. Generally, patients with anterograde amnesia will fail to encode most events and happenings around them. The consequences of such memory failure are usually more evident to the family and acquaintances of patients with the disorder than they are to the patients themselves. Anosognosia (lack of awareness) for the deficit of anterograde amnesia is very common, though not universal. Patients who most vehemently complain of memory loss are often suffering from depression rather than focal cognitive dysfunction.

Because some degree of forgetting is ubiquitous in human experience, it is challenging to distinguish between "everyday" forgetting and forgetting that is pathologic. All adults occasionally misplace important items, overlook an appointment, or forget some part of a conversation. In cognitively normal individuals, distraction, preoccupation, inattention, exhaustion, sleep deprivation, or other major life stressors inevitably produce some instances of excess forgetting. Pathologic forgetting as a result of a brain disorder produces a much greater degree of forgetting than occurs in the course of normal daily life, but there is no formulaic description of the boundary at which normal forgetting ends and pathologic forgetting begins.

DIAGNOSIS

The diagnosis of anterograde amnesia begins with a complaint of memory impairment from the patient or from someone close to the patient. Testing of memory can be performed at the bedside in alert patients. The patient is asked to learn three or four words and recall them after 1 or 2 minutes. A patient with severe anterograde amnesia will recall none or at most one of the words, whereas individuals with normal memory can recall all of the words or all but one.

In patients with questionable memory difficulties, assessment by an experienced neuropsychologist is often a necessary part of the evaluation. Standardized tests of memory have greater precision and reliability and involve the use of lengthier material to be remembered and a longer delay between learning and recall.

Determining the Cause

Alzheimer's disease is the most common disorder in which anterograde amnesia occurs (Chapter 409). In Alzheimer's disease, anterograde amnesia is usually the dominant cognitive symptom, particularly early in the illness. Hippocampal atrophy is common (see Fig. 409-3). Anterograde amnesia also occurs in other dementing illnesses, such as vascular dementia and dementia with Lewy bodies.

Strokes can damage regions involved in episodic memory. Occlusion of the medial temporal branch of the posterior cerebral artery causes infarction of the hippocampus. Infarction in the territory of penetrating branches of the tip of the basilar artery causes bilateral medial thalamic infarcts.

Anterograde amnesia may be a major residual deficit after herpes simplex encephalitis (Chapter 382). Herpes simplex encephalitis has a predilection for damaging structures at the base of the cerebral hemispheres; frequently, the temporal lobes are severely damaged. Korsakoff's syndrome, the residual of the encephalopathy of thiamine deficiency (Chapter 425), is characterized by profound anterograde amnesia. Hemorrhagic necrosis of the mammillary bodies occurs in Korsakoff's syndrome. Survivors of closed head injuries (Chapter 406) may have anterograde amnesia because the medial temporal lobes are vulnerable to trauma as a result of their close proximity to the temporal bone. Survivors of an episode of anoxic-ischemic encephalopathy may also have dense anterograde amnesia. The pyramidal neurons of the CA1 region of the hippocampus are particularly vulnerable to hypoxic injury.

The syndrome of transient global amnesia involves anterograde amnesia, but the duration of the amnesia is a matter of 6 to 12 hours rather than the weeks or months seen in post-traumatic amnesia or the permanent deficits in patients with Alzheimer's disease or Korsakoff's syndrome. Transient global amnesia generally affects middle-aged or elderly individuals. Its cause is not known, although it is not usually due to typical cerebrovascular disease or epilepsy. Electroencephalography is typically not specifically abnormal, but diffusion-weighed MRI often shows distinctive abnormalities of the hippocampus a day or more after the onset of transient global amnesia.

THE APHASIAS

DEFINITION

Aphasia is a disorder of language at the conceptual level. Aphasics may have difficulty producing language, comprehending language, or both.

PATHOBIOLOGY

In more than 99% of right-handed individuals, language is localized to the left hemisphere. In left-handed individuals, language is also predominantly localized to the left hemisphere, although varying degrees of bilateral or rarely right hemispheric dominance may be seen. The hemisphere involved in language is referred to as the dominant hemisphere. Anatomic differences in the temporal and parietal lobes of the dominant hemisphere versus the other hemisphere also reflect its specialization for language.

In clinical practice, lesions in the dominant hemisphere's auditory association areas cause receptive language dysfunction. The critical regions are located in the superior temporal lobes adjacent to the primary auditory cortex and in the adjacent supramarginal and angular gyri of the inferior parietal lobule, an area known as Wernicke's area. Lesions in the dominant hemisphere's lateral inferior posterior frontal lobes, often referred to as Broca's area, result in expressive language deficits. Loss of access to one's vocabulary for either understanding spoken language or expressing oneself results from lesions in any portion of the region of the dominant hemisphere around the sylvian fissure, including the lateral posterior inferior frontal lobe, the inferior parietal lobule, and the superior and middle temporal gyri. Coronal and axial MRI scans give a detailed view of the critical language regions (see Fig. 408-1).

CLINICAL MANIFESTATIONS

The language comprehension difficulties in persons with aphasia must be distinguished from hearing disorders (Chapter 436), and the motor speech dysfunction in aphasia must be distinguished from dysarthria. Errors of articulation in persons with aphasia reflect altered conceptual selection of what is to be said. In aphasia, mispronunciation of a sound within one word may be followed by perfect pronunciation of the same sound in a different

word. In dysarthria, by comparison, the errors in articulation or phonation are consistent.

Aphasia has three principal components: impaired verbal comprehension, disordered verbal expression, and impaired naming. Disorders of reading, writing, and sentence repetition are additional elements of the aphasia syndrome. The disordered verbal comprehension may range from profound to mild. When profound, patients are unable to grasp the meaning of single words. In milder forms of disordered comprehension, patients may be able to follow one-step, but not two- or three-step commands. Usually, the comprehension difficulty involves both spoken and written language, but each can be affected separately. Anomia, which is an inability to produce names of people or objects, is common in almost all aphasic syndromes.

In expressive aphasic syndromes, written material and spoken speech are most often affected in parallel. Speech is labored in the expressive aphasias, and it lacks the normal melody and variation in intonation that characterize normal speaking. Melody and intonation are referred to as the prosody of speech. Speech is often grammatically impoverished. The number of words per utterance is greatly reduced, thus giving the speech a choppy, staccato character. These features are referred to as speech apraxia. Nonfluency is a related term that describes the reduced number of words and the terseness of verbal output. In some aphasic syndromes, speech is often degraded by anomia and paraphasic errors (word or syllable substitutions), even when fluency, melody, and intonation are preserved.

Specific Aphasic Syndromes

Specific, common aphasic syndromes exhibit various combinations of receptive and expressive difficulty (Table 408-2).

WERNICKE'S APHASIA

In Wernicke's aphasia, verbal comprehension of both written and verbal language is severely impaired. Patients with Wernicke's aphasia have difficulty understanding the meaning of individual words and may not be able to follow any command consisting of greater than one step. Their speech is fluent but marred by paraphasia and anomia. Wernicke's aphasics tend to lack awareness of the extent of their communicative difficulties and are often unaware that the words they are uttering are fundamentally incorrect. The location that typically causes Wernicke's aphasia is the dominant posterior superior temporal lobe or inferior supramarginal gyrus (see Fig. 408-1).

BROCA'S APHASIA

Broca's aphasia is a syndrome in which expressive language is prominently affected. Patients with Broca's aphasia have nonfluent, labored speech. The location of the lesion that typically causes Broca's aphasia is the dominant posterior inferior frontal lobe (see Fig. 408-1). Patients with Broca's aphasia have largely preserved comprehension and, as a result, are acutely aware of their difficulties and become frustrated with them. Depression is common in Broca's aphasics.

GLOBAL APHASIA

Global aphasia occurs when both expressive and receptive problems are present. Global aphasia often appears acutely after a major infarction, hemorrhage, or traumatic brain injury involving the dominant hemisphere.

ANOMIA

Anomia is at the milder end of the spectrum of language disorders. Some anomic aphasics also have difficulty with sentence repetition, even in the presence of relatively preserved comprehension and verbal expressive abilities. There is some controversy whether this latter syndrome, called conduction aphasia, represents a disconnection between the perisylvian centers for comprehension and expression or whether it represents a lesion in the cortical auditory areas involved in immediate auditory memory.

IDEOMOTOR APRAXIA

Ideomotor apraxia is a disorder at the interface between comprehension and execution of facial or limb motor actions. Patients with ideomotor apraxia have no paresis of the face or limb musculature and are able to carry out simple tasks, but they are unable to execute more complex tasks or commands. For example, in a woman who is able to name a comb and use her right hand to point to parts of her body, ideomotor apraxia can be demonstrated if she is unable to indicate through her actions how she would use the comb.

DIAGNOSIS

The diagnosis of aphasia is made by listening to the patient speak and by examining comprehension, naming ability, reading, and writing in a standardized fashion. Frequently, the diagnosis of aphasia is made during attempts to obtain a history from the patient. It is helpful to prompt patients to speak about a neutral topic, such as what they had for their last meal or what they did the previous day. Listening to their spontaneous speech allows the examiner to characterize its fluency, grammatical form, articulation, melody, and intonation, as well as difficulty finding words, the presence of paraphasias, and the overall information content.

Comprehension should be examined formally by asking the patient to perform tasks that range from one to at least three steps. Naming can be tested by asking the patient to name a series of common objects, such as the parts of the hand and arm (e.g., thumb, palm, knuckles, wrist, elbow). In general, the more commonly a word is used in the language, the easier it will be to name, whereas infrequent words are harder for aphasics. Reading and writing should also be tested.

Portions of the dominant perisylvian cerebral cortex may be damaged by infarction (Chapters 414 and 415), hemorrhage, and other space-occupying brain lesions such as neoplasms (Chapter 195) and abscesses (Chapter 421). Aphasia secondary to stroke has an abrupt onset, usually with some subsequent improvement. Recovery from aphasia after a stroke may occur as ischemic zones around an infarction eventually regain function. Regions remote from the infarction may also be synaptically depressed acutely after a stroke ("diaschisis") but eventually regain function. Finally, regions in the nondominant hemisphere may become more active over the course of recovery. Aphasia that has a gradual and slowly progressive onset occurs in the degenerative dementia syndromes of progressive aphasia and semantic dementia (Chapter 409).

TREATMENT Rx

Speech therapy may be helpful for patients in the first few months after a brain injury that causes aphasia.

TABLE 408-2 MAJOR APHASIC SYNDROMES

APHASIA SYNDROME	REGIONAL LOCALIZATION	SPONTANEOUS SPEECH ABNORMALITIES	AUDITORY COMPREHENSION	CONFRONTATION NAMING	SENTENCE REPETITION
Broca's aphasia	Lateral inferior frontal lobe	Nonfluent, labored, agrammatic	Preserved	Poor	Poor
Wernicke's aphasia	Posterior superior temporal-parietal supramarginal gyrus	Fluent, many paraphasic errors, very little information content	Very impaired	Poor	Poor
Global aphasia	Major portions of the frontoparietal operculum and superior temporal lobe	Nonfluent or virtually absent	Very impaired	Poor	Poor
Anomic aphasia	Small lesion somewhere in the perisylvian region	Fluent, may contain some paraphasias	Normal or mildly impaired	Poor to moderately impaired	Preserved or impaired

CORTICAL DISORDERS OF VISUAL FUNCTION AND HEMISPATIAL NEGLECT

DEFINITIONS

Cortical disorders of vision and spatial cognition are caused by lesions in the occipitoinferotemporal or occipitoposteroparietal lobes. The principal disorders of cortical visual functioning are alexia (impaired reading), object agnosia (impaired recognition of visual forms), and prosopagnosia (impaired face recognition). The principal disorders of spatial cognition are simultanagnosia (impaired integration of complex visual scenes), dressing apraxia, and visual hemispatial neglect (lack of awareness of the personal or extrapersonal hemispace). Diagnosis of a cortical visual disorder requires integrity of primary visual function from the cornea to the lateral geniculate nuclei.

PATHOBIOLOGY

Higher visual function is localized to a network centered in the occipital lobe and includes the inferior temporal and posterior parietal lobes (see Fig. 408-1). From area 17, processing of visual information passes to visual association areas 18 and 19. From there it proceeds in several directions. Disorders of higher visual function can be related to a ventral or to a dorsal pathway. The ventral pathway from the visual centers to the medial temporal lobe links visual information to meaning ("What is the object?"). The dorsal visual processing pathway, which links the visual centers to the parietal lobes, is concerned with locating objects in space and determining spatial relationships among objects in order to grasp a complete visual scene ("Where is the object?"). Cortical control of the extraocular muscles in the parietal lobes is an integral part of the process whereby the eyes are directed to various elements of a visual scene so that the individual elements are synthesized into a coherent ensemble.

Alexia occurs as a result of lesions in the ventral pathway of the dominant hemisphere. Object agnosia may also occur with lesions, usually bilateral, in the ventral pathway. Simultanagnosia, dressing apraxia, and hemispatial neglect are syndromes caused by lesions in the dorsal pathway. Simultanagnosia usually requires bilateral posterior parietal lesions. Dressing apraxia and hemispatial neglect arise from unilateral lesions, most often in the nondominant hemisphere. Cortical blindness is a consequence of bilateral occipitoparietal pathology.

CLINICAL MANIFESTATIONS

Alexia may occur as an isolated deficit, or it may occur in the context of other evidence of aphasia. Patients may be able to recognize individual letters but are unable to recognize a string of letters as a word. In pure alexia, auditory comprehension of words and sentences is preserved. Patients with object agnosia may be unable to identify objects visually, but they will be able to recognize the object based on its characteristic sound or how it feels to touch. In simultanagnosia, patients may be able to identify small objects easily if they happen to appear within the narrow viewing area at the center of their visual field. At the same time, such patients will fail to grasp the bigger visual picture. They may appear to be functionally blind. This clinical picture is referred to as Balint's syndrome.

Patients with cortical disorders usually have difficulty with visuoconstructional tasks such as copying figures or drawing simple objects such as a flower, a house, or a clock. Dressing apraxia represents a deficit of practical significance in which patients are unable to comprehend the orientation of articles such as a shirt or a blouse and to manipulate them.

The most severe form of a cortical disorder of visuospatial processing is cortical blindness. In this condition, in which the anterior visual pathways can be reasonably believed to be intact, patients appear functionally blind. On occasion, they also exhibit anosognosia for the blindness and claim that they can see. This latter condition is referred to as Anton's syndrome.

Hemispatial neglect occurs in the setting of acute strokes involving the nondominant perisylvian region. Even when there is no hemianopia as measured by single visual stimuli, presentation of double simultaneous stimuli to the patient reveals unawareness in the nondominant field. Hemispatial neglect can be demonstrated at the bedside with a task such as drawing a clock. A patient with hemispatial neglect will fail to place the numbers on the nondominant side (i.e., the left side in a right-handed person). Patients with hemispatial neglect may sometimes deny that their paretic limb belongs to them.

DIAGNOSIS

Information about visual functioning can be obtained from the history. The patient or the patient's informant may report that the patient cannot read, cannot read a clock, or cannot find objects when asked to get something off a table or out of a cupboard. There is often a history of motor vehicle accidents in which the patient failed to see another vehicle, the curb, or the side of a garage. Patients may report difficulty recognizing people's faces, even though they are able to recognize them by their voices or by other cues.

Bedside tests that screen for visuospatial deficits include either copying a simple geometric design or drawing an object. Intersecting pentagons and a cube are objects used clinically. Clock drawing is a brief, but informative exercise. Reading of words or commands and naming of objects can be done at the bedside as well. Face recognition is more difficult to assess at the bedside. Formal testing of visuospatial function in the neuropsychology laboratory involves the use of specially designed instruments to characterize visual processing.

The etiology of lesions that cause deficits in cortical vision and spatial cognition ranges from focal cerebrovascular disease, neoplasms, infectious processes, and brain trauma to neurodegenerative disorders. When a stroke causes a disorder of cortical visuospatial processing or hemispatial neglect, it is usually abrupt in onset. Space-occupying brain lesions such as neoplasms or brain abscesses that cause cortical visual disorders do so on a subacute basis. Disordered visuospatial function may also appear insidiously when caused by the degenerative disorder posterior cortical atrophy.

EXECUTIVE COGNITIVE DYSFUNCTION AND CONTROL OF PERSONAL BEHAVIOR

DEFINITIONS

Integrative abilities that are broadly referred to as executive cognitive function include mental agility, abstract reasoning, and problem solving. Executive cognitive function represents processes that support mental flexibility, adaptability, focus, and tenacity. Control of personal actions and regulation of interpersonal relationships are also closely related to executive cognitive dysfunction. The term "comportment" denotes how a person behaves, particularly toward other people.

PATHOBIOLOGY

The anatomic basis of executive cognitive function and comportment is a network of brain regions anchored by the prefrontal and anterior temporal lobe neocortex (see Fig. 408-1). These regions receive input from multiple cortical and subcortical regions. The caudate nucleus is the site of a major frontal lobe efferent pathway. The medial thalamus is a major afferent source to the frontal lobes. The anterior temporal lobes are also part of the same integrative circuitry as the prefrontal regions. Lesions in the lateral prefrontal regions are associated with slowing of cognitive processing, difficulty with set shifting (switching from one idea or task to another), difficulty initiating tasks, and loss of mental flexibility. The frontal and anterior temporal lobes are involved in the modulation of personal behavior and interpersonal relationships. Patients with lesions in the medial prefrontal lobes are often apathetic and lack initiative. Patients with lesions in the orbital frontal or right anterior temporal lobe may exhibit disinhibition, impulsivity, and a striking loss of ability to interpret or predict the feelings of others.

Traumatic brain injury (Chapter 406) is a common cause of frontal lobe and anterior temporal damage. The orbital frontal, frontal polar, and anterior temporal regions are particularly vulnerable to contusions because of their proximity to the skull. Patients with traumatic brain injuries may also suffer diffuse white matter damage as a result of shear injuries. Disconnection of the frontal and anterior temporal lobes from other parts of the brain can produce executive cognitive dysfunction and altered control of personal behavior.

CLINICAL MANIFESTATIONS

Executive cognitive functioning and control and regulation of behavior are usually affected concurrently. Patients with executive dysfunction are deficient in goal-oriented behavior; they lose the ability to predict the consequences of their actions or words. Patients with executive dysfunction also exhibit poor mental agility and inflexibility in their thinking and control of their actions. They are easily distracted and exhibit a tendency to perseverate, in which the answer to a prior question is repeated in response to subsequent questions. They are disinhibited; as a consequence, when asked to recall a

specific event, they may glibly answer with a fabrication, a phenomenon referred to as confabulation.

Patients with lateral prefrontal pathology exhibit poor performance on tests of abstract reasoning and mental agility. In a test such as verbal similarities, they tend to be very concrete and narrowly focused. They become easily distracted and are slow in performing tasks that require sustained attention. Because of their mental rigidity and difficulty in set shifting, they do poorly on tests that require the ability to vary their response strategies, such as verbal fluency tests.

Patients with medial frontal lesions are often profoundly apathetic and lack initiative and motivation. They may be laconic and completely unable to express emotion, whether it be anger, sadness, or elation. They tend to be indifferent to their surroundings, a state referred to as "abulia." The majority of patients with substantial prefrontal or anterior temporal lobe pathology lack insight into the extent of their inappropriate behavior.

In contrast, other patients with altered comportment exhibit different manifestations of dysregulation of personal actions and interpersonal behavior. These alterations may include difficulty controlling impulsivity, poor social graces manifested as rude behavior or caustic comments, a disregard for the feelings of others (loss of empathy), and a general failure to understand what constitutes acceptable behavior in a particular social context. If the underlying disease is progressive, gross alterations in table manners and loss of interest in maintaining personal hygiene may appear. Inappropriate sexual behavior may occur. Patients with prominent disease of the frontal lobes may also exhibit hyperorality, which is a compulsion to put nonfood objects into their mouths. Hyperorality can be life-threatening, depending on the substance ingested.

DIAGNOSIS

The clinical history is essential for documenting the characteristic changes in personality, behavior, and interpersonal relationships. The history must almost always be obtained from an informant who knows the patient well because the patient may assert that there are no problems.

Mental status examination is an integral part of the diagnosis of an executive cognitive disorder. Simply interacting with the patient may be quite revealing. The patient may exhibit abulia, disinhibition, socially inappropriate behavior, or easy distractibility. Tests of executive cognitive function that are suitable for bedside use include verbal similarities and differences, the digits backward test, reciting the months of the year backward, or spelling a word backward. Verbal fluency, which is a very useful test of mental flexibility and set shifting, is tested by asking patients to produce as many words as they can that begin with a particular letter of the alphabet in 60 seconds. Frequently, a patient with a frontal lesion will quickly produce two or three words and then stop.

Bedside testing of executive cognitive dysfunction provides only a superficial view of the cognitive domain. Assessment in the neuropsychology laboratory gives a more refined estimate of the degree of executive dysfunction.

Space-occupying lesions of the frontal lobes such as neoplasms or brain abscesses can lead to the cognitive and behavioral syndromes of frontal lobe dysfunction. With these diseases, executive cognitive dysfunction and alteration of control of personal behavior develop over a period of weeks.

Neurodegenerative diseases such as frontotemporal lobar degeneration (Chapter 409) are associated with dysfunction and brain loss in the prefrontal (see Fig. 409-4) and anterior temporal lobes. These disorders may produce the entire spectrum of executive cognitive dysfunction and altered control of personal behavior over a period of a year or longer.

Some diseases that do not directly damage the frontal or anterior temporal neocortex may cause executive cognitive dysfunction and alteration of control of personal behavior because of the interconnectedness of the frontal and anterior temporal lobes with other cortical and subcortical regions. Multiple sclerosis (Chapter 419), a disorder of white matter pathways, may cause abnormalities in cognition and behavior of the frontal type. Similarly, Huntington's disease (Chapter 417) and progressive supranuclear palsy, which affect the caudate nuclei, may also resemble a frontal cognitive and behavioral syndrome and result in executive cognitive dysfunction and alterations in comportment.

TREATMENT

Rx

Cognitive-behavioral therapies offer modest, but definite benefit for patients with aphasia and for those with mild attention deficits and mild memory deficits caused by brain injury.

ALZHEIMER'S DISEASE AND OTHER DEMENTIAS

DAVID S. KNOPMAN

DEMENTIA

DEFINITION

Dementia, which is a disorder of cognition, interferes with daily functioning and results in loss of independence (Table 409-1). The majority of dementias are of gradual onset, are progressive in course, and occur in persons with previously normal cognition. However, none of these features are necessary aspects of the definition of dementia. Some dementias, such as those caused by an acute neurologic illness secondary to stroke, encephalitis, or head trauma, may begin abruptly and then remain static for long periods. Conversely, a small subset of dementias, such as Creutzfeldt-Jakob disease (Chapter 424), have a rapid onset and a course that can run for less than a year. Dementia may also occur in persons with developmental disabilities and long-standing cognitive deficits.

EPIDEMIOLOGY

The prevalence and incidence of dementia increase with advancing age. Dementia is uncommon before 50 years of age. In individuals older than 65 years, the prevalence of dementia of all types is about 7%. In the age range of 65 to 69 years, the prevalence of dementia is only 1 to 2%, but it increases to 20 to 25% in the 85- to 89-year age range and continues to rise steadily thereafter. The incidence of new cases of dementia is about 1 per 100 per year at the age of 70 years and rises to about 2 to 3 new cases per 100 per year by about the age of 80 years. Incidence rates continue to rise into the ninth and tenth decades of life. With the dramatic increase in longevity in North America, the societal burden of dementia has risen substantially.

In absolute numbers, far more women than men have dementia because women live longer. However, men and women have an equal age-adjusted risk for the development of dementia. There are no racial or ethnic differences in the risk for dementia.

TABLE 409-1 DEFINITION OF DEMENTIA

Based on evidence from the history and mental status examination, a disorder characterized by the presence of at least two of the following: Impairment in learning and retaining new or recently acquired information (impairment in episodic declarative memory) Impairment in handling complex tasks and reasoning abilities (impairment in executive cognitive functions) Impaired visuospatial ability and geographic orientation Impaired language functions
The cognitive disturbance significantly interferes with work, usual social activities, or relationships with others
The cognitive disturbance and the consequences for daily functioning represent a significant decline from a previous level of functioning
The cognitive disturbance does not occur exclusively during the course of delirium (which includes reversibility as a criterion)
The disturbance is not better accounted for by a major psychiatric diagnosis

PATHOBIOLOGY

Dementia is the culmination of dysfunction in the cerebral hemispheres, especially the association cortices, hippocampal formations, their supporting subcortical nuclear structures such as the caudate nuclei and thalamus, and their white matter interconnections (see Fig. 408-1). Specific diseases that cause dementia do so by affecting particular parts of the cerebral cortex, subcortical nuclei, or the underlying white matter pathways linking different cortical regions.

CLINICAL MANIFESTATIONS

Any of the major domains of cognition—declarative episodic memory, executive cognitive functioning, visuospatial function, or language—may be affected in dementia (Chapter 408). Because Alzheimer's disease is the most common dementia, anterograde amnesia is typically present first and most intensely in the majority of dementia patients. In other dementing illnesses, deficits in the other cognitive domains may be dominant. A pervasive and nearly invariant aspect of dementia is a loss of insight (anosognosia) into the extent of one's cognitive and functional losses.

Neuropsychiatric symptoms are also common in dementia. Apathy and loss of initiative are almost always present. Depression and anxiety are frequent, as are irritability, paranoia, delusional thinking, and hallucinations. Daily functioning of patients with dementia is compromised. In early dementia, difficulty is likely to be present in management of finances and medications, independent travel, preparation of meals, and keeping of appointments. In more advanced disease, difficulty becomes evident in basic activities of daily living, such as bathing, dressing, toileting, and feeding oneself. Dementias secondary to cerebrovascular or Lewy body disease are often associated with specific abnormalities in strength, coordination, gait, or balance. Alzheimer's disease, the most common dementia, typically has no associated motor abnormalities.

DIAGNOSIS

Clinical Examination

Dementia is strictly a clinical diagnosis based on evidence of cognitive dysfunction in both the history and the mental status examination. The key elements of the history flow from the definition of dementia: What is the evidence for impairment in one or more domains of cognition? What is the evidence that daily functioning is affected? The mental status examination is necessary to establish that alertness is preserved (i.e., the patient does not have delirium; Chapter 27) and to determine what specific areas of cognition exhibit directly observable impairment. For diagnosis of the syndrome of dementia, no laboratory test supersedes the clinical history and the mental status examination. Laboratory testing is critical, however, to determine the cause of the dementia.

Bedside testing of mental status is based on the principles of cognitive neurology (Chapters 27 and 408). For moderate or severe dementia to be distinguished from normal cognitive states, a bedside mental status examination such as the Mini-Cog test (Table 26-4) is accurate. However, for mild dementia, bedside mental status examinations lack sensitivity (i.e., they fail to diagnose some cases of mild dementia). For patients with suspected mild dementia, neuropsychometric testing is a useful adjunct to the bedside examination. The neurologic examination is also important for evaluation of signs of specific causes of dementia, including signs of cerebrovascular disease (e.g., hemiparesis; Chapter 413) and signs of extrapyramidal disease (e.g., rigidity, bradykinesia, resting tremor; Chapter 416).

Differential Diagnosis

Dementia must be distinguished from other disorders of cognition (Fig. 409-1). Delirium (Chapter 27) also affects cognition directly; key features distinguishing it from dementia include impaired arousal and attention. Delirium is almost always of sudden onset, whereas the majority of cases of dementia are of gradual onset.

Primary psychiatric diseases (Chapter 404) such as major depression, bipolar disorder, and schizophrenia may also impair cognition. In dementia, however, the impairment in cognition is typically equivalent to or more pervasive than the changes in mood and behavior.

The principal diseases that cause dementia are three neurodegenerative diseases—Alzheimer's disease, Lewy body disease, and frontotemporal lobar degeneration—and cerebrovascular disease (Fig. 409-2). The neurodegenerative diseases that cause dementia are typically slow and insidious in onset and inexorably progressive. Dementia secondary to cerebrovascular disease may be of either sudden or gradual onset.

Many much less common secondary causes account for less than 2% of all dementias. Drug intoxication (Chapter 33), metabolic disorders (Chapter 425), central nervous system infections (Chapters 420 and 422), and brain structural lesions (Chapter 195) are typically subacute in onset; if they are diagnosed and treated early, the cognitive deficits improve or resolve completely. A number of medications such as sedatives, pain medications, corticosteroids, digoxin, and others cause mental confusion, particularly but not always at toxic levels (Chapter 110). Metabolic disorders that may also cause subacute confusion and produce a cognitive disorder include hypothyroidism or hyperthyroidism (Chapter 233), vitamin B_{12} deficiency

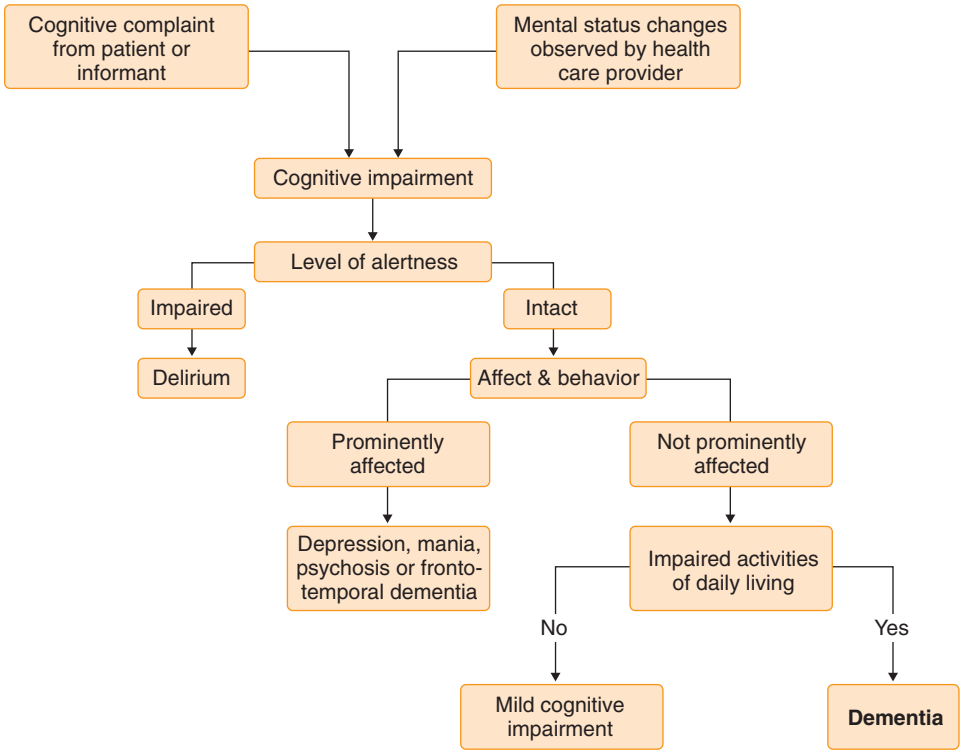

FIGURE 409-1. Flow diagram to establish the diagnosis of dementia.

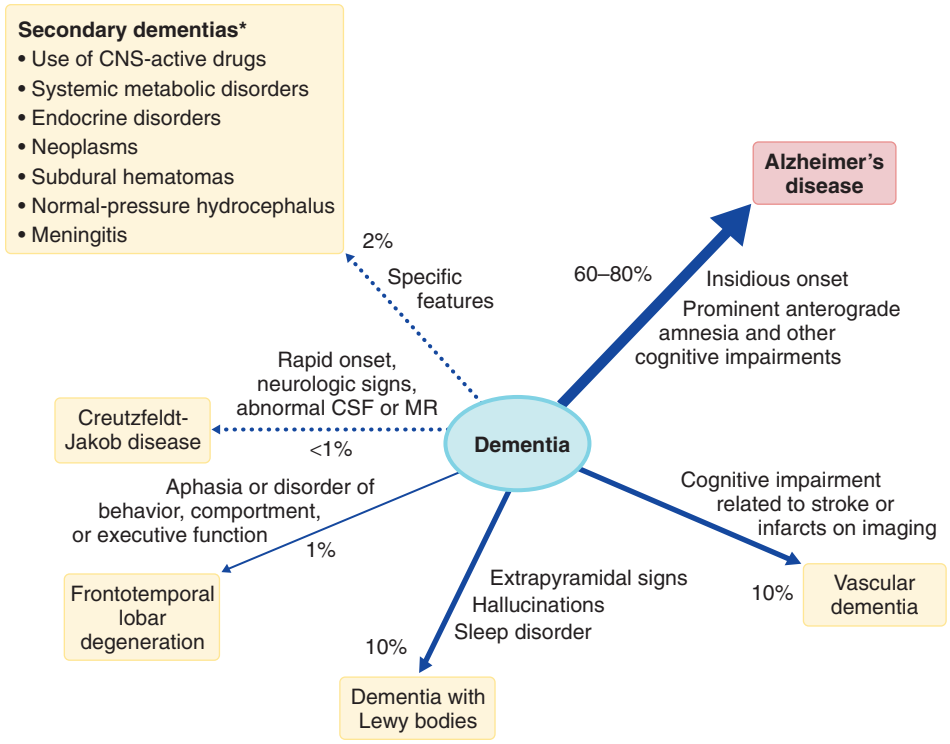

FIGURE 409-2. Flow diagram for the differential diagnosis of dementia. The percentage contributions of various diagnoses are approximate. *The list of secondary causes of dementia is not exhaustive. CNS = central nervous system; CSF = cerebrospinal fluid; MR = magnetic resonance imaging.

(Chapter 425), chronic liver disease (Chapter 156), chronic renal failure (Chapter 132), and hypocalcemia or hypercalcemia (Chapter 253). Chronic viral infections of the brain, especially human immunodeficiency virus infection, frequently cause dementia (Chapter 401). Chronic meningitides in the differential diagnosis of dementia include cryptococcal meningitis (Chapter 344), tuberculous meningitis (Chapter 332), and tertiary syphilis (Chapter 327). Finally, structural lesions of the brain, including primary and metastatic tumors (Chapter 195), chronic subdural hematomas (Chapter 406), and normal-pressure hydrocephalus (Chapter 195), can cause a syndrome resembling dementia that consists of a subacute or slowly progressive decline in cognition with few or no other neurologic symptoms or signs.

PROGNOSIS

Except for the secondary causes of dementia and the rare dementing illnesses caused by single episodes of brain injury, such as severe head trauma or anoxic encephalopathy, dementia is a condition that invariably leads to worsening of cognition and function. Almost all dementia patients progress from mild stages to severe dementia during the course of several years, if they do not die prematurely. The rate of cognitive decline is variable among individuals and, of course, also varies with the specific disease. In general, dementia can be said to decrease life expectancy by half compared with the life expectancy of nondemented individuals.

End-of-Life Care

The terminal stage and end-of-life care issues (Chapter 3) associated with the common dementias are usually similar. Dementia itself does not directly cause death, but it is strongly linked to reduced survival. Patients with dementia typically die of the same illnesses that affect debilitated individuals, such as sepsis, pneumonia, pulmonary embolism, or heart disease.

Most patients with dementia experience their terminal illnesses in hospitals or extended care facilities. Given the inexorably progressive nature of most dementing illnesses and their likelihood of producing severe and completely disabling cognitive and functional impairment, it is widely accepted that patients with end-stage dementia should receive conservative care. Feeding tubes and ventilatory support should not generally be considered.

MILD COGNITIVE IMPAIRMENT

DEFINITION

Mild cognitive impairment represents the transition between the state of normal cognition and dementia. Patients with mild cognitive impairment have abnormalities in a specific aspect of cognition to such an extent that it is clearly different from normal performance but does not interfere with daily functioning to any appreciable degree. More than one domain of cognition may be affected. The amnesic form of mild cognitive impairment, in which declarative episodic memory is impaired, is the most common. Alterations in attention, concentration, and mental agility may also be seen (Table 409-2). The term "cognitively impaired, not demented" includes patients whose mild cognitive impairment may progress to dementia but also encompasses anyone who is neither cognitively normal nor demented, such as individuals with stable, lifelong cognitive impairment.

TABLE 409-2 DIAGNOSTIC CRITERIA FOR AMNESIC MILD COGNITIVE IMPAIRMENT

The presence of a new memory complaint, preferably corroborated by an informant
Objective evidence of an impairment in episodic declarative memory (for age)
Normal general cognitive functions
No substantial interference with work, usual social activities, or other activities of daily living
No dementia

EPIDEMIOLOGY

The prevalence and incidence of mild cognitive impairment are about the same as those of dementia. Both increase with advancing age.

PATHOBIOLOGY

Mild cognitive impairment is a risk state for the subsequent development of dementia. Alzheimer's disease, followed by cerebrovascular disease and Lewy body disease, is the most common underlying cause.

CLINICAL MANIFESTATIONS

Patients with mild cognitive impairment may have more insight into their emerging cognitive difficulties than do patients with dementia. Hence, some patients with mild cognitive impairment may themselves seek medical consultation because of concern about their memory or their thinking. They or their family members may report a milder extent of many of the symptoms of dementia. Patients with mild cognitive impairment forget recent events and conversations or have trouble with mental flexibility, multitasking, problem solving, or completing mentally challenging activities at the speed that they once did. Mental status testing will sometimes corroborate the complaints, but neuropsychometric testing may be needed to document impairment. Other patients with mild cognitive impairment may have

virtually no insight into their memory loss, but the impairment is diagnosed after family members force the patient to undergo an evaluation.

DIAGNOSIS

When mild cognitive impairment is suspected, the principal alternative diagnosis is that the person is cognitively intact or that the person has dementia. The diagnosis of normal function should be straightforward when the patient and family have no complaints of cognitive impairment and the patient scores normally on bedside cognitive testing. However, a number of circumstances may cloud the issue, including very low or very high levels of prior educational and occupational achievement, instances in which English (or whatever the dominant language is) was a second language, severe hearing loss or blindness, and major alterations in mood or major motor disabilities that interfere with daily functioning. In such circumstances, the history of cognitive difficulty and the examination of cognitive status may be so confounded by these other phenomena that distinguishing between normal cognitive function and mild cognitive impairment is challenging. Conversely, distinguishing between mild cognitive impairment and dementia may be straightforward when daily functioning is obviously impaired. In other circumstances, it may be difficult to ascertain whether a person is functioning fully independently or not. For example, many older people reside in assisted living facilities that provide services such as cooking and housekeeping. In such individuals with few daily responsibilities, it is difficult to determine whether they are functionally impaired.

TREATMENT Rx

As of 2011, no treatments have been approved for mild cognitive impairment, although a randomized trial demonstrated that donepezil therapy, 10 mg/day, significantly reduced the rate of development of dementia secondary to Alzheimer's disease at 1 year but not at 3 years. Physical activity appears to provide a modest slowing of cognitive decline.

PROGNOSIS

Mild cognitive impairment should be viewed as a risk state for the subsequent development of dementia. With use of the definition of amnesic mild cognitive impairment in Table 409-2, the rate of evolution from mild cognitive impairment to dementia is 15% per year.

ALZHEIMER'S DISEASE

DEFINITION

Alzheimer's disease is defined as a dementing illness in which anterograde amnesia is a dominant symptom (Table 409-3). The clinical diagnosis implies that the causative pathologic process is of the Alzheimer type, whereas the pathologic diagnosis rests on the findings of characteristic histopathologic features.

EPIDEMIOLOGY

Between 60 and 80% of all dementing illness is due to Alzheimer's disease. Among all individuals older than 65 years, the prevalence of Alzheimer's disease is estimated to be about 5%. As with dementia in general, the prevalence doubles in every 5-year interval after 65 years of age, and the incidence continues to rise into the 10th and 11th decades of life. Men and women may be equally affected, although on an absolute basis, far more women have prevalent Alzheimer's disease because women live longer than men do. There are no ethnic or racial differences in the predilection for Alzheimer's disease.

TABLE 409-3 DIAGNOSTIC CRITERIA FOR THE ANTEROGRADE AMNESIC SYNDROME OF ALZHEIMER'S DISEASE

Dementia (as defined in Table 409-1) with:
Major impairment in learning and retaining new information and at least one other domain of cognitive impairment:
Impairment in handling complex tasks and reasoning abilities (impairment in executive cognitive functions)
Impaired visuospatial ability and geographic orientation
Impaired language functions
The cognitive disturbance is of insidious onset and is progressive, based on evidence from the history or serial cognitive examinations
The cognitive disturbance is not better accounted for by a systemic disease or another brain disease

Risk Factors

Established risk factors for Alzheimer's disease include advancing age and a family history. Putative risk factors include diabetes mellitus, hypertension, cardiovascular disease, and head trauma; evidence for and against each of these four conditions is inconclusive, but the consensus is that at least diabetes and hypertension may play a role in the pathogenesis of Alzheimer's disease. Low educational achievement is also a consistent risk factor, but most experts believe that educational level is a proxy for some other factor, such as socioeconomic status or the early childhood medical and psychosocial environment. Protective factors have also been proposed, but their status is much debated.

PATHOBIOLOGY

The histopathologic diagnosis of Alzheimer's disease is based on the joint presence of a substantial cerebral burden of neuritic plaques and neurofibrillary tangles. Neuritic plaques consist of a core of aggregated β-amyloid peptide surrounded by degenerating neurites, which are fragments of axons and dendrites. β-Amyloid contains 39 to 42 amino acids and is proteolytically derived from a larger protein, the amyloid precursor protein. Neurofibrillary tangles are intracellular aggregations of an excessively phosphorylated form of the microtubule-associated protein tau. Neurofibrillary tangles, which are self-aggregates of tau, are thought to represent a nonspecific response to a cellular injury, which in Alzheimer's disease is triggered by β-amyloid. The altered tau protein self-aggregates and forms neurofibrillary tangles. In a low-powered microscopic section of frontal, temporal, or parietal cortex, at least six neuritic plaques and neurofibrillary tangles should be visible for the diagnosis of Alzheimer's disease to be made.

Pathophysiology

The progression of changes of β-amyloidosis follows a roughly predictable pattern in Alzheimer's disease. Positron emission tomographic imaging with ligands that bind to β-amyloid shows that β-amyloid begins to accumulate in the neocortex as long as 20 years before dementia occurs. Soluble aggregates of β-amyloid in oligomeric (consisting of a small number of monomers) forms may be the key pathogenic molecules that eventually induce neuronal injury. By the time that clinical dementia due to Alzheimer's disease is present, large numbers of β-amyloid peptide–containing deposits invariably are found in neuritic plaques in the neocortex. Neuritic plaques represent the end-stage of the Alzheimer process. Because β-amyloidosis begins well before clinical symptoms appear and probably reaches a plateau in terms of abundance, the amount of β-amyloidosis does not closely mirror the severity of dementia in Alzheimer's disease.

The regional extent of neurofibrillary tangles in Alzheimer's disease also follows a remarkably predictable pattern. The location of the earliest accumulation of neurofibrillary tangles is in the entorhinal cortex and hippocampus. At the time that clinical symptoms develop, neurofibrillary tangles are found in association neocortices of the frontal, parietal, and temporal lobes. It is only in the most severe and final stages that neurofibrillary tangles are found in the occipital lobes and primary motor and sensory cortices. The location of neurofibrillary tangles corresponds faithfully to the clinical evolution of specific symptoms and severity of Alzheimer's disease. In mild cognitive impairment, the earliest clinical manifestation of Alzheimer's disease, the most intense burden of neurofibrillary tangles is in the entorhinal cortex and hippocampi, precisely the regions that are involved in declarative episodic memory. Hippocampal atrophy is characteristic, and reductions in hippocampal volumes may be observed on magnetic resonance imaging (MRI; Fig. 409-3). Involvement of the association neocortices with neurofibrillary tangles represents the histopathologic correlate of the progression to dementia. Quantitative MRI in patients with mild cognitive impairment who later progress to dementia shows increasing atrophy of key cortical association areas, such as the lateral temporal lobes, inferior parietal lobes, posterior cingulate cortex, and lateral frontal lobes. Reflecting the spread to association neocortex, language functions, visuospatial functions, and executive cognitive functions typically become impaired some time after declarative episodic memory dysfunction occurs.

The most consistent neurotransmitter deficit in Alzheimer's disease is in cholinergic neurotransmission. The cells of origin of hippocampal and neocortical cholinergic projections are located in the septum, diagonal band, and

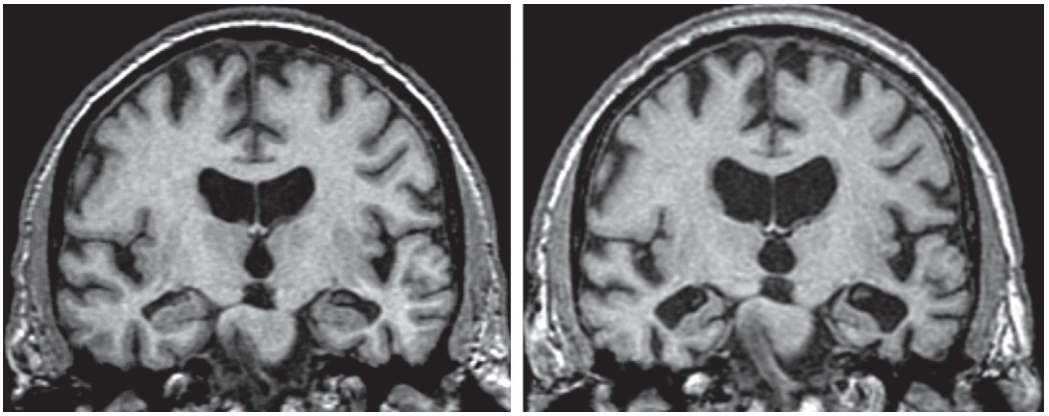

FIGURE 409-3. Serial coronal images from MRI of a patient with Alzheimer's disease. The scan on the *left* was performed when the patient was clinically normal. The scan on the *right* was performed 11 years later when the patient was demented. Hippocampal atrophy has increased dramatically from the first to the subsequent scan. (Courtesy of Maria Shiung and Clifford Jack.)

nucleus basalis. Neurofibrillary tangles accumulate in the neurons in these regions as Alzheimer's disease develops, but there is also neurochemical evidence that these neurons are stressed much earlier in the disease.

Genetics

The overwhelming majority of Alzheimer's disease is due to sporadic (not genetic) disease. However, in a very small number of instances, Alzheimer's disease occurs as an autosomal dominant disease. The three known genes involved in autosomal dominant Alzheimer's disease all are directly involved in the production of β-amyloid peptide. The first is the amyloid precursor protein (*APP*) gene, located on chromosome 21q21.3. Eighteen known mutations in this gene lead to excess production of β-amyloid and are reliably associated with a very early onset (20 to 50 years of age) of Alzheimer's disease. Another line of evidence implicating the *APP* gene in Alzheimer's disease is the invariable appearance of the pathologic process of Alzheimer's disease in individuals with Down syndrome (trisomy 21; Chapter 40), who have an extra copy of the *APP* gene as a result of the trisomy.

The other two genes associated with autosomal dominant Alzheimer's disease are the presenilin 1 and 2 genes, located on chromosomes 14q24.3 and 1q31.42. A large number of presenilin 1 mutations account for the majority of autosomal dominant Alzheimer's disease. Both genes code for a similar protein known as presenilin. Presenilin is involved in degradation of the APP molecule at the gamma cleavage site. It is believed that the Alzheimer's disease–causing mutations in presenilin 1 and 2 lead to a "toxic gain of function" that produces excess β-amyloid peptide. The presenilin mutations are also associated with early-onset (40 to 60 years of age) Alzheimer's disease.

Studies of the familial aggregation of Alzheimer's disease have shown that later-onset disease also displays genetic risks, but only one gene has been definitively linked to later-onset Alzheimer's disease. That gene, located on chromosome 19q13.2, encodes apolipoprotein E (apo E), a protein involved in lipid transport. In humans, three allelic variants of apolipoprotein gene (*APOE*) are determined by differences in the amino acids cysteine and arginine at positions 112 and 158 of the 299–amino acid protein. One of the allelic variants, with arginine at both positions, designated the ε4 variant, is strongly associated with a 14-fold increased risk for Alzheimer's disease in homozygotes and a 3-fold increase in heterozygotes. In many series, almost 50% of Alzheimer's disease patients but only about 25% of nondemented controls have at least one copy of the *APOE* ε4 allele. The presence of an *APOE* ε4 allele does not always cause Alzheimer's disease in that the disease never develops in some carriers of the genotype. The mechanism by which the *APOE* ε4 allele predisposes to Alzheimer's disease is not established, but the tertiary structure of the APOE protein with arginine at positions 112 and 158 may lead to impaired binding to β-amyloid, which in turn reduces the clearance of β-amyloid from cells.

CLINICAL MANIFESTATIONS

The early course of Alzheimer's disease is dominated by difficulties with anterograde amnesia. Some of the usual complaints include forgetting recent events and conversations, misplacing items, problems with keeping track of the date, getting lost in familiar surroundings, and problems with remembering to complete tasks. The frequency and severity of the memory lapses progress from occasional difficulty to more pervasive and consistent failure.

In mild Alzheimer's disease, declarative episodic memory function may be lost. Familiarity and access to previous knowledge may allow patients to function in their usual daily routines as long as nothing out of the ordinary is required of them. They may still retain the ability to prepare simple meals and to take walks in their neighborhood without getting lost. However, even in mild Alzheimer's disease, medication-taking errors and difficulty managing money or balancing a checkbook are likely to occur. Traveling to unfamiliar places often accentuates confusion. Changes in personality commonly accompany the cognitive losses. Apathy, loss of initiative, and loss of interest in previous hobbies and pastimes are ubiquitous in early Alzheimer's disease.

As the disease progresses, the ability to perform necessary daily tasks becomes more and more difficult to the point that the patient will need assistance preparing meals, paying bills, taking transportation, and keeping house. As the disease moves into the severe stages, assistance and supervision in basic activities such as bathing, dressing, toileting, and eating become necessary.

In the terminal stages of the disease, all communicative abilities may be lost. Mobility may still be preserved until late in the disease. Alzheimer's disease patients commonly die of illnesses that strike other debilitated elderly individuals, such as sepsis, pneumonia, and congestive heart failure.

The duration of the course of clinical Alzheimer's disease is long but variable. The time from mild dementia to death may be as short as 2 to 3 years or may be well over a decade. For patients in whom mild dementia is diagnosed, about 10% per year reach the stage of severe dementia.

Rarely, Alzheimer's disease is associated with prominent symptoms in cognitive domains other than memory. The most common of the atypical syndromes is one in which profound visuospatial deficits occur without the typical severe anterograde amnesia. This syndrome is referred to as posterior cortical atrophy.

DIAGNOSIS

The diagnosis of Alzheimer's disease, like that of dementia itself, is largely a clinical one based on the history and examination. The key elements in the history are a gradual onset and insidious progression of cognitive impairment, especially anterograde amnesia. The mental status examination should demonstrate impairment in short-term memory and other cognitive deficits. Alzheimer's disease should be thought of as a diagnosis of inclusion: if the history and examination are compatible with Alzheimer's disease and if certain exclusions can be verified, the diagnosis can be made with confidence.

No laboratory tests can confirm the diagnosis of Alzheimer's disease with sufficient sensitivity and specificity. For example, the presence of the *APOE* ε4 allele increases diagnostic accuracy only marginally after consideration of the history and physical examination. Findings on MRI, such as a decreased hippocampal volume, are useful when atrophy is present, but hippocampal atrophy is neither sensitive nor specific enough to be useful in diagnosis. Positron emission tomography with fluorodeoxyglucose or with newer amyloid-binding agents has yet to deliver the necessary precision or predictive abilities to warrant use in routine practice.

Differential Diagnosis

A number of other conditions that bear similarity to Alzheimer's disease must be excluded on clinical or laboratory grounds (see Fig. 409-2). One is dementia with Lewy bodies, which is suggested by the presence of parkinsonism, prominent visual hallucinations, and a specific sleep disorder. At autopsy, the pathologic processes of Lewy body disease and Alzheimer's disease often coexist, thus suggesting that the diagnoses overlap. Frontotemporal lobar degeneration is suggested by prominent behavioral and personality changes

or by prominent language difficulties early in the course. Hippocampal sclerosis has unique neuropathologic findings but is virtually impossible to distinguish from Alzheimer's disease by clinical features. Other neurodegenerative conditions in the differential diagnosis of Alzheimer's disease include Huntington's disease (Chapter 417), progressive supranuclear palsy, corticobasal degeneration, amyotrophic lateral sclerosis (Chapter 418), and Wilson's disease (Chapter 218); however, these diseases invariably have prominent motor manifestations early in their course.

It is particularly challenging to distinguish dementia caused by cerebrovascular disease from Alzheimer's disease (see later). The fact that Alzheimer's disease and cerebrovascular disease often coexist requires clinicians to consider both simultaneously.

PREVENTION AND TREATMENT

Rx

There are no established preventive therapies. Although a healthy diet, physical exercise, and stimulating cognitive leisure activities are sensible, they have not been shown to protect against Alzheimer's disease. Except in patients who have folate or vitamin B_{12} deficiency, vitamin B supplementation is not effective in slowing cognitive decline.[1] Treatment of diabetes (Chapters 236 and 237) and hypertension (Chapter 67) is beneficial for other reasons, but it is not clear that such treatment alters the course of Alzheimer's disease.

Once Alzheimer's disease becomes symptomatic, support for family caregivers is a critical intervention that cannot be overemphasized. Support groups through the Alzheimer's Association (available at *www.alz.org*) can benefit families coping with the disease.

Important safety issues include supervision of medications, supervision of finances, and close scrutiny of motor vehicle operation. Operation of other potentially dangerous tools, firearms, appliances, and equipment should also be carefully monitored or avoided. Patients with Alzheimer's disease often wander and can become lost long distances from home. Identification of patients can prevent tragic occurrences *(www.alz.org/Media/newsreleases/2003/033003wandering.asp)*.

Evidence-Based Treatments

Two classes of drugs are approved for the treatment of Alzheimer's disease: cholinesterase inhibitors and memantine, a glutamate receptor antagonist. The rationale for the use of cholinomimetic drugs (donepezil, 5 or 10 mg/day; galantamine, 16 or 24 mg/day; or rivastigmine, 6 to 12 mg/day) is the reduced levels of cholinergic markers in the neocortex of patients dying of Alzheimer's disease. All three agents delay the progression of symptoms to a statistically significant but clinically marginal extent at 6 to 12 months in patients with mild to moderate Alzheimer's disease, but not at 3 years.[1,4,5] Furthermore, there is no compelling evidence that they alter its biologic progression. Individual patients often do not show any clear benefits of treatment.

Memantine, which is a low- to moderate-affinity, uncompetitive *N*-methyl-D-aspartate receptor antagonist that acts on glutamate neurotransmission, also delays the progression of functional decline at a dose of 10 mg twice per day.[6] It is not clear why modulation of glutamate neurotransmission is beneficial in Alzheimer's disease, and studies of memantine in patients with mild to moderate Alzheimer's disease have not yet been published.

One study of patients with moderately severe Alzheimer's disease showed that vitamin E was effective in delaying progression, but recent studies showed no benefit in subjects with mild cognitive impairment.[1] By comparison, donepezil appears to be beneficial for severe as well as for mild disease,[7] although it has not been proven useful for the agitation that may accompany Alzheimer's disease.[8]

PROGNOSIS

Alzheimer's disease is inevitably progressive, and severe cognitive impairment and complete dependence on others develop in virtually all patients, unless they die prematurely. Alzheimer's disease also contributes to premature death; the mortality rate in patients with Alzheimer's disease is about 10% per year. In patients with advanced dementia, the 6-month mortality is about 55%; pneumonia, fever, and eating problems are associated with poor prognosis.

FUTURE DIRECTIONS

Intensive research on the pathogenesis of Alzheimer's disease is elucidating information on production and degradation of the β-amyloid molecule and mechanisms of induction of tau aggregation. Research is also focusing on the development of biomarkers, cerebrospinal fluid (CSF) markers, and imaging techniques for the early diagnosis of Alzheimer's disease. A number of therapeutic agents are also being studied.

TABLE 409-4 DIAGNOSTIC CRITERIA FOR THE SYNDROME OF DEMENTIA CAUSED BY CEREBROVASCULAR DISEASE (VASCULAR DEMENTIA)

Dementia as defined in Table 409-1
Clinically important cerebrovascular disease is demonstrable by *either* of the following:
Onset of the cognitive disturbance *or* dramatic worsening of an existing disturbance that occurred within 3 months of a stroke, where stroke is defined as a focal neurologic deficit of acute onset in which the symptoms and signs persist for more than 24 hours
Neuroimaging evidence of bilateral brain infarctions rostral to but including the thalamus

VASCULAR DEMENTIA

DEFINITION

Vascular dementia is a dementing illness in which the underlying cause is cerebral infarction. For a cognitive disorder to be attributed to cerebrovascular disease from a neuropathologic perspective, there must be sufficient cerebral infarction in locations known to be responsible for the cognitive deficits in the absence of other neurodegenerative neuropathologic changes (Table 409-4). When cerebrovascular disease produces cognitive impairment that is not severe enough to meet the criteria for dementia, it is referred to as vascular cognitive impairment.

EPIDEMIOLOGY

In clinical studies, as many as 20% of dementia patients have cerebrovascular disease. Like Alzheimer's disease, it is less common in patients younger than 65 years and increases steadily thereafter. In neuropathologic studies, about 25% of all cases of dementia have some vascular component. Roughly half that number are relatively pure vascular dementia; the remainder consists of vascular disease mixed with Alzheimer's disease. Men and women are equally affected.

Risk Factors

Risk factors for vascular dementia include cardiovascular disease, diabetes, and hypertension. There are no known protective factors other than treatment of these risk factors. Populations with high rates of generalized vascular disease should have higher rates of vascular dementia, but competing mortality from cardiovascular disease may obscure part of the relationship. In the first year after a stroke, the risk for development of dementia is about 9-fold higher than the rate in persons without a stroke; the risk remains about 2-fold higher in subsequent years.

PATHOBIOLOGY

The majority of vascular disease causing cognitive impairment is due to atherosclerosis. One mechanism is through large infarctions, such as those secondary to occlusive disease in major cerebral vessels, including the carotid arteries and the anterior, middle, and posterior cerebral arteries (Chapter 413). A second mechanism of infarction is at the arteriolar level, with lacunar infarctions in the thalamus, basal ganglia, and subcortical white matter. Both these processes can be detected by brain MRI. Infarcts in the hippocampal formations, medial thalamus, caudate nuclei, and parietal association areas are highly likely to produce cognitive impairment but not necessarily dementia. Microinfarcts, which are small zones of infarction that are not visible to the naked eye but can be observed with light microscopy, may also contribute to the dementia. The simultaneous presence of Alzheimer's disease is common in vascular dementia.

There are other uncommon causes of vascular dementia. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a very rare inherited disease that usually becomes clinically evident between the ages of 30 and 50 years and causes severe white matter disease, headaches, and dementia. The cause of CADASIL is mutations in the *notch3* gene on chromosome 19q12. Cerebral amyloid angiopathy, a β-amyloidosis in which the β-amyloid peptide accumulates in the media of small to medium-sized arteries in the leptomeninges and superficial cortex, causes cerebral hemorrhages that may lead to dementia if it occurs in sufficient number and in critical locations. Cerebral amyloid angiopathy is also seen in Alzheimer's disease, but its hemorrhagic manifestations may occur in

individuals with little evidence of Alzheimer's disease clinically and modest evidence pathologically. Cerebral vasculitis (Chapter 278) is a very rare cause of dementia.

CLINICAL MANIFESTATIONS

The spectrum of cognitive changes in patients with cerebrovascular disease is broad. The more common cognitive syndromes in cerebrovascular disease include mild cognitive impairment, a dementia with prominent anterograde amnesia, and a dementia with prominent changes in personality and executive function. Some patients with vascular cognitive impairment without dementia may have deficits in only one domain (Chapter 408). A number of aphasia syndromes are a result of cerebral infarction or hemorrhage in the perisylvian regions of the dominant hemisphere. Infarction or hemorrhage in the occipitotemporal or occipitoparietal regions may produce one of the disorders of visual cognition, such as alexia or visual agnosia. Infarcts in the caudate nuclei, particularly if they are bilateral, may produce a cognitive syndrome that includes both amnesia and disordered executive function, thus mimicking dementia. Large infarcts in the right parietal lobe can also produce dementia. Infarcts in the medial thalami or in the hippocampal formations can produce isolated amnesia.

The evolution of symptoms in vascular dementia does not follow a stereotypical pattern. In some, the dementia syndrome may remain static. In others, new strokes may lead to substantial declines in cognition and function. Some patients with vascular dementia may experience a gradually declining illness. Patients with vascular cognitive impairment without dementia or vascular dementia may also have other neurologic signs typical of patients with cerebrovascular disease, such as hemiparesis, hemianopia, hemisensory changes, or cranial nerve abnormalities.

DIAGNOSIS

The diagnosis of vascular dementia is based on the neurologic history and examination. Brain imaging, preferably with MRI, is essential to establish the presence of infarcts. The cardinal diagnostic features of vascular dementia are that (1) the cognitive disorder should have begun within 3 months of a clinical stroke event and (2) there should be multiple, bilateral infarcts in the cerebral hemispheres visible on brain imaging studies. A temporal link between the onset or worsening of cognitive impairment and a stroke is important in demonstrating that cerebrovascular disease is etiologically relevant to the cognitive impairment. Brain imaging of infarcts in the cerebral cortex, basal ganglia, thalamus, and cerebral white matter has obvious value for establishment of cerebrovascular disease. In contrast to actual infarcts on imaging, the presence of white matter hyperintensities without infarcts on brain MRI is much less specific.

The accuracy of the clinical diagnosis of vascular dementia is generally lower than that of Alzheimer's disease. The combination of (1) a temporal relationship between dementia and a stroke and (2) imaging evidence of bilateral infarcts is diagnostically specific for vascular dementia but is insensitive. Broader diagnostic criteria (see Table 409-4) are more sensitive but less specific. The usual alternative diagnosis is Alzheimer's disease, and there is typically no way to be certain whether and how much Alzheimer's disease is simultaneously present.

PREVENTION AND TREATMENT

Rx

Some cases of vascular dementia should be preventable. With early, lifelong aggressive treatment of diabetes (Chapters 236 and 237), hypertension (Chapter 67), and hyperlipidemia (Chapter 213), the number of cerebral infarcts should be reduced, with a corresponding reduction in the number of cases of vascular dementia. Evidence for this link comes from large-scale studies in which the treatment of hypertension reduced the frequency of strokes and incident dementia. Once vascular dementia develops, cholinesterase inhibitors have shown some benefit,■ but the major goal is to prevent future strokes.

PROGNOSIS

Patients with vascular dementia can often be expected to have severe cardiovascular disease and a greater likelihood of future strokes and cardiac ischemic events. Survival of patients with vascular dementia is poorer than that of patients with Alzheimer's disease.

TABLE 409-5 DIAGNOSTIC CRITERIA FOR THE DEMENTIA SYNDROME ASSOCIATED WITH LEWY BODY PATHOLOGY

Dementia as defined in Table 409-1
The cognitive disturbance is of insidious onset and is progressive, based on evidence from the history or serial cognitive examination
The presence of at least two of the following: Parkinsonism (rigidity, resting tremor, bradykinesia, postural instability, parkinsonian gait disorder) Prominent, fully formed visual hallucinations Substantial fluctuations in alertness or cognition Rapid eye movement sleep behavior disorder (see Chapter 412) Severe worsening of parkinsonism by antipsychotic drugs
The disturbance is not better accounted for by a systemic disease or another brain disease

DEMENTIA WITH LEWY BODIES

DEFINITION

Dementia with Lewy bodies is a multifaceted dementing disorder in which the underlying pathologic process includes Lewy bodies in limbic and cortical structures (Table 409-5). Some clinicians make a distinction between patients in whom parkinsonism preceded the cognitive disorder and those in whom the cognitive disorder occurred either simultaneously with or before the movement disorder. This distinction may be somewhat useful in clinical practice, but there are few clinical or neuropathologic differences based on different sequences of signs and symptoms. The diagnosis of dementia with Lewy bodies is similar in principle to diagnosis of both dementia and Parkinson's disease (Chapter 416) in the same individual, but dementia with Lewy bodies is a term with broader connotations because of other features (hallucinations, fluctuations, and sleep disorder) that may be more apparent than the movement disorder.

EPIDEMIOLOGY

Dementia with Lewy bodies is about a quarter as common as Alzheimer's disease. Lewy body disease becomes more common with advancing age, and the prevalence of dementia with Lewy bodies increases with advancing age as well. As with the other dementias, there are no known ethnic or racial differences, but dementia with Lewy bodies may be more common in men. There are no known risk factors for dementia with Lewy bodies. Dementia develops in up to 30% of patients with Parkinson's disease, and advancing age is the major risk factor.

PATHOBIOLOGY

The pathology of dementia with Lewy bodies is a mixture of Lewy body disease and Alzheimer's disease. In general, the more intense the Lewy body disease, the less abundant the Alzheimer disease. Lewy bodies, which are intraneuronal inclusions that contain α-synuclein, are found in the nucleus basalis, pars compacta of the substantia nigra, locus caeruleus, other brain stem structures, amygdala, cingulate gyrus, and neocortex. The earliest locations of Lewy bodies are the brain stem, where they affect nuclei involved in sleep and arousal, and the substantia nigra, the locus caeruleus, and cranial nerve nuclei IX and X. Typically, the nucleus basalis, transentorhinal cortex, cingulate gyrus, and neocortex become involved later.

In Lewy body disease, the α-synuclein protein becomes misfolded and aggregates intraneuronally. Mutations in the α-synuclein gene have been seen in a few families with autosomal dominant Parkinson's disease, but most cases of dementia with Lewy bodies are sporadic.

CLINICAL MANIFESTATIONS

The clinical manifestations of dementia with Lewy bodies include four major abnormalities: the cognitive disorder, the neuropsychiatric disorder, the motor disorder, and the disorder of sleep and wakefulness. The cognitive disorder may differ from Alzheimer's disease, although there is considerable overlap. In a typical patient with dementia with Lewy bodies, visuospatial deficits, impaired concentration, and impaired attention dominate the picture. In some patients, the deficits in executive functions may be similar to what is seen in frontotemporal lobar degeneration. Anterograde amnesia is usually present but milder than in Alzheimer's disease. Language deficits are not prominent. The neuropsychiatric manifestations of dementia with

Lewy bodies, including prominent apathy, loss of initiative, and depression, may be more disabling than the cognitive symptoms. The motor manifestations include bradykinesia, gait disturbances, postural disturbances, and rigidity. Rest tremor is less common in dementia with Lewy bodies in patients in whom the cognitive disorder appears before the parkinsonism. Visual hallucinations, fluctuations in alertness, and REM sleep disorders are part of a broader disorder of the regulation of sleep and wakefulness. Visual hallucinations are often graphic, detailed, and bizarre, perhaps because the sleep phenomenon of dreaming intrudes into wakefulness. Patients with dementia with Lewy bodies have large fluctuations in their alertness and arousal from day to day.

REM sleep behavior disorder (Chapter 412) is a parasomnia in which patients exhibit dream enactment behavior, often with violent, threatening overtones. Patients typically relate that they feel as though they are being chased by something or someone. Their behavior, while they are asleep, consists of excessive talking, calling out or shouting, and thrashing about, often to the point of striking a bed partner or falling out of bed. The REM sleep behavior disorder may precede the development of Parkinson's disease and dementia with Lewy bodies by years.

DIAGNOSIS

The diagnosis of dementia with Lewy bodies is based on clinical information that corroborates the presence of abnormalities in cognition, motor function, neuropsychiatric behavior, and regulation of sleep and wakefulness. Formal neuropsychological testing is often helpful in evaluating memory, executive function, and visuospatial function in a detailed manner. Neuroimaging has only a limited role in the diagnosis of dementia with Lewy bodies.

Differential Diagnosis

Other disorders that must be considered in patients with dementia and a movement disorder include progressive supranuclear palsy (Chapter 417), which can resemble dementia with Lewy bodies in terms of both the dementia and the motor disorder. In progressive supranuclear palsy, patients are much less likely to have disorders of arousal and typically have other distinctive signs and symptoms, including the characteristic supranuclear gaze palsy and other brain stem findings. The corticobasal degenerations, which are members of the family of frontotemporal lobar dementias (see later), may also produce a movement disorder and dementia. Huntington's disease (Chapter 417) is associated with dementia and a movement disorder, but the movement disorder of Huntington's disease includes prominent chorea and athetosis, neither of which is present in dementia with Lewy bodies.

Normal-pressure hydrocephalus (Chapter 195) is a rare disorder typically characterized by the triad of a gait disorder, dementia, and urinary incontinence. Normal-pressure hydrocephalus can be suspected when computed tomography or MRI shows ventricular enlargement that is out of proportion to the amount of sulcal widening. Predicting a favorable response to ventriculoperitoneal shunting in suspected normal-pressure hydrocephalus has proved to be difficult. Imaging studies that measure CSF flow through the aqueduct of Sylvius or that measure flow of radiolabeled CSF with radionuclide cisternography have not been useful. Clinical response to the removal of a high volume (e.g., 30 mL) of CSF through lumbar puncture is sometimes used to select patients for surgery, although its positive and negative predictive value is unclear. Normal-pressure hydrocephalus is very rare relative to dementia with Lewy bodies and Alzheimer's disease.

TREATMENT

Rx

Management of patients with dementia with Lewy bodies is challenging because of the simultaneous appearance of a cognitive disorder, a neuropsychiatric disorder, a motor disorder, and a sleep and wakefulness disorder. Treatment of the motor disorder is accomplished with antiparkinsonian drugs such as levodopa and dopaminergic agonists (Chapter 416). Treatment with these agents should be instituted for dementia with Lewy bodies if there are prominent gait or balance problems that threaten safety and interfere with independence. These medications may worsen hallucinations and exacerbate confusional states, but this concern should not preclude a treatment trial if the motor symptoms pose safety risks or interfere with independence. Cholinesterase inhibitors, which do not exacerbate parkinsonian symptoms, have a beneficial effect on neuropsychiatric symptoms but not clearly on the cognitive disorder.[10]

Hallucinations and agitation impair quality of life for the patient and family and often require treatment. Some antipsychotic agents that might otherwise control these symptoms dramatically exacerbate the parkinsonism in dementia with Lewy bodies. Atypical antipsychotics are usually recommended, but there is insufficient experience from controlled clinical trials. Many movement disorder specialists prefer to use quetiapine in doses of 25 to 200 mg/day or clozapine at 6.25 to 50 mg/day because these agents appear to have the lowest rate of extrapyramidal side effects. However, it is not possible to make any strong statements about the relative efficacy of atypical antipsychotics in treating the hallucinations in dementia with Lewy bodies, especially in view of the possibility that atypical antipsychotic agents may be associated with higher than expected mortality.

The REM sleep behavior disorder (Chapter 412) can be disabling, but there are no controlled clinical trials to inform treatment. Some sleep disorder specialists typically use either melatonin, 3 to 12 mg, or clonazepam, 0.5 to 2 mg, at bedtime.

Treatment of depressive symptoms may substantially improve a patient's functioning. Use of one of the newer generation of antidepressants, such as sertraline in a dose of 25 to 100 mg/day or citalopram in a dose of 10 to 20 mg/day, may be beneficial and does not necessarily interfere with management of the other symptoms (Chapter 404).

PROGNOSIS

As opposed to patients with Alzheimer's disease, some studies show that patients with dementia with Lewy bodies have a more rapidly progressive course and poorer survival. As a result of the combination of manifestations, patients with dementia with Lewy bodies may become disabled sooner in their course.

FUTURE DIRECTIONS

Because the REM sleep behavior disorder often precedes the development of dementia with Lewy bodies, early diagnosis offers an opportunity for early intervention. Progress in understanding of the production and degradation of α-synuclein may lead to more specific therapies.

FRONTOTEMPORAL LOBAR DEGENERATION

DEFINITION

The frontotemporal lobar degenerations are a group of neurodegenerative disorders with distinctive clinical manifestations and a predilection for the prefrontal and anterior temporal neocortices. The most common clinical syndrome is a disorder of behavior and personal relationships (comportment) with a loss of executive functions (Table 409-6). This syndrome is referred to as behavior-variant frontotemporal dementia. Other syndromes in the clinical spectrum of frontotemporal lobar degeneration involve different aspects of language or motor dysfunction of the limbs.

EPIDEMIOLOGY

Unlike Alzheimer's disease, the frontotemporal lobar degenerations have a peak age at onset in the 50- to 70-year range, and the incidence declines after the age of 70 years. In patients with dementia who are younger than 70 years, frontotemporal lobar degeneration makes up 10 to 20% of cases. However,

TABLE 409-6 DIAGNOSTIC CRITERIA FOR FRONTOTEMPORAL DEMENTIA

Based on evidence from the history and mental status examination, a disorder characterized by the early *and* predominant presence of *either* of the following: Decline in regulation of personal or social interpersonal conduct (as characterized by loss of empathy for the feelings of others; socially inappropriate behavior that is rude, caustic, irresponsible, or sexually explicit; mental rigidity; impulsivity typically with poor judgment; inflexibility in interpersonal relationships or emotional blunting; apathy; disregard for personal hygiene and grooming; deviations in previous dietary preferences or habits; binge eating) Impairment in mental agility, reasoning, or handling of complex tasks out of proportion to impairment in the domains of declarative episodic memory or visuospatial abilities
The cognitive or behavioral disturbances are of gradual onset and are progressive, based on evidence from the history or serial cognitive examination
The cognitive disturbance significantly interferes with work, usual social activities, or relationships with others
The cognitive disturbance and the changes in daily functioning represent a significant decline from a previous level of functioning
Not occurring exclusively during the course of delirium
The disturbance is not better accounted for by a major psychiatric diagnosis, a systemic disease, or another brain disease

across the entire age spectrum, the frontotemporal lobar degenerations are much less common than Alzheimer's disease, dementia with Lewy bodies, or vascular dementia. Both men and women are affected equally. There are no known risk factors for the frontotemporal lobar degenerations except a family history.

PATHOBIOLOGY

The clinical syndrome in frontotemporal lobar degeneration is determined by the lobar location of the pathologic process. Right prefrontal or anterior temporal disease and brain atrophy produce behavioral syndromes like frontotemporal dementia. Left frontal involvement tends to produce progressive nonfluent aphasia. Predominant left anterior temporal lobe involvement may produce semantic dementia.

On histopathologic grounds, patients with frontotemporal lobar degeneration can be divided into three groups: those whose inclusions contain the microtubule-associated protein tau; those whose inclusions contain the TAR DNA-binding protein 43 (TDP-43); and those whose inclusions contain the fused in sarcoma (FUS) protein, another nucleic acid–binding protein. Each type includes both genetically determined and sporadic forms.

Among the tau-positive varieties are Pick's disease, in which intracellular tau-positive inclusions known as Pick bodies are seen. Several other pathologic tau-positive subtypes occur, including progressive supranuclear palsy, corticobasal degeneration, and the disorder associated with mutations in the tau gene. Nearly 50 mutations in the tau gene on chromosome 17q21 are associated with autosomal dominant frontotemporal lobar degeneration syndromes, each with a slightly different clinical and neuropathologic phenotype. The most common is a proline to leucine mutation at codon 301, located in exon 10. The tau gene undergoes alternative splicing, resulting in six isoforms of the tau protein. Pathologic mutations appear to disrupt splicing of alternative isoforms of tau protein, which in turn adversely affects the binding of tau to microtubules in neurons. Reduced binding of tau to microtubules is deleterious to microtubule function and neuronal integrity.

The TDP-43–positive frontotemporal lobar degenerations are almost equally common. Immunostaining shows that there are distinctive TDP-43–containing inclusions. Mutations in the granulin (*GRN*) gene, also located on chromosome 17q21, cause familial, autosomal dominant forms of frontotemporal lobar degeneration with TDP-43–positive inclusions. Nearly 70 different mutations in the granulin gene are linked to frontotemporal lobar degenerations. All of the mutations lead to premature degradation of the messenger RNA, a process termed haploinsufficiency. Granulin mutation carriers have an abnormally low amount of the protein progranulin. The normal function of granulin in the brain is unclear, and the pathophysiologic basis for dementia in persons with granulin gene mutations is unknown. The link between alterations in TDP-43 and *GRN* mutations is also unknown at this time.

Frontotemporal lobar degenerations that are FUS positive are much less common. At this time, all FUS-positive cases have had the behavioral variant of frontotemporal dementia.

CLINICAL MANIFESTATIONS

The clinical manifestations of the syndrome of frontotemporal dementia begin insidiously. Apathy, loss of initiative, and flattening of affect are common early symptoms. As the disease progresses, the entire spectrum of behavioral changes associated with dysfunction of the frontal and anterior temporal lobes appears. On cognitive assessments, patients may have preserved memory functions, but they typically have difficulty with tests of executive cognitive function. When frontotemporal dementia progresses to moderate or severe stages, the behavioral changes remain prominent, but the disease becomes more difficult to distinguish from other dementias such as Alzheimer's disease. The neuropathology of behavior-variant frontotemporal dementia may be either tau positive or TDP-43 positive.

In some patients with frontotemporal lobar degeneration, signs and symptoms of motor neuron disease develop, such as weakness, atrophy, and fasciculation in the limbs or the bulbar musculature (Chapter 418). In other patients with frontotemporal lobar degeneration, asymmetrical limb apraxia develops that is part of the corticobasal syndrome. Features of progressive supranuclear palsy may also appear in patients with behavior-variant frontotemporal dementia.

Frontotemporal lobar degeneration can be manifested as a progressive nonfluent aphasia in which patients experience a feeling of hesitancy in selecting words in their speech, a problem that may be difficult for others to appreciate at first. Anomia is an early sign. Gradually, the patient's speech becomes laconic and labored. Eventually, a nonfluent, apractic, agrammatic speech develops. In other cognitive domains, progressive nonfluent aphasics as well as progressive anomic aphasics often have no deficits. As the diseases progress, however, a pervasive cognitive disorder develops in some patients. Other progressive nonfluent aphasics may eventually become virtually mute, even though they may appear to have preserved memory and visuospatial functions. Patients with progressive nonfluent aphasia often have tau-positive neuropathologic findings.

Semantic dementia is a disorder that involves dissolution of the meaning of words or objects. A patient with semantic dementia may also become unable to access knowledge about objects (object agnosia) and people's faces (prosopagnosia). The most striking demonstration of the deficit in semantic dementia is when a patient can produce the name of an object—a watch, for example—but then cannot say what a watch is for when asked. Often, patients with semantic dementia have preservation of the ability to learn a list of words, even if their knowledge of the meaning of the words is diminished. Patients with semantic dementia usually have TDP-43–positive neuropathologic findings.

DIAGNOSIS

Frontotemporal lobar degeneration must first be suspected on clinical grounds, based on the appearance of one of the distinctive clinical syndromes such as frontotemporal dementia (see Table 409-6) or one of the aphasic subtypes. Neuropsychological testing can also aid in the diagnosis by detecting abnormalities in executive function and verifying that memory function is preserved, as it often is. For all of the frontotemporal lobar degeneration syndromes, MRI showing focal atrophy of the frontal (Fig. 409-4) or temporal lobes is highly likely to be diagnostic. Imaging with fluorodeoxyglucose-enhanced positron emission tomography can also be useful when the clinical diagnosis is uncertain and MRI is nondiagnostic.

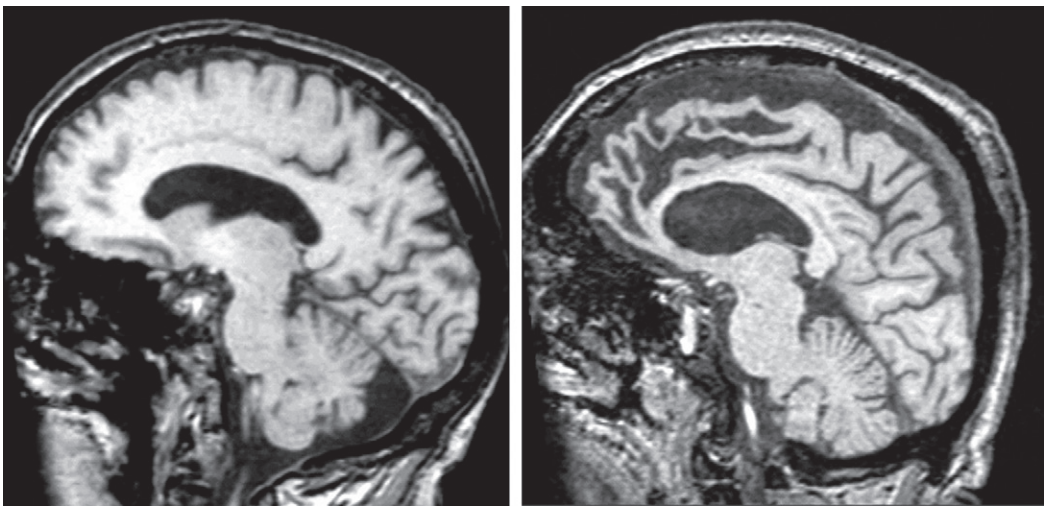

FIGURE 409-4. Parasagittal image from MRI of a patient with frontotemporal dementia *(left)*. Atrophy of the frontal lobes is dramatic compared with the brain of a normal individual *(right)*. (Courtesy of Maria Shiung and Clifford Jack.)

TREATMENT

Rx

There is no symptomatic therapy specifically for frontotemporal lobar degeneration. In patients with agitation, paranoia, delusions, or obsessive behavior, atypical antipsychotics (e.g., quetiapine, 25 to 200 mg/day) are used, but no controlled clinical trials are available. There are no preventive treatments of frontotemporal lobar degeneration.

PROGNOSIS

Specific frontotemporal lobar degeneration syndromes have dramatic differences in their clinical course and outcome. In patients with motor neuron signs and symptoms, the prognosis is usually poor, with survival of only about 2 years from the time of diagnosis. Patients with semantic dementia and progressive nonfluent aphasia have much more protracted and gradual trajectories; survival for more than 10 years is not uncommon. Frontotemporal dementia itself can also exhibit a more protracted course.

FUTURE DIRECTIONS

Drugs that delay or prevent the pathologic consequences of tau protein dysfunction could be of great value for many patients with frontotemporal lobar degeneration.

410 THE EPILEPSIES

SAMUEL WIEBE

DEFINITION

A *seizure* is defined by transient focal or generalized signs or symptoms due to abnormal excessive or synchronous neuronal activity in the brain. *Focal seizures*, which originate within neuronal networks limited to one cerebral hemisphere, produce signs and symptoms corresponding to the specific region of the brain that is affected by the seizure. *Generalized seizures* rapidly affect extensive neuronal networks on both cerebral hemispheres, and their signs and symptoms are consistent with substantial involvement of both sides of the brain.

Seizures are not synonymous with epilepsy. The epilepsies should be distinguished from situations in which acute brain insults (e.g., infections, trauma, intoxication, metabolic disturbances) cause one or more seizures without a resulting chronic seizure tendency. *Acute symptomatic seizures*, or *provoked seizures*, constitute about 40% of all incident cases of nonfebrile seizures, typically respond to treatment of the provoking factor, and do not require long-term treatment with antiepileptic drugs.

The *epilepsies* are a group of conditions in which an underlying neurologic disorder results in a chronic tendency to have recurrent, unprovoked seizures. Under these circumstances, *the occurrence of two or more seizures establishes the diagnosis of epilepsy.* The causes, types, and clinical expression of the epilepsies are numerous and varied. However, some of the epilepsies conform into identifiable *epileptic syndromes*, which consist of clusters of clinical and electroencephalographic (EEG) features that have specific causes, respond to particular treatments, and may have specific prognostic implications.

EPIDEMIOLOGY

Incidence and Prevalence

Seizures are common in the general population, and about 1 in 10 people will experience a seizure in their lifetime. Most of these seizures are provoked by acute events and are not related to epilepsy. The overall annual incidence of acute symptomatic seizures, excluding febrile seizures, in developed countries is about 39 per 100,000 people. The incidence is higher in men and follows a bimodal age distribution. Incidence is at its highest peak in the first year of life (up to 300 per 100,000), reaches a nadir of 15 per 100,000 in the third and fourth decades of life, and rises again to 123 per 100,000 after 75 years of age. These differences are attributable to the high incidence of acute symptomatic seizures associated with metabolic, infectious, and encephalopathic causes during the neonatal period, and of cerebrovascular and degenerative diseases in elderly people.

The *epilepsies* are common and affect humans of any age. After headache, the epilepsies are the most frequent chronic neurologic condition seen in general practice worldwide. In developed countries, the prevalence of active epilepsy ranges from 5 to 7 per 1000 people, and the annual incidence ranges from 35 to 52 per 100,000, varying by age. The incidence of epilepsy peaks in children younger than 5 years at 60 to 70 per 100,000, decreases throughout adolescence to 30 per 100,000 in early adulthood, and rises again after the sixth decade, reaching a peak of 150 to 200 per 100,000 people older than 75 years. Overall, the incidence and prevalence of the epilepsies are higher in developing countries, largely owing to a higher frequency of perinatal insults, trauma, and infectious disorders of the brain and to suboptimal treatment. In these countries, the median prevalence of active epilepsy is 12.5 per 1000 (range, 5 to 57 per 1000), and the annual incidence ranges from 78 to 190 per 100,000. Furthermore, the patterns of age-specific incidence are quite different in developing countries, where incidence peaks in young adults, not in elderly people.

Risk Factors

Among all age groups, the top five risk factors for developing *acute symptomatic seizures* are head trauma (16%), stroke (16%), infectious disorders (15%), toxic-metabolic disorders (15%), and drug and alcohol withdrawal (14%) (Table 410-1).

The risk factors for developing *epilepsy* differ in adults and children. In childhood, excluding inherited epilepsies, the risk is increased by febrile seizures, head trauma, infections of the brain, mental retardation, cerebral palsy, and attention-deficit hyperactivity disorder. Perinatal insults do not carry an increased risk for epilepsy unless they are accompanied by mental retardation or cerebral palsy.

In adults, risk factors for developing *epilepsy* can be identified in only one third of patients, in whom head trauma, brain infections, stroke, and Alzheimer's disease are the most common. The risk of developing epilepsy is increased more than 500-fold by a history of a military head injury, 30-fold by a severe civilian head injury (Chapter 406), 20-fold each by stroke (Chapter 414) and brain infections (Chapters 420 and 422), and 10-fold each for Alzheimer's disease (Chapter 409), migraine headache (Chapter 405), and hypertension.

In Latin America, the most frequently identified risk factor is brain infection. In endemic areas, neurocysticercosis (Chapter 362) accounts for about 10% of all newly diagnosed cases of epilepsy.

Pathobiology

Pathogenesis

The pathologic substrates and mechanisms underpinning initiation and propagation differ for focal and generalized seizures. In focal seizures, an aggregate of cortical or subcortical neurons develop high-frequency bursts of sodium-dependent action potentials caused by a shift in calcium conductance, thereby resulting in the typical EEG spike discharge (Fig. 410-1). Spread of bursting activity to other neurons is normally prevented by surrounding inhibitory mechanisms, such as hyperpolarization and inhibitory interneurons. When a sufficient number of neurons are engaged in sustained bursting, further excitatory phenomena ensue, including the increased release of excitatory neurotransmitters owing to presynaptic accumulation of Ca^{2+}, depolarization of surrounding neurons owing to increased extracellular K^+, and further neuronal activation caused by depolarization-induced activation of *N*-methyl-D-aspartate (NMDA) receptors. As excitation increases and inhibition decreases, additional neurons are recruited regionally and distantly, thereby resulting in seizure propagation. The mechanisms by which neurons develop a tendency toward anomalous bursting activity include alterations in neurotransmitters, membrane receptors, ion channels, second-messenger systems, and gene expression of various proteins.

Considerably less is known about the basic mechanisms underlying generalized seizures, which depend prominently on thalamocortical circuits. In absence seizures, the classic generalized spike-and-wave discharges seen on EEG (Fig. 410-2) are related to alterations in oscillatory rhythms generated by circuits that connect the thalamus and cortex and that involve T-type Ca^{2+} channels, which are located in the reticular nucleus of the thalamus. In generalized convulsive seizures, cortical neurons exhibit prolonged depolarization during the tonic phase, followed by rhythmic depolarization and repolarization during the clonic phase. Activation of NMDA receptors increases calcium Ca^{2+} influx, thereby leading to further neuronal excitation. The initiation and modulation of generalized convulsive seizures involve cholinergic, noradrenergic, serotonergic, and histaminergic afferents from the brain stem and basal forebrain structures, which modulate excitability of hemispheric motor mechanisms.

TABLE 410-1 COMMON CAUSES OF ACUTE SYMPTOMATIC (PROVOKED) SEIZURES

METABOLIC
Hypernatremia, hyponatremia, hypocalcemia, hypoxia, hypoglycemia, nonketotic hyperosmolar hyperglycemia, renal failure
DRUG INDUCED
Theophylline, meperidine, tricyclic antidepressants, ephedra, gingko, phenothiazines, quinolones, β-lactams, isoniazid, antihistamines, cyclosporine, interferons, tacrolimus, cocaine, lithium, amphetamines
DRUG WITHDRAWAL
Alcohol, benzodiazepines, barbiturates
ENDOCRINE
Hyperthyroidism, hypothyroidism, peripartum
OTHER SYSTEMIC CONDITIONS
Sickle cell crisis, hypertensive encephalopathy, systemic lupus erythematosus, polyarteritis, eclampsia, high fever
CENTRAL NERVOUS SYSTEM DISORDERS
Trauma, stroke, intracerebral hemorrhage, encephalitis, abscess, bacterial meningitis

Genetics

Only 15% of patients have one or more first-degree relatives who also suffer from epilepsy, and of those, about 75% have just one affected relative. However, the risk is still higher in first-degree relatives of patients with epilepsy than in the general population. In a large population-based study, the cumulative incidence of epilepsy to age 20 years was 2.5-fold higher in siblings and 3.4-fold higher in offspring of patients with epilepsy.

The genetic aspects of epilepsy can be categorized in three large groups: *Conditions in which epilepsy forms part of a mendelian disorder* include over 200 rare conditions, which encompass neurocutaneous disorders (Chapter 426), neurodegenerative disorders, inherited malformations of cortical development (Chapter 426), and inherited metabolic disorders. For example, genes have been identified in progressive myoclonic epilepsies (e.g., Unverricht-Lundborg disease, Lafora's disease, and the neuronal ceroid lipofuscinosis), X-linked myoclonic epilepsy with mental retardation, and cortical malformation syndromes, such as polymicrogyria, pachygyria, and periventricular nodular heterotopia.

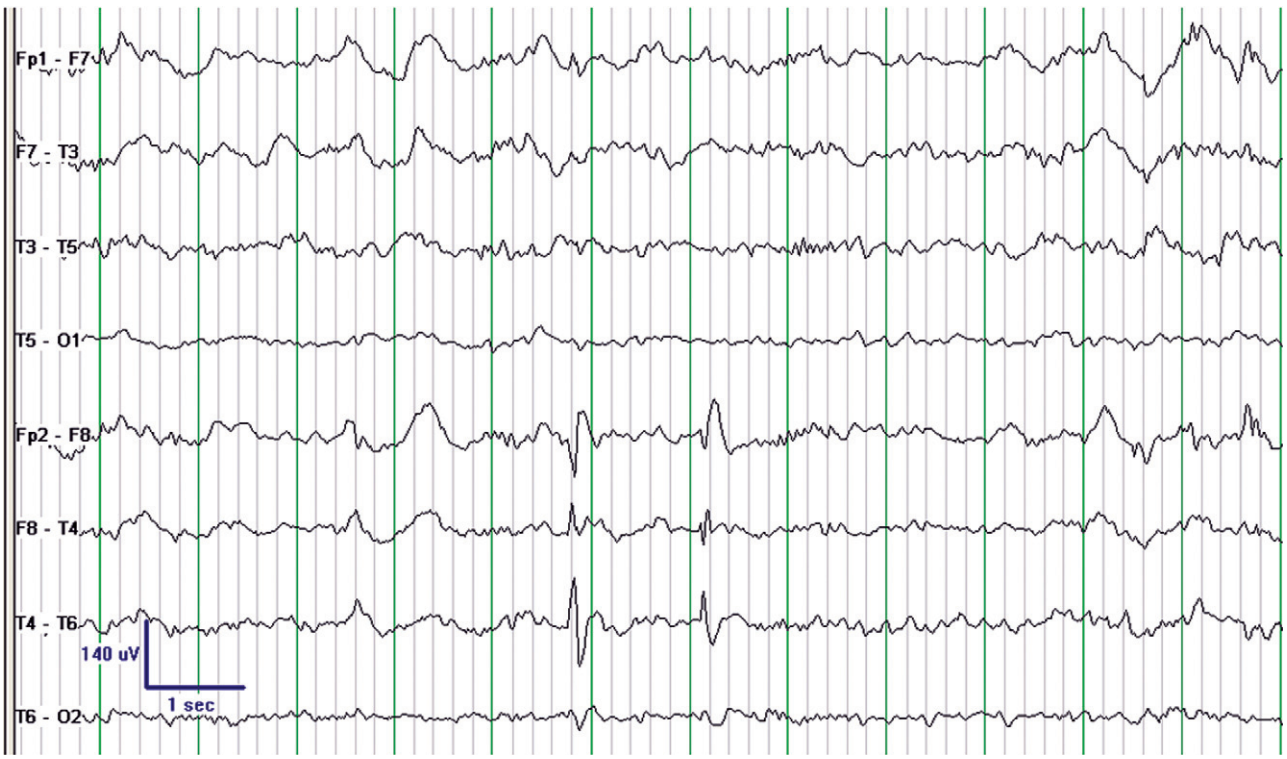

FIGURE 410-1. Selected electroencephalogram channels showing a typical right anterior temporal spike, the archetypal interictal footprint of temporal lobe epilepsy. The patient had right hippocampal sclerosis.

FIGURE 410-2. Electroencephalogram pattern of 3-Hz generalized spike and wave, the characteristic correlate of generalized absence seizures. This episode lasting 6 seconds had no discernible clinical manifestations.

Epilepsies that can be directly explained by simple mendelian inheritance are rare and account for only about 1% of all epilepsy cases. More than a dozen genes have been identified in the following eight autosomal dominant epilepsy syndromes, of which all but two encode voltage-gated or ligand-gated ion channels. Benign familial neonatal seizures are associated with mutations in the potassium-channel genes *KCNQ2* and *KCNQ3*. Benign familial neonatal-infantile seizures are associated with mutations in the sodium-channel *SCN2A*. Generalized epilepsy with febrile seizures plus is associated with mutations in the genes for sodium-channel subunits *SCN1A*, *SCN1B*, and *SCN2A* and the *GABRG2* subunit of the $GABA_A$ receptor. Childhood absence epilepsy with febrile seizures is associated with mutations in the *GABRG2* subunit of the $GABA_A$ receptor. Autosomal dominant juvenile myoclonic epilepsy has been associated with a mutation in the *GABRA1* subunit of the $GABA_A$ receptor and in *EFHC1*, which regulates calcium currents. Autosomal dominant idiopathic generalized epilepsy is associated with mutations in the chloride-channel gene *CLCN2*. In autosomal dominant nocturnal frontal lobe epilepsy, mutations have been found in the genes encoding nicotinic acetylcholine receptor subunits *CHRNA4* and *CHRNB2*. In autosomal dominant partial epilepsy with auditory features, mutations have been found in the *LGI1* gene, which appears to be involved in development of the central nervous system (CNS).

In some patients, the epilepsy is associated with *"complex" disease genes.* In this large group, which constitutes about 50% of all patients with epilepsy, multiple genes with individually small but additive effects act in combination with environmental factors to produce an increased risk for epilepsy.

CLINICAL MANIFESTATIONS

The clinical expression of seizures varies widely depending on the type of seizure and the areas of the brain that are involved by the epileptic activity. Accurate identification of the specific types of seizures determines the syndrome and dictates the type of drug that the patient should receive.

Focal Seizures

Focal seizures originate within neuronal networks limited to one area of one cerebral hemisphere and produce signs and symptoms corresponding to the function subserved by the area of cerebral cortex engaged by the seizure (Table 410-2). Focal seizures are now subclassified according to their clinical expression; if consciousness or awareness is predominantly impaired, they are referred to as dyscognitive seizures. For example, patients who formerly were classified as having simple partial seizures now are classified as having focal seizures with preserved consciousness.

An *aura* consists of sensory, autonomic, or psychic symptoms that are experienced at the start of an observable seizure. The aura is a focal seizure itself, and it is often missed because patients and clinicians focus on the more dramatic dyscognitive or convulsive seizure that follows. Careful inquiry about the occurrence of an aura is of crucial importance for three reasons. First, it points to a focal as opposed to a generalized onset, thereby implying an underlying focal structural or functional brain abnormality (e.g., a tumor) that requires further investigation. Second, focal seizures have important implications for therapy and for prognosis (see later). Third, the nature of the symptoms points to the area of the brain that gives rise to the seizure and that could be a target for surgical treatment.

The neuronal discharge causing the focal seizure may remain confined to the region where it began (as an aura or more objective focal event), or it may spread to involve additional brain areas. Thus, a focal seizure originating in the cortical area that represents sensation of the hand (rolandic area) may begin with contralateral hand tingling and then progress to involve additional cortical regions ipsilaterally, producing more extensive sensory symptoms as well as clonic motor signs. Seizures of rolandic origin in particular exhibit a peculiar type of propagation, in which the seizure activity "marches" from hand to arm to leg area ipsilaterally, a process referred to as a jacksonian march. After the clonic motor activity ends, patients are often weak; a postictal or Todd's paralysis may last hours or even a day or two, with gradual resolution. The seizure may also propagate to distant ipsilateral or contralateral regions along known anatomic pathways.

In dyscognitive seizures, seizure propagation sufficiently involves limbic and bilateral structures to cause alteration of consciousness. Focal seizures originating from any region can become dyscognitive seizures, and unilateral focal seizures can progress to involve bilateral brain areas and cause a convulsive seizure. Such convulsive seizures usually take the form of generalized tonic-clonic events rather than another type of generalized seizure (Table 410-3).

The evolution of the focal clinical seizure reflects the evolution of the EEG changes, which in turn reflects the pathophysiology of the process. A

TABLE 410-2 CLINICAL MANIFESTATIONS OF DIFFERENT TYPES OF FOCAL SEIZURES AND AREAS OF THE BRAIN INVOLVED

SEIZURE TYPE	AREAS OF BRAIN INVOLVED	CLINICAL EXPRESSION
Somatosensory	Postcentral rolandic; parietal	Contralateral intermittent or prolonged tingling, numbness, sense of movement, desire to move, heat, cold, electric shock. Sensation may spread to other body segments.
	Parietal	Contralateral agnosia of a limb, phantom limb, distortion of size or position of body part
	Second sensory; supplementary sensory-motor	Ipsilateral or bilateral facial, truncal or limb tingling, numbness, or pain. Often involve lips, tongue, fingertips, feet
Motor	Precentral rolandic	Contralateral regional clonic jerking, usually rhythmic, may spread to other body segments in jacksonian motor march. Often accompanied by sensory symptoms in same area
	Supplementary sensory-motor	Bilateral tonic contraction of limbs causing postural changes, may exhibit classic fencing posture, may have speech arrest or vocalization
	Frontal	Contralateral head and eye version, salivation, speech arrest or vocalization; may be combined with other motor signs (as above) depending on seizure spread
Auditory	Heschl's gyrus—auditory cortex in superior temporal lobe	Bilateral or contralateral buzzing, drumming, single tones, muffled sounds
Olfactory	Orbitofrontal; mesial temporal cortex	Often described as unpleasant odor
Gustatory	Parietal; rolandic operculum; insula; temporal lobe	Often unpleasant taste, acidic, metallic, salty, sweet, smoky
Vertiginous	Occipitotemporal-parietal junction; frontal lobe	Sensation of body displacement in various directions
Visual	Occipital	Contralateral static, moving, or flashing colored or uncolored lights, shapes, or spots. Contralateral or bilateral, partial or complete loss of vision.
	Temporal; occipitotemporal-parietal junction	Formed visual scenes, faces, people, objects, animals
Limbic	Limbic structures: amygdala, hippocampus, cingulum, olfactory cortex, hypothalamus	Autonomic: abdominal rising sensation, nausea, borborygmi, flushing, pallor, piloerection, perspiration, heart rate changes, chest pain, shortness of breath, cephalic sensation, lightheadedness, genital sensation, orgasm Psychic: déjà vu, jamais vu, depersonalization, derealization, dreamlike state, forced memory or forced thinking, fear, elation, sadness, sexual pleasure, hallucinations or illusions of visual, auditory, or olfactory nature
Dyscognitive	Usually bilateral involvement of limbic structures (see above)	Previously known as "complex partial seizures," characterized by a predominant alteration of consciousness or awareness. The current definition requires involvement of at least two of five components of cognition: perception, attention, emotion, memory, and executive function.

Note: Focal seizures may evolve into bilateral convulsive seizures.

TABLE 410-3 GENERALIZED SEIZURES: CLASSIFICATION AND CLINICAL EXPRESSION

SEIZURE TYPE	SUBTYPE	CLINICAL EXPRESSION
Absence	Typical	Abrupt cessation of activities, with motionless, blank stare and loss of awareness lasting about10 seconds. The attack ends suddenly, and patient resumes normal activities immediately.
	Atypical	Longer duration than typical absence, often accompanied by myoclonic, tonic, atonic, and autonomic features as well as automatisms
	With myoclonias	Absence with myoclonic components of variable intensity
Myoclonic	Myoclonic	Sudden, brief (<100 msec), shocklike, involuntary, single or multiple contractions of muscle groups of various locations
	Myoclonic Atonic	A sequence consisting of a myoclonic followed by an atonic phase
	Myoclonic Tonic	A sequence consisting of a myoclonic followed by a tonic phase
Tonic		Sustained increase in muscle contraction lasting a few seconds to minutes
Clonic		Prolonged, regularly repetitive contractions involving the same muscle groups at a rate of 2-3 cycles per second
Atonic		Sudden loss or diminution of muscle tone lasting 1-2 seconds, involving head, trunk, jaw or limb musculature
Tonic-clonic		A sequence consisting of a tonic followed by a clonic phase

simultaneous rhythmic, localized discharge (often in the 4- to 7-Hz range) becomes higher in amplitude and lower in frequency as the seizure continues (Fig. 410-3). Some seizures that begin in the association cortex (e.g., frontal or parietal lobes) have bizarre or extremely brief clinical manifestations, without postictal deficits, and create diagnostic challenges. The stereotyped nature of the clinical events, with the identification of EEG changes if present, may be the only way to make an appropriate diagnosis. The diagnosis can be even more challenging if the seizure spreads to different cortical regions during different seizure episodes, thereby producing variable constellations of clinical findings at different times.

Focal seizures with or without dyscognitive features can also occur as a series of single events without intervening normal behavior, thereby resulting in focal status epilepticus. Focal status epilepticus with dyscognitive seizures is characterized by prolonged confused behavior. EEG findings may be normal in a focal seizure without altered awareness, even in patients with status epilepticus, but the diagnosis is usually evident from the clinical features. In status epilepticus of focal dyscognitive seizures, EEG recordings show continuous abnormalities that are not of the same nature as seen in single seizures in that individual. The most common are a slow background with superimposed rhythmic high-amplitude sharp waves or repetitive rhythmic seizure discharges (Fig. 410-4). This type of status epilepticus is most frequent with frontal lobe seizures but can occur in temporal lobe seizures as well. The factors that precipitate status epilepticus are not well defined, nor are the implications for treatment or prognosis.

Nonconvulsive status epilepticus consists of a state of confusion or impaired mental status in patients with various neurologic diagnoses (i.e., trauma, stroke) in the acute intensive care unit setting. It also denotes a condition that can occur de novo in older adults without a precipitating cause and that is characterized by prolonged confusional episodes, which are caused by generalized slow spike-and-wave status epilepticus. Clinical suspicion should prompt an EEG study, which is essential for diagnosis (Fig. 410-5).

Generalized Seizures

Generalized seizures rapidly affect both cerebral hemispheres, and their clinical expression is consistent with substantial involvement of both sides of the brain (see Table 410-3). *Convulsive seizures,* which are also referred to as grand mal seizures, consist of excessive, abnormal muscle contractions that may be sustained or interrupted, and usually are a combination of tonic and

FIGURE 410-3. Right temporal lobe dyscognitive seizure in a patient with right hippocampal sclerosis. The focal onset is characteristic, with 4-Hz rhythmic waves in the right anterior temporal region.

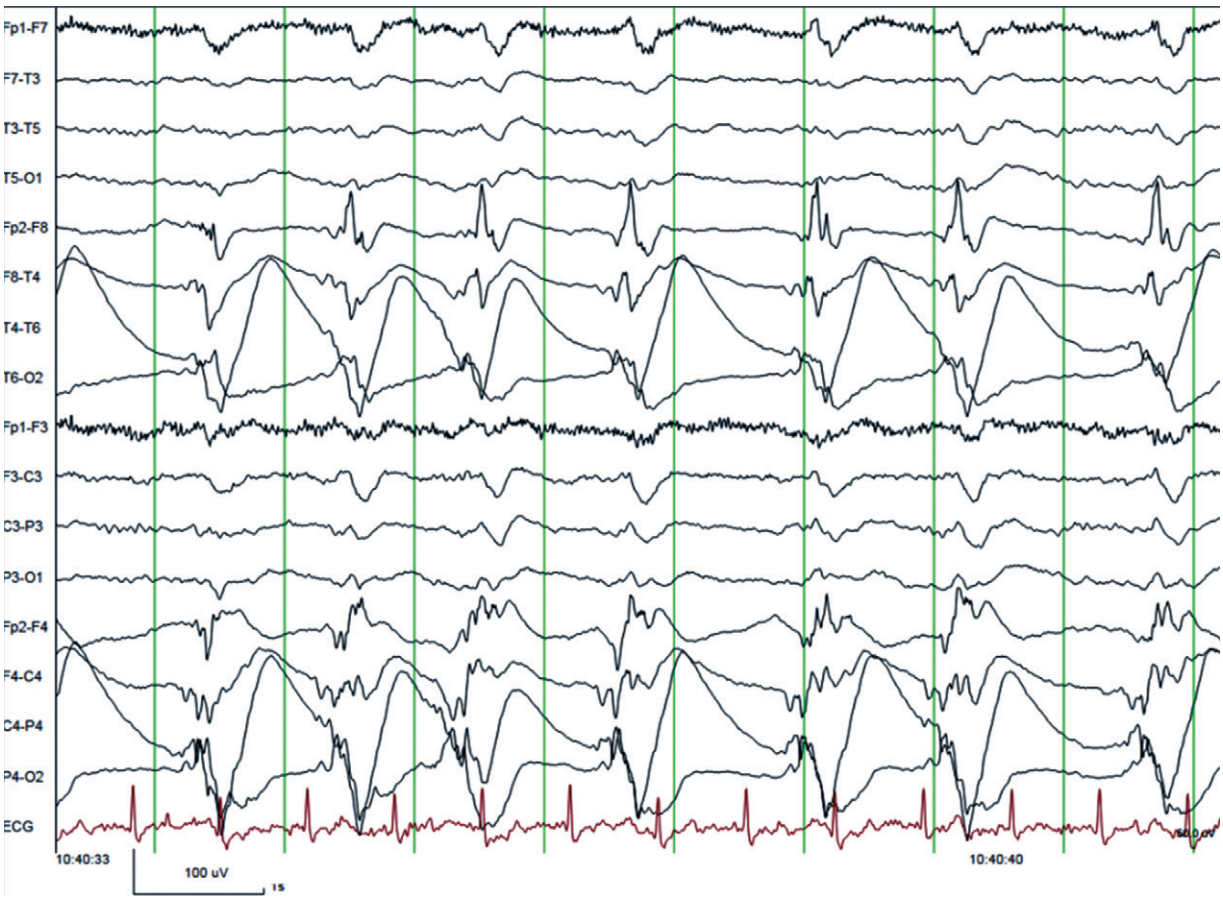

FIGURE 410-4. Focal, right hemisphere nonconvulsive status epilepticus in a comatose patient with a large right hemisphere infarct.

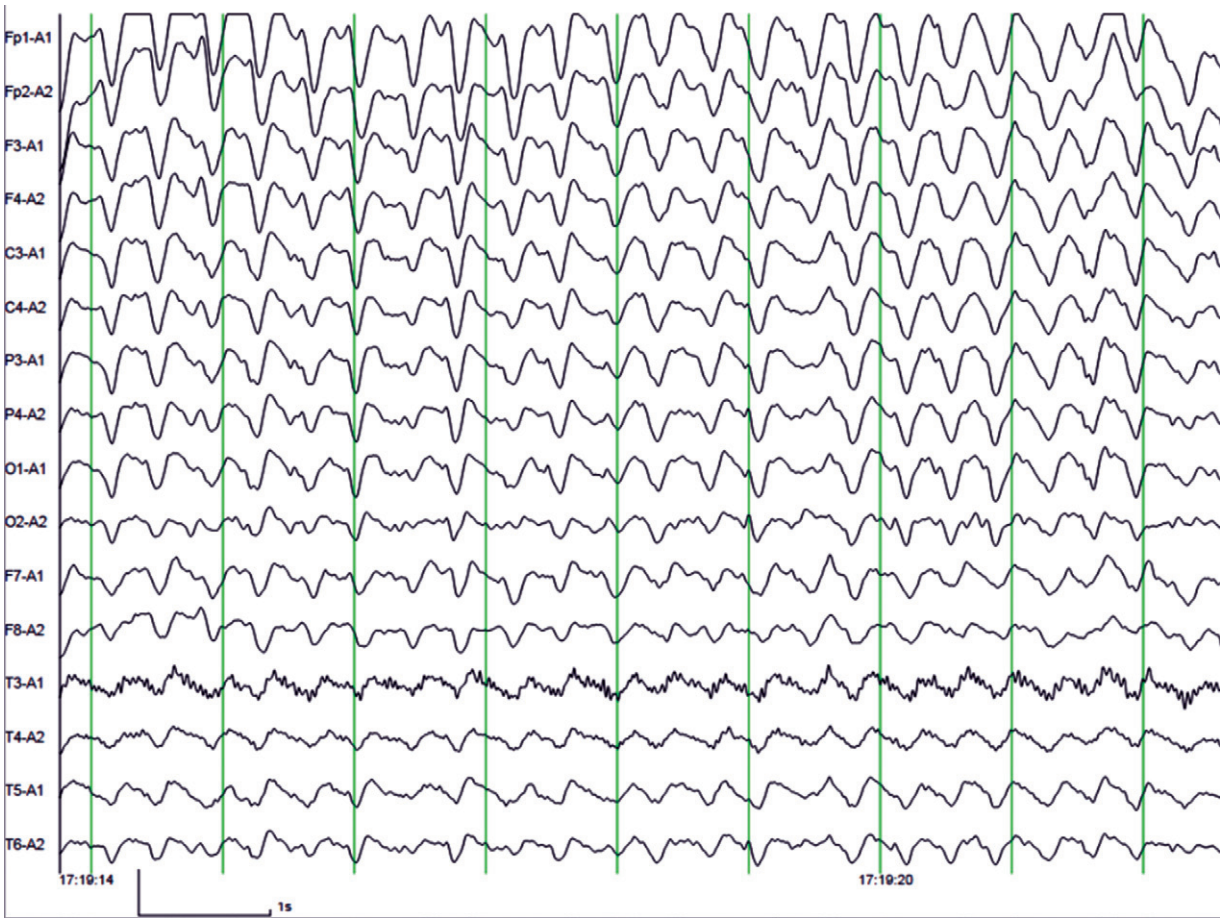

FIGURE 410-5. Generalized nonconvulsive status epilepticus in an older adult presenting with a prolonged episode of confusion and catatonic behavior.

clonic phases (generalized tonic-clonic seizures). This type of seizure may involve both hemispheres at the onset or may result from propagation of a focal seizure. These dramatic seizures often frighten witnesses and cause severe disruption of social interaction and development. They may begin with a "cry" as a result of abrupt air movement across the glottis from sudden tonic muscle contraction. The patient becomes diffusely stiff, usually with limb and body extension. Breathing is suspended, cyanosis occurs, and urinary incontinence is common. After 15 to 45 seconds, the tonic activity gives way to clonic, rhythmic, sometimes asymmetrical jerking of all four extremities. The rhythmic contractions gradually become slower in frequency until the event stops; the patient is apneic, comatose, and diaphoretic, but breathing with stridor and gasping begins within 60 seconds. Patients who have generalized tonic-clonic seizures in public often prompt bystanders to initiate resuscitation efforts, although such patients begin spontaneous respiration within 1 minute or so. Postictal stupor persists for a variable length of time. The patient generally sleeps for 2 to 8 hours and then complains of severe headache, sore muscles, a bitten tongue, and the inability to concentrate for a day or more. After generalized tonic-clonic seizures, some individuals have severe memory loss that gradually improves, sometimes over a period of weeks. Generalized tonic-clonic seizures also are a common expression of many metabolic, toxic, traumatic, or ischemic insults (see Table 410-1), but these provoked seizures do not qualify for the diagnosis of epilepsy.

Absence seizures, or petit mal seizures, are the second most common type of generalized seizure. Patients experience an abrupt onset and termination of a momentary lapse of awareness. Patients have no perception of any aspect of the event and may or may not realize that some time was lost, although individuals often lose their train of thought. Because consciousness is abruptly lost and immediately regained, there is neither an aura nor residual postictal symptoms. These seizures begin in childhood, and school teachers are often the first to notice them. Absence seizures may be accompanied by brief eye blinking or myoclonic movements (see Table 410-3), particularly if the event, as judged by EEG, extends beyond 10 seconds. These seizures can occur many times a day but are not associated with progressive neurologic disease. They can also occur in a more continuous form as nonconvulsive status epilepticus with resultant confusion (see Fig. 410-5).

Some patients with extensive bilateral brain disease have a variation of absence seizures, known as *atypical absence.* The event is similar in terms of loss of contact, but there is more motor, autonomic, or automatic activity, and the EEG demonstrates discharges that are slower than the 3-Hz spike and wave of typical absence seizures.

Myoclonic seizures consist of brief episodes of sudden motor contraction (see Table 410-3), which can be focal, with one arm involved, or bilateral and massive, with involvement of both upper extremities and the trunk. Consciousness is preserved but can be difficult to evaluate because of the brevity of these seizures. Myoclonic seizures form part of three main clinical constellations: juvenile myoclonic epilepsy, which starts in childhood or adolescence and often persists into adulthood; epilepsy with various combinations of absence and myoclonic seizures; and epilepsy in the setting of degenerative or inherited syndromes with bilateral cerebral involvement and abnormal cerebral function. Myoclonic seizures most commonly occur in the morning after awakening and often increase in frequency to culminate in a generalized tonic-clonic seizure.

Atonic and tonic seizures are brief but extremely disabling motor events that are characterized by a sudden increase or decrease in muscle tone. The result is falls and injuries with variable impairment of awareness. Such seizures frequently begin in children with diffuse CNS disease and multiple types of seizures, but they persist during adulthood.

DIAGNOSIS

The basic diagnosis of seizures is established by the clinical history. Although EEG, imaging, and laboratory studies are commonly required to determine the type of epilepsy, epilepsy syndrome, site of origin of focal seizures, and occurrence of nonepileptic seizures, the answer to the basic question of whether the patient's episodes are seizures or not rests almost entirely on a careful clinical history. Because epilepsy is defined as the occurrence of two or more unprovoked seizures, this diagnosis is also established by history.

Differential Diagnosis

The first question facing clinicians is whether the episodes under consideration are indeed seizures. The diverse clinical expression of seizures entails a

large differential diagnosis among conditions that produce episodic neurologic dysfunction (Table 410-4). Common conditions resembling seizures include syncope (Chapters 50 and 62), transient ischemic attacks (Chapter 414), migraine (Chapter 405), movement disorders (Chapter 417), and psychogenic nonepileptic seizures (see Table 410-4).

A number of historical elements dramatically change the likelihood of this diagnosis. Three essential elements help determine whether an episode is a seizure (Table 410-5) and distinguish seizures from other causes of temporary loss of consciousness, especially syncope (Chapters 50 and 62):

1. The clinical context, including medical and family history, and circumstances under which the episode occurred
2. Specific triggers or provoking factors
3. A detailed clinical description that entails four components:
   - What is the first symptom or sign (presence and type of aura, evidence of focal seizure at onset)?
   - How does it evolve after onset (what happens during the seizure proper, what are the signs or symptoms, how long does it last)?
   - How does it end (gradually or abruptly)?
   - Are there any neurologic deficits after the seizure ends?

Because patients have limited or no recall, the history from others is crucial. Observers can contribute important information about the patient's activity, responses, and appearance, including changes in color, diaphoresis, respirations, vocalization, and muscle tone. This information is often essential to characterize the type of seizure and to distinguish seizures from conditions that resemble seizures.

Migraine (Chapter 405) and focal seizures not only resemble each other but also coexist as comorbid conditions. Features that favor a diagnosis of seizures over classic migraine include an inconsistent occurrence of headache during the event, a brief duration, and the occurrence of more severe seizures. Myoclonus (Chapter 417) occurs in a variety of settings (e.g., metabolic encephalopathies) without any association with epilepsy or the EEG changes seen in myoclonic epilepsy.

Frontal lobe seizures arise predominantly during sleep and can have dramatic motor expression. They can be confused with nonepileptic psychogenic seizures, sleep disorders (Chapter 412), or movement disorders (Chapters 416 and 417). Video EEG monitoring may be necessary for diagnosis.

Patients with panic attacks (Chapter 404) can experience events that mimic focal seizures with autonomic and psychic features. However, panic attacks usually have a longer duration, do not progress to more severe seizures, and can be linked to specific circumstances. Nevertheless, focal seizures with limbic symptoms are often misdiagnosed as panic attacks.

Psychogenic nonepileptic seizures are behaviors that resemble seizures and are often part of a conversion reaction (Chapter 404) precipitated by underlying psychological distress. Psychogenic seizures can be difficult to diagnose because they can mimic almost any type of seizure, and they often coexist with epilepsy in the same patient. An erroneous diagnosis of nonepileptic seizures poses a risk for inappropriate discontinuation of medication, with resulting status epilepticus. Conversely, an erroneous diagnosis of seizures can result in iatrogenic illness owing to unnecessary therapy, excessive sedation, and cardiorespiratory depression. Features suggesting nonepileptic seizures include variable clinical manifestations across episodes, frequent and prolonged episodes, lack of response to antiseizure medication, out-of-phase upper and lower body movements, prominent pelvic thrusting, and lack of rigidity. Secondary gain is usually evident, and there is often a history of sexual abuse. Nevertheless, the peculiarities of these attacks may require continuous video EEG monitoring for diagnosis.

TABLE 410-4 DISORDERS RESEMBLING SEIZURES

VASCULAR AND PERFUSION DISORDERS
Migraine, syncope, transient ischemic attack, transient global amnesia, arrhythmia/hypoperfusion
PSYCHIATRIC DISORDERS
Psychogenic nonepileptic seizures, panic disorder, dissociative disorder
MOVEMENT DISORDERS
Tics, paroxysmal dystonia, paroxysmal choreoathetosis, paroxysmal ataxia
SLEEP DISORDERS
Night terrors, sleep walking, sleep myoclonus, narcolepsy/cataplexy, rapid eye movement sleep intrusions
METABOLIC DISTURBANCES
Alcoholic blackouts, delirium tremens, hypoglycemia, hallucinogenic drugs
OTHER
Breath-holding spells, paroxysmal vertigo, migraine with recurrent abdominal pain and cyclic vomiting

TABLE 410-5 CLINICAL FEATURES THAT HELP DISTINGUISH A GENERALIZED TONIC CLONIC SEIZURE FROM SYNCOPE

	SEIZURE	SYNCOPE
Clinical context and circumstances	Neurologic or systemic conditions that predispose to seizures, family history of seizures. Mental fatigue, sleep deprivation, alcohol use or withdrawal, systemic illness	Cardiovascular disorders, dehydration, anemia. Family history of syncope
Triggers	Usually none (unless reflex epilepsy)	Orthostatic hypotension, venipuncture, painful and noxious stimuli, emotional stress, micturition, Valsalva maneuver
Clinical features		
Onset	No warning unless there is an aura. Abrupt loss of consciousness, generalized stiffening, and fall. Occurs in any position	Tiredness, nausea, diaphoresis, tunneling of vision. Loss of consciousness over few seconds and fall. Occurs usually standing
Course	Prominent tonic phase then clonic movements lasting about 1 minute, cyanosis, labored breathing, may bite tongue or cheeks, sometimes urinary incontinence	Usually loss of tone, pallor, multifocal myoclonic jerks lasting less than 15 seconds, sometimes urinary incontinence, usually no tongue or cheek biting
Offset	Postical sleepiness and confusion lasting up to hours, headache, myalgia	Rapid recovery over seconds to less than few minutes, no confusion, headache or myalgia. May have fatigue

Diagnostic Investigations

A detailed history, EEG recordings, and magnetic resonance imaging (MRI), can lead to a definitive diagnosis of epilepsy and its cause in up to 50% of patients. In other patients, the information is insufficient or inconsistent, but the physiologic and CNS abnormalities surrounding the actual event allow it to be placed provisionally into a specific diagnostic category in about another 30% of patients. Continuous video-EEG monitoring in an inpatient epilepsy unit can increase diagnostic sensitivity.

Single Seizures

Acute symptomatic seizures (see Table 410-1) are the known consequence of an acute condition, and investigations should be directed at the possible cause of these seizures. When no known cause is readily apparent, the seizures are considered to be *unprovoked.* The evaluation of patients who present with a first unprovoked seizure includes either brain computed tomography (CT) or MRI, which reveals a possible cause in about 10% of patients. An EEG obtained after the seizure will demonstrate abnormalities with prognostic significance in 20 to 25% of these patients. Blood tests (including levels of serum electrolytes, glucose, calcium, and magnesium; tests of liver and kidney function; a complete blood cell count; and screening for suspected toxins) will reveal abnormalities in up to 15% of these patients but are often nonspecific. Lumbar puncture is indicated if CNS infections are suspected and in all patients infected with human immunodeficiency virus (HIV), even in the absence of clinical findings suggestive of infection.

Epilepsy

Electroencephalogram

The EEG is the keystone investigation in all patients with seizures and epilepsy. Between seizures, the EEG can assess overall brain function and the

type, location, and amount of epileptiform (spike) discharges. The EEG is crucial in determining the epilepsy syndrome and choosing appropriate antiepileptic drugs. In focal epilepsies, the EEG often demonstrates focal slowing and spike discharges in the area of abnormality.

The EEG can establish the definitive diagnosis of epilepsy if electrical changes consistent with a seizure are recorded during a clinical seizure. However, the EEG may fail to demonstrate electrical changes during a typical clinical seizure if the seizure focus is too small (at least 6 cm^2 of cortical involvement is needed to create an EEG epileptiform change), the seizure focus is deep or in the mesial or inferior surfaces of the brain, or the event in question may not be an epileptic seizure. The EEG is always abnormal during generalized convulsive and absence seizures.

The initial EEG is normal in up to 60% of people with known epilepsy. However, epileptiform abnormalities occur in more than 80% of individuals with focal epilepsy if three or more interictal EEG studies are performed. In generalized epilepsies, interictal epileptiform discharges are more common and are easier to capture in the EEG (see Fig. 410-2).

The type of abnormality points to the epileptic syndrome. For example, the EEG can show hypsarrhythmia in West's syndrome (see later), or the classic 3-Hz generalized spike wave in generalized epilepsies with absence seizures (see Table 410-3; see Fig. 410-2).

In some circumstances, it is imperative to record seizures, such as in the evaluation of patients for epilepsy surgery and when the diagnosis of seizures is in question. Continuous video EEG monitoring for prolonged periods has made it possible to capture these events. Continuous EEG is also used in comatose patients in the intensive care unit setting when nonconvulsive seizure or status epilepticus is suspected.

Magnetoencephalography

Magnetoencephalography measures the small magnetic fields that are generated by electrical activity in the brain and approximates their location using mathematical models. Its use is largely restricted to the evaluation of patients for epilepsy surgery, in whom it is used for mapping interictal discharges and the localization of brain function when superimposed on brain MRI.

Imaging Studies

Brain MRI, which can demonstrate lesions in most patients whose epilepsy is associated with a structural cause, should be performed in essentially all patients with new-onset seizures. The use of fluid-attenuated inversion recovery (FLAIR) sequences increases the sensitivity to detect abnormalities of cortical development as well as hippocampal sclerosis, which point to the need for chronic anticonvulsant therapy or possible surgical treatment. Functional imaging procedures such as positron emission tomography (PET) for analysis of metabolism and single-photon emission computed tomography (SPECT) for determination of blood flow are also used to help localize areas of the brain to be targeted with epilepsy surgery.

Epileptic Syndromes and Constellations

Epileptic syndromes include 27 age-related syndromes, of which all but 6 begin or occur in infancy and childhood (Table 410-6). In addition, specific clinical constellations represent diagnostically meaningful forms of epilepsy, with specific implications for treatment, especially surgery, and also categorize for structural-metabolic causes, epilepsies of unknown cause, and conditions characterized by seizures that are not a form of epilepsy (e.g., febrile seizures). The diagnosis of epileptic syndromes and constellations is based on the types of seizures, the setting in which seizures occur, the patient's neurologic and cognitive status, age at onset, family history, and results of diagnostic studies, including EEG and MRI. The selection of specific drug and surgical treatment depends on the types of seizures present (see Table 410-8, later). The need for lifelong treatment, the risk for genetic transmission, the likelihood of concurrent neurologic diseases, the risk for comorbid conditions, and the long-term prognosis are critical factors that can be addressed only with knowledge of the specific epileptic syndrome or constellation.

TABLE 410-6 EPILEPTIC SYNDROMES AND CONSTELLATIONS ACCORDING TO THE NEW INTERNATIONAL CLASSIFICATION

BY AGE AT ONSET
Neonatal Period
Benign familial neonatal epilepsy
Early myoclonic encephalopathy
Ohtahara's syndrome
Infancy
Epilepsy of infancy with migrating partial seizures
West's syndrome
Myoclonic epilepsy in infancy
Benign infantile epilepsy
Benign familial infantile epilepsy
Dravet's syndrome
Myoclonic encephalopathy in nonprogressive disorders
Childhood
Febrile seizures plus (can start in infancy)
Panayiotopoulos' syndrome
Epilepsy with myoclonic atonic (previously astatic) seizures
Benign epilepsy with centrotemporal spikes
Autosomal-dominant nocturnal frontal lobe epilepsy
Late-onset childhood occipital epilepsy
Epilepsy with myoclonic absences
Lennox-Gastaut syndrome
Epileptic encephalopathy with continuous spike and wave during sleep
Landau-Kleffner syndrome
Childhood absence epilepsy
Adolescence-Adult
Juvenile absence epilepsy
Juvenile myoclonic epilepsy
Epilepsy with generalized tonic-clonic seizures alone
Progressive myoclonus epilepsies
Autosomal dominant partial epilepsy with auditory features
Other familial temporal lobe epilepsies
LESS SPECIFIC AGE RELATIONSHIP
Familial focal epilepsy with variable foci (childhood to adult)
Reflex epilepsies
DISTINCTIVE CONSTELLATIONS
Mesial temporal lobe epilepsy with hippocampal sclerosis
Rasmussen's syndrome
Gelastic seizures with hypothalamic hamartoma
Hemiconvulsion-hemiplegia-epilepsy

Some Specific Seizure Syndromes and Constellations

Neonatal and Infantile Epilepsy Syndromes

Benign neonatal convulsions occur in previously healthy newborns on about day 5 as focal or generalized tonic seizures. Mutations in two potassium channel genes (*KCNQ2*, *KCNQ3*) have been associated with this syndrome. Potassium-channel regulation may be age dependent and therefore account for the age-related appearance of the seizures. The EEG shows rhythmic slow-wave activity or spiking with seizures. The seizures are refractory to treatment, are recurrent over a brief interval, and disappear within a month. About 90% of such infants subsequently have normal development, whereas 10% have subsequent seizures.

Generalized epilepsy with febrile seizures plus is a syndrome that consists of febrile seizures in combination with other nonfebrile types of seizures, including myoclonic, absence, atonic, tonic-clonic, and focal seizures. Mutations in at least four different voltage-gated ion channel and GABA receptors genes have been identified.

Dravet's syndrome (severe myoclonic epilepsy of infancy) starts in the first year of life with myoclonic seizures plus other seizure types, including absence, atonic, and focal. In this devastating syndrome, the seizures are resistant to treatment and are accompanied by developmental and cognitive decline. Mutations in the *SCN1A* sodium channel have been identified.

West's syndrome comprises a triad of epileptic spasms, developmental arrest, and an EEG pattern called hypsarrhythmia (a markedly abnormal EEG pattern with high-amplitude slowing and superimposed multifocal spikes, polyspikes, and spike and slow-wave complexes). It appears before the age of 12 months and ceases by 5 years of age, often to be replaced by other epilepsy syndromes such as Lennox-Gastaut syndrome. Tuberous sclerosis (Chapter 426) and hypoxia are among the common causes, but a cause may not be found. Associated abnormalities often include developmental delay, porencephaly, atrophic lesions, calcifications, and agenesis of the corpus callosum.

Childhood Epilepsy Syndromes

Childhood absence epilepsy begins before age 12 years, and its onset peaks at age 5 to 7 years, with a strong genetic tendency. It is more common in girls

than boys and is characterized by very frequent daily absence seizures (up to hundreds per day), rarely with other types of generalized seizures. It occurs in the setting of otherwise normal brain structure and function, and it is self-limited in about 40% of cases. The seizures are accompanied by a characteristic 3-Hz spike-and-wave EEG discharge, which appears in short bursts between seizures and in continuous runs during seizures. Remission usually occurs before the age of 12 years, but generalized tonic-clonic seizures occasionally may develop in adolescence.

Lennox-Gastaut syndrome is one of the most severe childhood epilepsies. It starts before age 8 years (peak from 3 to 5 years) and is characterized by a triad of mental retardation, multiple types of generalized seizures (atypical absence, generalized tonic-clonic, tonic, atonic), focal seizures that are highly resistant to treatment, and a typical EEG pattern of slow spike and wave (slower than the typical 3 Hz associated with absence seizures) and bursts of fast rhythms at 10 to 12 Hz during sleep. It often follows the resolution of West's syndrome.

Benign epilepsy with centrotemporal spikes (*benign rolandic epilepsy*) starts between 3 and 13 years of age and is characterized by almost exclusively nocturnal focal motor or sensory seizures that have a facial or oral onset and often evolve to convulsive seizures. Nearly 50% of cases have a family history of epilepsy, but most patients have no known brain abnormality. The EEG shows spiking in the centrotemporal region. In some cases, the disorder may not require treatment because it usually remits spontaneously.

Adolescence and Adult Epilepsy Syndromes and Constellations

Juvenile myoclonic epilepsy usually starts in the second decade with generalized tonic-clonic and myoclonic seizures. Mutations in GABA receptors, including *GABRG1,* can be found. Seizures typically occur in the morning, immediately after awakening. The seizures are especially linked to sleep deprivation and tend to appear in college students. A proportion of these patients have had absence seizures as well. The EEG typically shows fast (4 to 6 Hz) generalized spike and wave. Lifetime treatment is generally needed.

Mesial temporal lobe epilepsy with hippocampal sclerosis is the most common epilepsy to produce focal dyscognitive seizures in adults. It is characterized by recurrent focal limbic seizures (see Table 410-2), with and without impaired awareness, that originate in mesial temporal and limbic structures. Up to 70% of patients have a risk factor, such as lengthy and complicated seizures before the age of 4 years, frequently associated with fever or with encephalitis, meningitis, or trauma. However, the characteristic seizures generally begin some years later. Most cases are sporadic, but there are familial forms of mesial temporal lobe epilepsy.

Various components of the mesial temporal limbic network (including the hippocampus, entorhinal cortex, amygdala, neocortical areas of the frontal and temporal lobes, and dorsal medial thalamus) are probably involved in the pathogenesis of these seizures. Mesial temporal sclerosis, also called hippocampal sclerosis, is characterized by neuronal loss and gliosis, mostly in the CA1 and CA3 regions of the hippocampus, with mossy fiber reorganization that is seen as sprouting of neuropeptide Y and dynorphin interneurons into the inner third of the dentate molecular layer. Whether hippocampal sclerosis is the cause or the result of seizures (or both) is not known. The seizures of mesial temporal lobe epilepsy often begin at 5 to 15 years of age. Seizures are typically dyscognitive with limbic symptoms; they begin with an aura of a rising epigastric sensation or a feeling of déjà vu, followed by oral and alimentary automatisms and later by contralateral arm dystonia and ipsilateral arm automatisms. The seizures are lengthy (lasting several minutes), rarely generalize, and typically occur three to five times a month. Auras without subsequent seizures are common. Hippocampal atrophy and increased hippocampal signal are best seen on T2-weighted and FLAIR coronal MRI sequences, and widespread interictal hypometabolism is seen in the temporal lobe on PET. Material-specific (verbal or visual) memory impairment corresponds to primary involvement of the dominant or nondominant hippocampus. EEG recordings show temporal lobe spikes interictally as well as rhythmic 4- to 7-Hz discharges over the appropriate temporal lobe during seizures.

Seizures with Less Specific Age Relationship

Reflex seizures are triggered reliably by specific simple (e.g., flashing lights) or elaborate (e.g., reading) stimuli. The mechanisms are diverse and may involve cortical and brain stem pathways, cortical dysregulation of extracellular calcium concentrations, and an imbalance between excitatory and inhibitory neurotransmitters. Visual-sensitive seizures (triggered by light or visual patterns) are the most common type of reflex seizures. They occur most commonly in females, and their incidence peaks around puberty, when they represent up to 10% of all new cases of epilepsy. Other triggers of reflex seizures include specific thoughts, actions, reading, tactile stimuli, adopting certain positions, eating, listening to music, startle, and contact with hot water. The triggered seizures can be myoclonic, convulsive, atonic, or focal, depending on the triggering stimulus. Avoiding the offending stimulus is crucial to avoid seizures, emphasizing the importance of careful questioning about seizure triggers in patients with epilepsy.

TREATMENT Rx

The treatment of seizures and epilepsy is guided by accurate knowledge of the type of seizure and epileptic syndrome, the probability of recurrent seizures, the likelihood and severity of psychosocial or physical consequences with further seizures, and whether the benefit from treatment substantially outweighs the risks for side effects. It is important to identify and correct any environmental, physiologic, or lifestyle factors, such as sleep deprivation and irregular sleep habits, that can lower the seizure threshold and trigger seizures in patients with epilepsy.

Single Unprovoked Seizures

The decision to treat single unprovoked seizures depends on the likelihood of recurrence according to prognostic variables (see Prognosis) and on the individual patient's profile and preference. A meta-analysis demonstrated that antiepileptic drug treatment after a first seizure reduces the absolute risk of having a second seizure in the short-term by 33%, corresponding to a number needed to treat (NNT) of 3.[1] However, at least two randomized trials have shown that treatment of the first seizure with antiepileptic drugs does not prevent the development of epilepsy in the long term.[2,3] Therefore, the decision to treat the first seizure should be individualized based on the patient's preference, the risk for and impact of recurrent seizures (e.g., driving and employment), and the risk for medication side effects.

Acute Symptomatic (Provoked) Seizures

Seizures that are provoked by specific exposures are usually self-limited and not associated with an enduring seizure tendency, so the primary therapeutic consideration should be identification and treatment of the underlying disorder (see Table 410-1). If antiepileptic drugs are needed to treat seizures acutely, they usually can be discontinued after the patient has recovered from the primary illness. Some acute conditions like stroke (Chapter 414), brain infections (Chapters 420 and 422), and trauma (Chapter 406) can produce both acute symptomatic seizures and an enduring seizure tendency, so it would seem logical to use long-term antiepileptic drug treatment. To date, however, randomized controlled trials have not been able to demonstrate that antiepileptic drugs prevent the development of epilepsy in these conditions, so long-term therapy is not recommended unless epilepsy develops.

Epilepsy Syndromes with a Favorable Course

In syndromes such as benign epilepsy of childhood with centrotemporal spikes and some types of childhood occipital epilepsy, seizures are mild, infrequent, or exclusively nocturnal, and they remit spontaneously, thereby making treatment generally unnecessary. In selected cases, treatment may be desirable to prevent recurrences and to help alleviate parental concerns. In such cases, drug treatment is usually limited to 1 to 2 years regardless of interictal EEG abnormalities, which can persist long after seizures have remitted. The recommended antiepileptic drugs are those used in focal epilepsy in children, including oxcarbazepine, carbamazepine, valproate, gabapentin, lamotrigine, and topiramate (Table 410-7). Some patients with reflex seizures may require antiseizure medication, which should be chosen according to seizure type (Table 410-8).

Choice of Antiepileptic Drugs

The ultimate goal of treatment is to obtain complete freedom from seizures without side effects. Some of the newer antiepileptic drugs (see Table 410-7) are better tolerated and have better pharmacokinetics than older drugs, but there is no robust evidence to support superior efficacy of one drug over another.[3,4] The choice of medication depends on the type of seizure, thereby making a correct diagnosis crucial, and the medication's side effects, cost, and ease of use. Specific drugs are effective for specific types of seizures, and some drugs can worsen other types of seizures. Knowledge of individual drugs as they relate to age, sex, comorbid conditions, drug interactions, sedation, tolerance, mood, and withdrawal is critical in the drug selection process (see Table 410-8).[3,4] For example, ethosuximide and valproic acid are more effective than lamotrigine for the treatment of childhood absence epilepsy.[5]

Drugs that cause enzyme induction (e.g., carbamazepine, phenytoin, phenobarbital, oxcarbazepine, topiramate) or inhibition (e.g., valproic acid) can be difficult to manage when additional medications, such as oral contraceptives, are used for independent conditions. For these settings and in elderly patients, gabapentin and levetiracetam are particularly useful because they have no appreciable drug interactions.

TABLE 410-7 CHARACTERISTICS OF MAJOR ANTIEPILEPTIC DRUGS

NAME	TOTAL MILLIGRAMS PER DAY (USUAL SCHEDULE)	THERAPEUTIC RANGE (μG/mL)	PROMINENT SIDE EFFECTS	OTHER EFFECTS	OTHER ISSUES
Carbamazepine	400-1600 (bid)	4-12	Diplopia, fatigue, hyponatremia	Mood stabilizer	Enzyme inducer
Ethosuximide	750-1250 (qd, bid)	40-100	Ataxia, lethargy	Skin rash, bone marrow suppression	
Gabapentin	600-6000 (tid, qid)	2-12	Fatigue	Treatment of pain	No drug interactions
Lamotrigine	100-600 (bid)	4-18	Insomnia, headache, tremor, anxiety	Mood stabilizer	Risk for Stevens-Johnson syndrome; slow start-up
Levetiracetam	500-3000 (bid)	3-63	Mood change, irritability, lethargy		No drug interactions
Oxcarbazepine	300-2400 (tid)	6-40	Diplopia, hyponatremia, sedation	Mood stabilizer	
Phenobarbital	60-240 (hs)	15-40	Fatigue, depression, sedation	Joint pain	Enzyme inducer
Phenytoin	200-600 (bid)	10-20	Fatigue, hirsutism, gingival hypertrophy	Treatment of some pain	Enzyme inducer
Topiramate	50-600 (bid)	2-12	Anorexia, weight loss, kidney stones, speech disturbance, distal paresthesias	Headache prophylaxis, mood stabilizer	Enzyme inducer
Valproate	500-6000 (tid)	50-100	Weight gain, hair loss, tremor	Headache prophylaxis, mood stabilizer	Enzyme inhibitor, parkinsonian effects in elderly patients
Zonisamide	100-600 (hs)	10-40	Anorexia, kidney stones, dizziness, distal paresthesias	Mood stabilizer	

TABLE 410-8 ANTIEPILEPTIC DRUG SELECTION BY SEIZURE TYPE

SEIZURE TYPE	COMMONLY USED (ALPHABETICAL ORDER)	LESS COMMONLY USED (ALPHABETICAL ORDER)	*Effectiveness (Grade A Recommendation)**	
			NEW-ONSET SEIZURES	REFRACTORY SEIZURES
Focal seizures with or without dyscognitive features or evolution to convulsions	Carbamazepine (CBZ) Gabapentin (GBP) Lamotrigine (LTG) Levetiracetam (LEV) Oxcarbazepine (OXC) Phenytoin (PHT) Tiagabine (TIAG) Topiramate (TPM) Valproate (VPA) Zonisamide (ZNS)	Acetazolamide (ACZ) Clonazepam (CLN) Clorazepate (CLZ) Phenobarbital (PB) Primidone (PRM) Felbamate (FBM)	CBZ* GBP* LTG* OXC* PB* PHT* TPM* VPA*	CBZ† GBP* LAM* LEV* OXC* PB† PHT† TIAG* TPM* VPA† ZNS*

*Supported by class I evidence (American Academy of Neurology).
†Often the "standard" of comparison, without evidence of effectiveness by randomized controlled trials.

In patients with newly diagnosed focal epilepsy, the underlying cause influences the response to antiepileptic drugs. The likelihood of achieving seizure freedom is higher for patients with vascular malformations, stroke, and tumors (63 to 78%), and lower for patients with hippocampal sclerosis and malformations of cortical development (40 to 50%). Among patients presenting with a new diagnosis of epilepsy, about 65% achieve seizure remission on antiepileptic drug treatment. Of these patients, about 45 to 50% achieve seizure remission with the first antiepileptic drug, 10 to 15% with the second, 1% with the third, and 3% with a combination of two or more antiepileptic drugs. Because the likelihood of achieving subsequent seizure remission is small if two drug trials fail, the 35% or so of patients who fail adequate trials of two antiepileptic drugs are considered to be *drug resistant*. In these patients, other forms of treatment, including surgery, should be considered. The first consideration in managing apparently drug-resistant patients is to ensure that the diagnosis is correct and the antiepileptic drug is appropriate. Other common issues include poor adherence to antiepileptic drugs, sleep deprivation, alcohol use, fatigue, emotional stress, systemic illnesses, use of concurrent medications, and nonepileptic seizures. After addressing these factors, patients who remain drug resistant should be considered potential candidates for surgical therapy.

Surgical Treatment

Surgical treatment entails resection or disconnection of the cerebral region that contains the seizure focus. Removal of an epileptogenic region requires accurate identification of the region as well as documentation of a lack of functional consequences after its removal. Video EEG monitoring with seizure recording from scalp electrodes, MRI protocols with special attention to areas

commonly associated with refractory seizures (e.g., the medial temporal and frontal lobes), and functional neuroimaging, including PET and SPECT, are used to make the assessment. In temporal lobe epilepsy, neuropsychological evaluation is essential to localize dysfunction and to establish the level of function in the region considered for resection. EEG localization of the region of seizure onset and mapping of brain function may require the surgical implantation of intracranial electrodes for recording and for stimulating cortical tissue. These procedures are performed by multidisciplinary teams in specialized epilepsy centers.

Epilepsy surgery interventions that have been subjected to rigorous randomized trials include temporal lobe resection compared with medical therapy for mesial temporal lobe epilepsy, comparison of different amounts of temporal lobe resection, different intensities of vagus nerve stimulation, and thalamic stimulation compared with medical therapy. The most dramatic surgical effect is seen for temporal lobe resection compared with medical therapy. In one series, 58% of surgical patients and only 8% of medical patients became seizure free (NNT of 2 at 1 year).■ As a result, patients with drug-resistant temporal lobe epilepsy should be evaluated for epilepsy surgery. Nonrandomized studies demonstrate enduring freedom from seizures at 10 years or more after hemispheric disconnection (61%), temporal lobe resection (64%), parieto-occipital resection (46%), and frontal lobe resection (27%). Palliative surgical procedures, such as callosotomy and multiple subpial transections, have lower success rates and are used when surgical resection of the seizure focus is not possible. Promising surgical therapies for epilepsy include radiosurgery and various types of electrical stimulation of the brain.

Status Epilepticus

Status epilepticus is a medical emergency in which seizures occur continuously or repeatedly without intervening resumption of consciousness for 30 minutes. However, even 5 minutes of generalized tonic-clonic seizures cause hypoxia, lactic acidosis, muscle breakdown, and neuronal damage. Most episodes of status epilepticus are caused by an acute brain insult in people without underlying epilepsy, so a cause should be sought promptly. After securing the airway and stabilizing cardiovascular function, immediate intervention with parenteral agents is needed to stop the seizures. Intravenous lorazepam (0.1 mg/kg given at 2 mg per minute) is the emergent treatment of choice, followed by intravenous phenytoin (15 mg/kg at a rate of 50 mg per minute) or fosphenytoin (15-20 mg/kg at a rate of 150 mg per minute) to provide a more long-lasting effect. If seizures continue for 10 to 15 minutes, options include phenobarbital (20 mg/kg intravenously) or continuous intravenous midazolam (0.1 to 2 mg/kg/hour), pentobarbital (0.5 to 3 mg/kg/hour), or propofol (2 to 4 mg/kg/hour), most appropriately in an intensive care setting. In refractory cases, general anesthesia for 24 hours is used.

Considerations in Women

Changes in hormone levels during the menstrual cycle may aggravate seizures perimenstrually in some women (i.e., catamenial epilepsy). The administration of oral contraceptives (Chapter 246), Depo-Provera, or acetazolamide (250 to 500 mg per day) may reduce perimenstrual seizures. Enzyme-inducing antiepileptic drugs (see Table 410-7) that reduce estrogen levels by enhancing its metabolism require patients to be treated with higher doses of estrogen or alternative methods of contraception.

Pregnancy poses challenges with regard to seizure control, teratogenesis, and outcomes of pregnancy. Nevertheless, pregnancy itself has no consistent effect on the frequency of seizures, and more than 90% of pregnancies in women with epilepsy are safe and successful. Freedom from seizures for at least 9 months preceding pregnancy is associated with a high probability of freedom from seizures during the pregnancy. Serum levels of lamotrigine, phenytoin, carbamazepine, levetiracetam, and oxcarbazepine may change during pregnancy and should be monitored. To reduce the risk for major congenital malformations, the use of valproate should be avoided if seizure control permits it. Similarly, polytherapy and high doses of antiepileptic drugs should be avoided, if possible, but antiepileptic drugs should not be discontinued. There is no increased risk for cesarean section or premature contractions, and epilepsy itself does not increase the risk for cognitive impairment in the child. Supplementation with at least 0.4 mg of folic acid daily should be given before conception and during pregnancy to reduce the risk for neural tube defects.

Discontinuing Antiepileptic Drugs

About 60% of patients have seizures that are easy to control with antiepileptic drugs. Medications may be slowly tapered over 4 to 6 months in patients who have remained free of seizures for 2 years or longer, have had few seizures before treatment started, and who have a normal neurologic examination and EEG. However, the increased absolute risk for recurrent seizures after withdrawal of medication is about 20% (number needed to harm of 5). The consequences of a recurrent seizure, the costs and side effects of drugs, and aspects such as personal preferences influence the decision to withdraw antiepileptic drugs in patients who have been free of seizures.

PROGNOSIS

The prognosis is favorable in the majority of patients who experience either unprovoked seizures or one of the epilepsies.

Prognosis after Febrile Seizures

Febrile seizures are common and usually consist of generalized tonic-clonic seizures. They are provoked by fever and therefore are not considered epilepsy. The seizures begin after 6 months of age and stop before 6 years of age. Usually, febrile seizures are left untreated because the prognosis is benign. When febrile seizures occur in the setting of a neurologic abnormality or are prolonged or complicated, the risk for later epilepsy is increased.

Prognosis after a Single Unprovoked Seizure

The risk of experiencing recurrent seizures after a first unprovoked seizure ranges from 21 to 69% at 2 years and from 34 to 70% at 5 years. The risk is lower in the general population than in hospital-based studies (36% at 1 year and 45% at 2 years). The probability of a relapse decreases with time; about 50% of recurrences occur within 6 months of the initial seizure, and 76 to 96% occur within 2 years. The two most consistent predictors of recurrence are the presence of a neurologic cause for the seizure, which is often uncovered on brain MRI or by the neurologic examination and history, and an epileptiform or slow EEG. The 2-year risk for recurrence is lowest for patients without an identified neurologic cause and with a normal EEG (about 25%), intermediate for patients with an identified neurologic cause or without a cause but with an abnormal EEG (48%), and highest for those with a neurologic cause and an abnormal EEG (about 65%). The risk rises dramatically if more than one seizure has occurred; after a second unprovoked seizure, the risk for a third seizure is 73%, and after a third seizure, the risk for a fourth seizure is 76%.

Prognosis of Epilepsy

The natural history of untreated epilepsy, mostly in developing countries, shows that 30 to 40% of patients obtain 5- to 10-year remissions without treatment. In developed countries, where treatment is generally started after two unprovoked seizures have occurred, the likelihood of 5-year remission is about 60% when patients are followed for 10 years, and about 70% when patients are followed for 20 years. The rate of 5-year remission in children is about 75%.

Conversely, the duration of active epilepsy before achieving control is one of the most powerful predictors of remission. If seizures remain uncontrolled during the first year after diagnosis, the chance of ever achieving control is only 60%. If the period of uncontrolled seizures extends to 4 years, the chance of ever achieving control is only 10%. The presence of multiple seizure types and frequent generalized tonic-clonic seizures is associated with a lower likelihood of remission. Less than 40% of patients with newly diagnosed mesial temporal lobe epilepsy will be controlled with medications, although familial cases are more easily managed medically.

Patients with epilepsy are at risk for poor psychosocial outcomes, depression, and increased mortality. The risk for death is two to three times higher in epilepsy than in the general population, and it can be up to six times higher in patients with frequent generalized convulsions and drug-resistant epilepsy. The major causes of death are underlying conditions such as stroke and pneumonia. Sudden unexpected death in epilepsy occurs in 1 per 1000 patient years and is particularly devastating because it affects young individuals with frequent, uncontrolled seizures.

COMA, VEGETATIVE STATE, AND BRAIN DEATH

JAMES L. BERNAT

Assessment and treatment of a comatose patient are among the most challenging and critical activities in clinical medicine. Physicians must systematically and rapidly identify the cause of coma while simultaneously supporting vital systems and reversing the pathologic process. For example, resuscitation from cardiac arrest (Chapter 63) is successful only if the brain is not irreversibly damaged by a hypoxic-ischemic injury that can cause a vegetative state or brain death.

Coma, stupor, the vegetative state, and the minimally conscious state are disorders of consciousness (Table 411-1) that must be differentiated from brain death and locked-in syndrome. Human consciousness has two measurable clinical dimensions that correspond to two distinct brain neuronal systems: (1) wakefulness, which is the organism's arousal and readiness to respond to internal or external stimuli and which is provided by the reticular system of the rostral brain stem and its thalamic and forebrain ascending projections, and (2) awareness of self and environment, which is provided by a diffuse parallel network of thalamocortical and corticocortical circuits. Wakefulness is a prerequisite for awareness, but as exemplified by patients in a vegetative state, awareness may be lost despite maintained wakefulness.

Consciousness is usually considered a global brain function. Focal cerebral hemispheric lesions (Chapters 403 and 413) may disturb fragments of consciousness and produce disturbances such as aphasia, apraxia, or agnosia. Although language, praxis, and gnosis are elements of normal consciousness, their selective loss does not usually result in a diminution of the quantity of consciousness, so these focal syndromes are not classified as disorders of consciousness.

COMA

Coma is a pathologic state of eyes-closed unresponsiveness in which the patient has neither awareness nor wakefulness and from which the patient cannot be aroused to awareness or wakefulness by vigorous stimuli. Stupor is a similar disorder in which stimuli can temporarily arouse the patient to limited responsiveness but, in the absence of stimuli, the patient returns to an unresponsive state. Sleep, by contrast, is a normal state of active cyclic unconsciousness from which subjects can be fully and persistently aroused to full normal consciousness.

Coma is not a univocal state; it has levels of depth depending on the degree of reflex response to stimulation. Disorders of consciousness comprise a continuum from the mildest state of lethargy to the deepest stage of coma. Obtundation is a nonspecific term that describes any degree of altered consciousness without stipulating its depth.

EPIDEMIOLOGY

The frequencies of the various causes of coma vary widely depending on the setting. In most settings, however, post-traumatic, metabolic, anoxic, and toxic causes are the most common (Table 411-2).

PATHOBIOLOGY

Wakefulness is provided by a network of neurons and their connections in the central tegmentum of the pons and midbrain (reticular system) that receives input at each level as it ascends into the central basal forebrain, thalamus, and cerebral cortex. Damage to this neuronal network by trauma, ischemia, hypoxia, edema, or metabolic or toxic insults leads to coma because the ascending arousal mechanism is disturbed.

Awareness of self and environment requires not only wakefulness but also normal functioning of massive parallel reverberating neuronal circuits between the thalamus and multiple cortical regions to provide an integrated and unified experience. These structures and their connections can be damaged by the same pathologic conditions that affect the arousal system, but thalamic and cortical neurons are more susceptible to damage because of their higher metabolic demands. A given global brain insult, such as systemic hypoxia and ischemia suffered during cardiac arrest, can selectively damage the cortical and thalamic neurons necessary for awareness while largely sparing the phylogenetically older and less metabolically demanding neurons of the arousal network of the reticular system. This selective damage can result in the vegetative state, which is characterized by wakefulness without awareness.

Coma can be caused by (1) structural damage as a result of brain trauma, edema, inflammation, ischemia, or mass lesions or (2) diffuse metabolic and toxic effects on brain neurons. Structural lesions can affect the arousal neuronal network of the brain stem and basal forebrain directly through local neuronal damage or indirectly by downward or lateral pressure or displacement that causes local ischemia. Metabolic and toxic encephalopathies diffusely affect all brain neurons, particularly the metabolically sensitive cortical and thalamic neurons.

Structural lesions that cause coma typically produce clinically recognizable syndromes of cerebral "herniation" in which intracranial pressure shifts produce caudal displacement and ischemia of the midbrain and medial temporal lobe through the tentorial incisura and induces dysfunction of cranial nerves, breathing, and motor systems. Central transtentorial herniation from slowly expanding axial lesions is uncommon; more common is uncal herniation from rapidly expanding and laterally placed lesions that trap the ipsilateral oculomotor nerve against the uncus of the temporal lobe. Lateral displacement of brain structures can supplement or exceed downward displacement. The ascending arousal system can also be damaged directly by primary brain stem catastrophes such as pontomesencephalic hemorrhage or infarction or indirectly by downward-directed pressure waves produced by hemispheric mass lesions such as from brain trauma (Chapter 406) or supratentorial neoplasms (Chapter 195), abscesses (Chapter 421), hemorrhages (Chapter 415) or large infarctions (Chapter 414).

Metabolic encephalopathies disturb the neuronal microenvironment by altering the precise metabolic conditions necessary for normal neuronal excitability. Disturbances in the neuronal milieu can be caused by alterations in blood flow, oxygen delivery, glucose concentration, temperature, electrolyte concentrations, and intracranial pressure, as well as by meningitis, seizures, and organ failure. The depth of the resulting alteration of consciousness depends on the severity of the metabolic disturbance: mild metabolic encephalopathies can cause slowness or lethargy, whereas severe metabolic encephalopathies can produce deep coma. The rapidity of onset is of particular importance. A sudden drop in the serum sodium concentration (Chapter 118) may result in coma and seizures, whereas a slow decline to an equivalent level may not. Toxic encephalopathies can be caused by poisoning with exogenous agents such as depressant drugs or by endogenous toxins resulting, for example, from renal or hepatic failure and produce the same continuum of severity. Acute meningeal inflammation, caused most commonly by bacterial meningitis, induces coma by a combination of inflammatory and vascular changes.

TABLE 411-1 COMPARISON OF DISORDERS OF CONSCIOUSNESS*

	AWARENESS	WAKEFULNESS	BRAIN STEM/ RESPIRATORY	MOTOR	EEG	EVOKED POTENTIALS	PET/FMRI	COMMENT
Brain death	Absent	Absent	Absent	Absent	ECS	Absent	Absent cortical metabolism	Legally dead in most jurisdictions
Coma	Absent	Absent	Depressed, variable	Reflex or posturing	Polymorphic delta, burst suppression	BAER variable; cortical ERPs often absent	Resting <50%	Prognosis variable
Vegetative state	Absent	Present, intact sleep-wake cycles	Intact	Reflex, nonpurposeful	Delta, theta, or ECS	BAER preserved; cortical ERPs variable	Resting <50%; primary areas stimulatable	Prognosis variable
Minimally conscious state	Intact but poorly responsive	Intact	Intact	Variable with purposeful movements	Nonspecific slowing	BAER preserved; cortical ERPs often preserved	Reduced; secondary areas also stimulatable	Prognosis variable
Locked-in syndrome	Intact but communication difficult	Intact	Intact breathing; often brain stem signs	Quadriplegia, pseudobulbar palsy	Usually normal	BAER variable; cortical ERPs normal	Normal or nearly normal	Not a disorder of consciousness

*The table lists typical findings, which are not necessarily present in all patients.
BAER = brain stem auditory evoked response; ECS = electrocerebral silence; EEG = encephalography; ERP = event-related potential; fMRI = functional magnetic resonance imaging; PET = positron emission tomography.

TABLE 411-2 CAUSES OF STUPOR AND COMA

- Traumatic brain injury*
  - Contusion
  - Intracerebral, epidural, subdural, or subarachnoid hemorrhage
  - Raised intracranial pressure
- Neoplasms and other mass lesions
- Infections
  - Meningitis
  - Encephalitis
  - Brain abscess or empyema
  - Sepsis or other infection, especially in the elderly or a demented patient*
- Cerebrovascular disease
  - Subarachnoid hemorrhage
  - Infarction in the brain stem or cerebellum or large hemispheric infarction
  - Hemorrhage in the brain stem or cerebellum or large hemispheric hemorrhage
  - Vasculitis, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura
- Seizures
  - Status epilepticus
  - Spike-wave stupor
  - Postictal state
- Metabolic encephalopathies*
  - Hypoglycemia, hyperglycemia
  - Hypercalcemia
  - Hyponatremia, hypernatremia
  - Hypoxemia, including anoxia after cardiac arrest
  - Acidosis
  - Organ system failure: hepatic, renal, pulmonary, cardiac
  - Endocrinopathy, e.g., myxedema coma
- Toxic encephalopathies
  - Drug intoxications*: alcohol, barbiturates, benzodiazepines, opioids, stimulants, salicylates, anticonvulsants, anticholinergics, psychotropic drugs, or others
  - Poisoning: carbon monoxide, industrial toxins
- Other encephalopathies
  - Hypertensive encephalopathy
  - Acute hydrocephalus
  - Pituitary apoplexy
- Other
  - Conversion, malingering, catatonia

*Most common causes.

TABLE 411-3 FOUR SCORE COMA ASSESSMENT SCALE*

EYE RESPONSE

E4 = Eyelids open or unopened, tracking or blinking to command
E3 = Eyelids open but not tracking
E2 = Eyelids closed but open to pain
E1 = Eyelids remain closed with pain stimuli

MOTOR RESPONSE

M4 = Thumbs up, fist, or peace sign
M3 = Localizing to pain
M2 = Flexion response to pain
M1 = Extension response to pain
M0 = No response to pain or generalized myoclonic status epilepticus

BRAIN STEM REFLEXES

B4 = Pupillary and corneal reflexes present
B3 = One pupil dilated and unreactive to light
B2 = Pupillary or corneal reflexes absent
B1 = Pupillary and corneal reflexes absent
B0 = Absent pupillary, corneal, or cough reflexes

RESPIRATION

R4 = Regular breathing pattern
R3 = Cheyne-Stokes breathing pattern
R2 = Irregular breathing pattern
R1 = Triggers or breathes above the ventilator rate
R0 = Apnea or breathes at the ventilator rate

*For nontraumatic coma and other disorders of consciousness.
From Wijdicks EFM. *The Comatose Patient*. New York: Oxford University Press; 2008:72a.

CLINICAL MANIFESTATIONS

A comatose patient is unresponsive and cannot be aroused to awareness or wakefulness. The level of consciousness can be assessed by loudly speaking the patient's name directly in the ear. Patients should be asked to look up and down to test for locked-in syndrome, in which vertical eye movements may be the only remaining voluntary movement. Noxious stimuli can be applied to elicit responses. Tickling the nasal hairs with a cotton-tipped swab is especially useful because it elicits primitive reflex mechanisms to protect the airway. Many painful stimuli should be avoided as unnecessary and cruel, but a sternal rub with fingers or knuckles is acceptable. Responses can be graded as voluntary movement, withdrawal, reflex posturing, and none.

Coma assessment scales are useful to describe the depth of coma, serially assess changes, and by correlation to outcomes, provide a prognosis. The widely used Glasgow Coma Scale (see Table 406-1) was devised to assess patients with traumatic brain injury. The FOUR Score scale is more useful for all causes of coma because it more accurately assesses brain stem function and quantifies awareness (Table 411-3).

DIAGNOSIS

The diagnosis of coma requires a rapid history, physical and neurologic examination (Table 411-4), laboratory tests, and neuroimaging studies, during which patient's vital functions must be supported. Immediate attention should be paid to whether the patient has signs of meningitis (e.g., fever, nuchal rigidity) or head trauma (Chapter 406) or focal findings suggestive of

a mass, lesion, bleeding, or ischemic injury. If signs of meningitis are present, a lumbar puncture should be performed without the delay of obtaining brain imaging if no marked focal signs (e.g., hemiparesis) are present. Brain computed tomography (CT) should be performed urgently in nearly every patient in coma.

The relevant history includes eyewitness accounts of any preceding headache, vomiting, confusional state, prescription and street drug use, alcohol consumption, diabetes, fever, head trauma, seizure activity, and medical illnesses, especially atrial fibrillation. The rate at which neurologic function declined can be especially helpful. On the general physical examination, assessment of vital signs, otoscopy, optic funduscopy, and inspection for head trauma, nuchal rigidity, and needle tracks can provide key findings.

TABLE 411-4 SOME INITIAL CLINICAL CLUES TO THE DIAGNOSIS OF STUPOR AND COMA

STRUCTURAL CAUSES
History
Abrupt onset of unconsciousness
Sudden headache
Vomiting
Examination
Focal neurologic signs (hemiparesis, posturing, asymmetrical reflexes)
Abnormal pupillary light reflexes
METABOLIC OR TOXIC CAUSES
History
Gradual onset of unconsciousness
Preceding confusional state
Seizures
Known cognitive impairment
Taking insulin or street drugs
Examination
Absence of focal neurologic signs
Presence of frontal release signs
Intact pupillary light reflexes
Tremor, asterixis, or multifocal myoclonus
Evidence of systemic infection
Needle tracks
MENINGITIS
History
Worsening headache
Neck stiffness and pain
Fever, chills
Progressive stupor and coma
Examination
Fever, rigors
Nuchal rigidity and signs of meningeal inflammation

Oximetry and a finger stick blood glucose assessment should be performed immediately. Emergency laboratory testing should generally include a complete blood count, serum electrolytes, a blood glucose level, tests of renal and liver function, coagulation tests, thyroid function tests, arterial blood gas analysis, a blood alcohol concentration, a urine drug screen, and an electrocardiogram.

The neurologic examination focuses on five systems whose careful assessment can distinguish structural from metabolic causes of coma and delineate the functional brain level caused by the pathologic process: the respiratory rate and pattern; the pupils' size, shape, and reactivity; eye movements and vestibulo-ocular reflexes; and motor responses to stimuli (Table 411-5).

The respiratory rate and pattern should be observed for 30 to 60 seconds. The earliest abnormalities seen in patients with altered consciousness are yawning, sighing, and posthyperventilation apnea, which occurs especially in those with metabolic encephalopathies. Stuporous patients should be asked to take five deep breaths and then be observed for the duration of subsequent apnea, which is normally less than 5 seconds. Cheyne-Stokes respiration (Chapter 86) is a periodic form of breathing whose amplitude forms a sine wave, with 5- to 45-second periods of apnea punctuating periods of hyperpnea; it is seen in the metabolic encephalopathies, especially those caused by heart failure, and during sleep. Central neurogenic hyperventilation, which is continuous hyperpnea and tachypnea that produces a pure respiratory alkalosis, occurs with lesions of the rostral brain stem tegmentum at the midbrain level; rapid, deep breathing (Kussmaul) that is compensating for a severe metabolic acidosis (Chapter 236) can look similar. Apneustic breathing, which is characterized by a prolonged inspiratory pause, is seen with pontine lesions. Ataxic breathing is an irregular and agonal sign of medullary failure.

Pupillary size and reactivity to a bright light stimulus can be assessed to evaluate the integrity of the optic and oculomotor nerves, the midbrain, and the sympathetic nerves. The reactivity of the pupils to light is an important sign that discriminates structural coma from metabolic-toxic coma. The pupils remain reactive through varying depths of metabolic-toxic coma, often until apnea ensues, whereas pupillary reflexes are lost earlier in structural coma that is caused by transtentorial herniation. The pupils are small, equal, and reactive in patients with metabolic encephalopathies. When the oculomotor nerve or the midbrain is involved, the ipsilateral pupil becomes unreactive to light because of damage to the parasympathetic pupilloconstrictors and dilates because of unopposed sympathetic pupillodilators. When herniation proceeds further, the brain stem sympathetic tracts are also damaged, so the pupil returns to midposition and becomes unreactive to light or dark. Lesions that affect only the pons and not the midbrain, such as pontine hemorrhage or infarction, can cause pinpoint pupils whose intact reaction to light can be seen with a magnifying glass. Preexisting disease (e.g., diabetes) or locally applied eye medications can also impair pupillary reflexes.

TABLE 411-5 BRAIN FUNCTIONAL LEVELS DETERMINED BY FINDINGS IN FIVE CLINICAL SYSTEMS

FUNCTIONAL LEVEL	CONSCIOUSNESS	RESPIRATION	PUPILS	VESTIBULO-OCULAR REFLEXES	MOTOR RESPONSES
CENTRAL TRANSTENTORIAL HERNIATION					
High diencephalic	Light stupor	Eupnea, yawning, posthyperventilation apnea	Small, reactive	Loss of checking component	Paratonia, grasp
Low diencephalic	Deep stupor	Cheyne-Stokes	Small, reactive	Loss of checking component	Decorticate posturing
Midbrain	Coma	Central neurogenic hyperventilation	Midposition, fixed	Loss of medial rectus function	Decerebrate posturing
Upper pons	Coma	Central neurogenic hyperventilation	Midposition, fixed	Loss of medial rectus function	Decerebrate posturing
Lower pons	Coma	Ataxic	Midposition, fixed	Absent	Flaccid
Medulla	Coma	Apnea	Midposition, fixed	Absent	Flaccid
UNCAL TRANSTENTORIAL HERNIATION					
Early third nerve	Unreliable	Normal	Ipsilateral dilated, fixed	Normal	Contralateral hemiparesis
Late third nerve	Coma	Cheyne-Stokes or central neurogenic hyperventilation	Ipsilateral dilated, fixed; contralateral dilated, fixed	Medial rectus dysfunction	Ipsilateral hemiparesis and contralateral decerebrate posturing
Midbrain-pons	Coma	Central neurogenic hyperventilation or ataxic	Midposition, fixed	Absent	Bilateral decerebrate posturing

Spontaneous eye movements may have localizing value. Conjugate horizontal eye deviation points to the side of brain lesions rostral to the brain stem (usually in the cerebral hemisphere) but to the side opposite brain stem lesions. Tonic downward eye deviation suggests acute lesions of the thalamus or dorsal midbrain. Tonic upward eye deviation is unusual but is seen in patients with hypoxic-ischemic lesions. Ocular bobbing with a rapid downward movement followed by a slow return upward suggests a pontine lesion. Reverse ocular bobbing with a slow downward and rapid upward movement ("ocular dipping") has poor localizing value but may be seen after hypoxic-ischemic insults and metabolic disorders. "Ping-Pong" gaze with alternating conjugate horizontal eye movements is nonspecific, but a slower and otherwise similar disorder, called periodic alternating gaze, is seen in those with portosystemic encephalopathy (Chapter 157). Ocular skew deviation, in which one eye is higher than the other on primary gaze, suggests a brain stem lesion.

The vestibulo-ocular reflex assesses brain stem and cerebral hemispheric function by reflexively inducing eye movements. First, the external auditory canal should be inspected to exclude perforation of the tympanic membrane and obstruction by cerumen. Ice water is then injected into the canal (10 mL for usual assessment but 50 mL for assessment of brain death), and the induced reflex eye movements are observed (see Table 411-5). In patients with normal consciousness, such as in psychogenic coma, marked horizontal nystagmus is produced. In those with stupor at a diencephalic level, such as from metabolic encephalopathy, the fast component of nystagmus is suppressed, so the patient responds with full tonic conjugate eye movements toward the injected ear. With lesions of the oculomotor or abducens nerves or lesions of the midbrain or pons, ophthalmoplegia of localizing value is observed. In brain death or total brain stem failure, no response is observed. The vestibulo-ocular reflexes may be ablated after treatment with ototoxic antibiotics.

Motor responses are observed after noxious stimulation, particularly nasal tickle, sternal rub, and ice water irrigation of the external auditory canal. In light coma from metabolic encephalopathy, symmetrical paratonia and grasp reflexes may be present. At lower functional levels of structural coma, limb posturing is often observed. Limb posturing is a unilateral or bilateral, stereotyped, tonic brain stem reflex movement induced by stimulation, especially noxious stimuli. Decorticate posturing, in which the arm is flexed and the ipsilateral leg is extended, suggests a midbrain functional level. Decerebrate posturing, in which both the arm and the ipsilateral leg are extended, suggests a pontine functional level. When the entire brain stem is destroyed, as in brain death, all limbs remain flaccid during stimulation. Metabolic-toxic encephalopathies usually produce symmetrical motor signs, whereas structural causes of coma frequently produce asymmetrical motor signs. Hypoglycemia and acute hyponatremia are exceptions in which aphasia, gaze paresis, and hemiparesis may be seen. Myoclonic seizures with continuous or intermittent rhythmic clonic movements frequently develop in patients who have suffered hypoxic-ischemic neuronal damage during cardiopulmonary arrest. Progression to myoclonic status epilepticus is a bad prognostic sign.

After the neurologic examination, screening laboratory tests, brain CT, and lumbar puncture have been accomplished, a tentative diagnosis can be made in most patients. If focal signs are present despite normal findings on CT, consideration should be given to an acute stoke involving the posterior circulation (Chapter 414). Brain CT angiography or magnetic resonance imaging (MRI) can clarify the diagnosis. If lateralizing signs are absent, metabolic and toxic causes are most likely. An electroencephalogram (EEG) is useful in patients in whom nonconvulsive seizure activity may be causing stupor or coma.

TREATMENT

Rx

Management of coma requires simultaneous diagnostic, supportive, and treatment measures (Table 411-6). Specific treatments, which depend on the causative diagnosis, include urgent attention to any head trauma (Chapter 406). Emergency stabilization of respiration and circulation and control of seizures are critical for all patients. In patients without focal findings or obvious meningitis, 50% dextrose (25 g intravenously), thiamine (50 mg intravenously), naloxone (0.4 to 2.0 mg intravenously), and flumazenil (0.2 mg intravenously) should be administered during the diagnostic assessment. If fever, nuchal rigidity, or leukocytosis is present, the patient should be treated presumptively for bacterial meningitis (Chapter 420) with intravenous antibiotics before neuroimaging and lumbar puncture.

Elevated intracranial pressure must be lowered urgently. Treatments include hyperventilation by bag or ventilator, intravenous hyperosmolar agents (Chapter 112) such as mannitol, and intravenous glucocorticoid drugs for patients with vasogenic edema from brain tumors (Chapter 195), abscesses (Chapter 421), or bacterial meningitis (Chapter 420). Intravenous barbiturate or benzodiazepine therapy remains of uncertain benefit. Therapeutically induced hypothermia for several days improves outcomes in patients who are in coma after diffuse hypoxic-ischemic neuronal damage caused by cardiac arrest.

PROGNOSIS

The prognosis is highly variable and depends on the cause, stage, degree of structural brain damage, and potential reversibility. Prediction rules for recovery apply only to a specific cause. The prognosis after traumatic brain injury is predicted by the Glasgow Coma Score (see Table 406-1). In patients who have survived cardiopulmonary arrest and resuscitation and in whom toxic and metabolic factors (e.g., sedation, neuromuscular blockade, hypothermia, organ failure, and shock) are not an issue, the likelihood for recovery of awareness is less than 1% if the following are present:

- Day 1: presence of myoclonic status epilepticus
- Days 1 to 3: bilateral absence of the N20 response of the somatosensory evoked potential
- Days 1 to 3: serum neuron-specific enolase concentration higher than 33 μg/L
- Day 3: absent pupillary or corneal reflexes; extensor or absent motor responses

If the patient remains comatose on day 3 without these findings and without a contribution from a potentially reversible metabolic or toxic encephalopathy, the probability of recovery of awareness is below 10% if there is no withdrawal response to painful stimuli and below 40% if the patient withdraws to painful stimuli but lacks spontaneous eye opening.

THE VEGETATIVE STATE

The vegetative state is a disorder of consciousness in which wakefulness is retained but awareness of self and environment is entirely absent, to the extent that it can be tested clinically. The vegetative state may be a transient stage during spontaneous recovery from coma to awareness, or it may be a chronic, unchanging state. Adjectives such as "persistent" or "permanent" should be avoided because they generate confusion by confounding the diagnosis and prognosis.

EPIDEMIOLOGY AND PATHOBIOLOGY

The vegetative state is caused by diffuse or multifocal brain lesions that disconnect the polymodal cerebral cortices from the thalami but spare the brain stem and hypothalamus. The prevalence of a transient vegetative state after brain injury is unknown. The prevalence of the chronic vegetative state is 19 per million.

Causative lesions can be located bilaterally in the thalami, diffusely in the cerebral cortex, or diffusely in the white matter that connects the thalami to the cortex. Two clinical disorders are most commonly responsible: diffuse hypoxic-ischemic neuronal damage to the thalami and cortex suffered during cardiopulmonary arrest and diffuse axonal injury from a traumatic injury

TABLE 411-6 EMERGENCY MANAGEMENT OF COMATOSE PATIENTS

1. Ensure oxygenation
2. Maintain the circulation
3. Administer 50% dextrose, 25 g IV, and control glucose
4. Lower raised intracranial pressure
5. Stop seizures with lorazepam, 1.0-2.0 mg IV
6. Search for and treat infections
7. Restore acid-base and electrolyte balance
8. Normalize body temperature
9. Administer thiamine, 50 mg IV, and multivitamins
10. Consider administration of opioid antagonists (naloxone, 0.4-2.0 mg IV)
11. Consider administration of benzodiazepine antagonists (flumazenil, 0.2 mg IV)
12. Control agitation
13. Protect the eyes
14. Consider inducing therapeutic hypothermia for diffuse hypoxic-ischemic causes

Modified from Posner JB, Saper CB, Schiff ND, et al. *Plum and Posner's Diagnosis of Stupor and Coma*, 4th ed. New York: Oxford University Press; 2007:311.

TABLE 411-7 DIAGNOSIS OF THE VEGETATIVE STATE

I. Absence of:
- Awareness of self or environment
- Purposeful or voluntary behavioral response to all stimuli
- Language comprehension or expression

II. Presence of:
- Intermittent wakefulness manifested by the presence of sleep-wake cycles
- Autonomic functions
- Cranial nerve and spinal reflexes

III. Potential behavioral repertoire:
- Breathe spontaneously
- Spontaneous roving eye movements
- Utter sounds but no words
- Grimace to pain, make facial expressions
- Yawn, make chewing jaw movements, swallow saliva
- Move limbs nonpurposefully, arch back, decorticate limb posturing
- Flexion withdrawal from noxious stimuli
- Move head or eyes briefly toward sound or movement
- Auditory startle

TABLE 411-8 DIAGNOSIS OF THE MINIMALLY CONSCIOUS STATE

Globally impaired responsiveness

Limited but discernable evidence of awareness of self and environment as demonstrated by the presence of one or more of the following behaviors that occur in a contingent relationship to relevant environmental stimuli and are not simply reflexive movements:
- Follow simple commands
- Gesture yes/no answers
- Make intelligible vocalizations or gestures in direct response to a question's linguistic content
- Reach for objects that demonstrates a clear relationship between object location and direction of reach
- Touch and hold objects in a manner that accommodates the size and shape of the object
- Sustain visual pursuit to moving stimuli
- Smile or cry appropriately to linguistic or visual content of emotional but not to affectively neutral topics or stimuli

caused by a torque force. These two disorders have different pathologies: hypoxic-ischemic injury affects cortical, thalamic, and cerebellar neurons, whereas diffuse axonal injury shears the axons at the gray matter–white matter junction in the cortex.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical features of the vegetative state (Table 411-7) are dominated by what patients do. A careful neurologic examination must be performed to search for any evidence of awareness because up to 40% of patients in whom a vegetative state is initially diagnosed are actually in a minimally conscious state (see later).

The vegetative state is a clinical syndrome with a spectrum of severity. The typical patient has diffuse slow-wave activity on the EEG, but the most severely affected patients have isoelectric EEGs. As determined by functional neuroimaging studies, an occasional patient with a clinically diagnosed vegetative state can perform ideational tasks on command, with evidence on functional MRI that they possess awareness. Such functional neuroimaging tests are not yet part of routine clinical practice but may become standard clinical assessment tools for patients who are suspected to be in a vegetative state.

TREATMENT AND PROGNOSIS

Rx

No treatments reverse or improve the vegetative state. The aggressiveness of medical treatment of patients in the vegetative state should ideally be guided by their previously stated wishes. Patients require the same medical and nursing care, physical therapy, and nutritional needs as patients in coma. Patients should be referred to specialized neurorehabilitation units when possible. Patients who are in a vegetative state from nontraumatic causes and who do not regain awareness within 3 months of the insult have less than a 1% chance of experiencing significant neurologic recovery. After traumatic brain injury, the prognosis cannot be estimated with a similar degree of certainty until after 1 year, although functional neuroimaging is a promising approach to identify patients who are destined to recover awareness.

THE MINIMALLY CONSCIOUS STATE

The minimally conscious state (Table 411-8) is a disorder of altered consciousness characterized by a profound lack of responsiveness but partial or intermittent evidence of awareness of self and environment. Patients may typically have suffered less severe injuries than patients in the vegetative state. The minimally conscious state is much more common than the vegetative state, from which it must be distinguished. When compared with patients in the vegetative state, patients in the minimally conscious state are more likely to respond to environmental and sensory stimuli, to stimulant medications such as levodopa or dopamine agonists (which stimulate thalamic dopaminergic neurons and are prescribed in the same dose ranges as for the treatment of Parkinson's disease, Chapter 416), and perhaps to deep brain electrical stimulation of the intralaminar thalamic nuclei. Patients in the minimally conscious state require the same specialized neurorehabilitation services as those in the vegetative state. There are no good prognostic data for the minimally conscious state other than for recovery after traumatic brain injury (Chapter 406).

THE LOCKED-IN SYNDROME

The locked-in syndrome, a state of profound paralysis, is not a disorder of consciousness but may be mistaken for one. In its classic form, it is produced when a large infarction or hemorrhage in the pontine tegmentum and base produces quadriplegia, pseudobulbar palsy, and paralysis of horizontal eye movements. Once the acute encephalopathy resolves, locked-in patients usually remain awake and alert, breathe spontaneously, and have normal consciousness and cognition, to the extent that they can be tested accurately. Inexperienced examiners may incorrectly diagnose locked-in patients as being comatose because of their profound paralysis, pinpoint pupils, and seeming unresponsiveness. A similar state of profound, global paralysis with intact cognition can be produced by advanced amyotrophic lateral sclerosis (Chapter 418), Guillain-Barré syndrome (Chapter 428), or critical illness polyneuropathy (Chapter 428).

Locked-in patients can be taught to communicate with voluntary vertical eye movements and eyelid movements, which are typically their only retained volitional movements because they are controlled rostral to the pons. Most affected patients die within a few months, but some otherwise healthy young patients who have become locked in as a result of basilar artery occlusion have survived for many years; occasional patients may recover function to become independent. Computerized systems can help patients communicate.

BRAIN DEATH

Brain death is the term popularly applied to the determination of human death based on tests that show irreversible cessation of all clinical brain functions. Once illness or injury has destroyed the brain or rendered its clinical functions irreversibly lost, a human being is dead. Brain death is a medically and legally accepted determination of human death throughout North America, Europe, Australia, most of the developed world, and much of the undeveloped world. Brain-dead patients serve as ideal multiorgan donors.

EPIDEMIOLOGY AND PATHOBIOLOGY

Most cases of brain death result from massive traumatic brain injury (Chapter 406), intracranial hemorrhage (Chapter 415), meningitis (Chapter 420), or diffuse hypoxic-ischemic neuronal damage secondary to cardiac arrest (Chapter 63) or asphyxia. Marked cerebral edema from the primary injury or illness produces severe intracranial hypertension. When intracranial pressure exceeds mean arterial blood pressure (or systolic blood pressure in some cases), intracranial blood flow ceases and widespread ischemic death of brain neurons ensues. Syndromes of transtentorial herniation commonly occur.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Brain-dead patients have no brain functions measurable at the bedside. The diagnosis should be suspected in any patient who is deeply comatose,

TABLE 411-9 TESTS FOR BRAIN DEATH

I. Preconditions showing irreversibility: all necessary
- Presence of a structural brain lesion sufficient to produce all the clinical signs
- Absence of reversible significant toxic or metabolic encephalopathy:
  - No depressant drug intoxication
  - No neuromuscular blockade (use electroneurography if uncertain)
  - No severe hypothermia
  - No severe hypotension
- Sequential repeated testing or one test followed by a confirmatory blood flow test

II. Signs showing complete cessation of all clinical brain functions: all necessary
- Coma: No spontaneous movements, no response to any stimuli, and no reflex movements integrated by the brain
- Apnea: No breathing or respiratory effort when the P_{ACO_2} ≥60 mm Hg while protecting the P_{AO_2}
- Brain stem areflexia: all necessary
  - Absent pupillary light and dark reflexes
  - Absent corneal touch reflexes
  - Absent facial movement to noxious stimuli
  - Absent vestibulo-ocular reflexes tested by caloric irrigation of the external auditory canal with 50 mL of ice water
  - Absent pharyngeal and tracheal reflexes to endotracheal tube suctioning

III. Confirmatory tests: optional but desirable; neuroimaging preferred
- Neuroimaging that shows complete absence of intracranial blood flow; one test
  - Intravenous radionuclide angiography
  - Transcranial Doppler ultrasound
  - Computed tomographic angiography
  - Magnetic resonance angiography or diffusion
  - Single-photon emission computed tomography
- Electrophysiologic testing (use only if intracranial pressure is not elevated)
  - Electroencephalography + brain stem auditory evoked responses + somatosensory evoked responses: all isoelectric

is unresponsive to stimuli, has absent pupillary light reflexes, and is completely ventilator dependent. The diagnosis requires a comprehensive evaluation (Table 411-9) that demonstrates both total loss of brain functions and its irreversibility as documented by at least two sequential examinations performed by an experienced physician or one examination followed by a neuroimaging test to confirm the complete absence of intracranial blood flow.

TREATMENT

Rx

There is no treatment. Once the diagnosis has been made, the patient is declared dead. If the family has agreed to allow the deceased patient to serve as an organ donor, the ventilator is reattached following the apnea test, and the patient is moved to the surgical suite. If the patient is not an organ donor, the ventilator is not reattached, and all lines and monitors are discontinued. Physicians should be knowledgeable about local laws that may restrict making the diagnosis in patients belonging to certain religious groups that do not accept brain death as human death.

DISORDERS OF SLEEP

MARK W. MAHOWALD

DEFINITION

Wake-sleep complaints are second only to complaints of pain as the reason that patients seek medical attention. Undiagnosed and untreated wake-sleep complaints extract an enormous toll at the personal level in terms of misery and at the societal level in socioeconomic consequences. Knowledge of sleep and its disorders has expanded rapidly over the past half century, particularly with the discovery that sleep is far more than the passive absence of wakefulness. Sleep is an active brain process that includes two divergent states: non–rapid eye movement (NREM) and rapid eye movement (REM) sleep. A complex array of neurotransmitters, neuropeptides, and circulating humoral sleep-promoting factors interact with multiple areas of the central nervous system to determine wakefulness, REM sleep, and NREM sleep.

PATHOBIOLOGY

Wakefulness is controlled by the reticular activating system of the rostral brain stem, which projects to the thalamus and cortex. Inhibition of these projections, which is modulated by neurons in the pons and midbrain, results in sleep. REM sleep, during which most dreaming occurs, is generated within the tegmentum of the pons with modulation from the norepinephrine- and serotonin-containing neurons of the locus caeruleus and the dorsal raphe nucleus. Electrical events generated in the pontine reticular formation (i.e., ponto-geniculo-occipital [PGO] waves) are propagated through the oculomotor and visual system during REM sleep simultaneously with REMs. PGO waves are suppressed by norepinephrine, and the serotonin neuronal systems suppress PGO waves and REM; cholinergic neurons are stimulatory. PGO input can induce an action potential in neurons below their usual threshold. Such PGO-facilitated activity in the visual system may play a role in the random imagery of dreaming.

Hypocretins (orexins) are sleep modulatory neuropeptides made in the lateral hypothalamus with projections to the locus caeruleus and dorsal raphe, as well as to the thalamus, where they modulate the release of excitatory (glutamate) and inhibitory (γ-aminobutyric acid) neurotransmitters. Disruption of this system induces narcolepsy in animals, and hypocretin neurotransmission is deficient in most narcoleptic patients.

Stage of Sleep

Sleep stages in humans are defined electroencephalographically and behaviorally (Table 412-1). Sleep includes NREM and REM sleep. NREM sleep can be divided into four stages. In *stage I NREM sleep*, patients are drowsy and may maintain some environmental awareness. The electroencephalogram (EEG) loses its alpha rhythm (8 to 13 Hz) and develops theta (3 to 7 Hz) activity; vertex potentials (i.e., negative deflections recorded from the midline) occur, especially in response to sensory stimuli. Slow lateral eye movements take place, and spontaneous motor activity, as monitored by electromyography (EMG), is diminished. Stage I represents about 5% of normal sleep time.

Stage II NREM sleep is characterized by sleep spindles (12 to 14 Hz), vertex sharp waves, and K complexes (i.e., biphasic, high-voltage slow waves often followed by sleep spindles). Slow lateral eye movements may persist. EMG activity is further reduced. Stage II NREM sleep represents 50 to 60% of sleep and increases with age.

Stages III and IV NREM sleep are characterized by slow or delta waves (<4 Hz) and are therefore called delta sleep or deep sleep. If 20 to 50% of the EEG is delta activity, the patient is in stage III sleep; if delta activity is 50% or greater, the sleep event is called stage IV. Deep sleep constitutes 10 to 20% of sleep time (less with advancing age). EMG activity is diminished. Eye movements are not seen, and ventilation is regular.

In REM sleep, the EEG resembles that of waking, with low-voltage, mixed frequencies. Abrupt REMs and irregular ventilation and heart rate are present. Penile tumescence occurs, and muscle tone is depressed because of suppression of activity in all somatic muscles except the diaphragm. REM

TABLE 412-1 STAGES OF SLEEP

SLEEP STAGE	EEG	EYE MOVEMENTS	EMG ACTIVITY	IMAGERY
Wakefulness	Alpha and beta activity (low voltage, fast)	Random, rapid	Active, spontaneous	Vivid, external
Non-REM sleep (NREM)				
Stage I (drowsiness)	Theta activity	Slow, rolling	Attenuated, episodic	Dulled
Stage II (light sleep)	Sleep spindles, K complexes	Slow or absent	Attenuated	Nonvivid
Stage III and IV (slow wave sleep)	Delta activity	Absent	Attenuated	
REM sleep	Low amplitude, irregular	Abrupt, rapid eye movements	Absent	Vivid, bizarre

EEG = electroencephalogram; EMG = electromyogram; REM = rapid eye movement.

TABLE 412-2 CAUSES OF HYPERSOMNIA (EXCESSIVE DAYTIME SLEEPINESS*)

Sleep deprivation
Obstructive sleep apnea (Chapter 100)
Narcolepsy
Circadian rhythm disorders Shift work sleep disorder Jet lag Advanced and delayed sleep phase syndrome
Restless legs syndrome (may be associated with extreme daytime sleepiness but is always manifested as insomnia)
Drug use
Syndromes associated with subjective sleepiness but usually without true, verifiable sleepiness by objective testing Depression Chronic pain Insomnia

*Excessive daytime sleepiness is usually confirmed by objective testing.

TABLE 412-3 EPWORTH SLEEPINESS SCALE

How likely are you to doze off or fall asleep in the following situations, in contrast to just feeling tired? This refers to your usual way of life in recent time. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation.

0 = would never doze
1 = slight chance of dozing
2 = moderate chance of dozing
3 = high chance of dozing

SITUATION	CHANCE OF DOZING
Sitting and reading	
Watching TV	
Sitting and inactive in a public place (theater or meeting)	
As a passenger in a car for an hour without a break	
Lying down to rest in the afternoon when circumstances permit	
Sitting and talking to someone	
Sitting quietly after lunch (without alcohol)	
In a car, while stopped for a few minutes in traffic	
Total	

From Johns MW. A new method for measuring daytime sleepiness: the Epworth Sleepiness Scale. *Sleep*. 1991;14:540-545.

sleep occupies 20 to 25% of sleep time. Dreaming occurs during all stages of NREM sleep and during REM sleep.

There is some evidence that procedural (i.e., motor learning such as typing) and declarative (i.e., episodic learning such as recalling places or events) memory consolidation occurs during REM sleep. REM sleep time increases after task training. After episodic learning, memory consolidation is accomplished during slow wave sleep by rapid reactivation of the hippocampal neurons previously activated by the place or event to be remembered. Alternatively, it has been hypothesized that dream sleep functions as a random stimulator of the cortex to remove weak memories and thus permit only stronger memories to be retained.

CLINICAL MANIFESTATIONS

Most sleep complaints fall into four categories: hypersomnia (excessive daytime sleepiness), insomnia (trouble falling or staying asleep), circadian rhythm (biologic clock) disorders, and parasomnias (complex behavior arising during the sleep period).

Hypersomnia is typically manifested as the tendency to fall asleep in inappropriate or undesirable settings such as at work, while talking with others, or while driving. Sleepiness from any cause can result in impaired sustained attention, with adverse, occasionally disastrous socioeconomic consequences in the classroom, in the workplace, or on the highways. The most common cause of hypersomnia is volitional sleep deprivation for social or economic reasons. Volitional sleep deprivation can usually be diagnosed by the history or sleep diary. Nonvolitional sleep deprivation–related sleepiness is almost always due to an underlying sleep disorder, most commonly either obstructive sleep apnea or narcolepsy (Table 412-2).

DIAGNOSIS

Subjective

Sleep Diaries and Sleepiness Scales

Sleep diaries kept for a period of 2 or 3 weeks may reveal valuable information about a patient's subjective perception of wakefulness and sleep. One useful scale is the Epworth Sleepiness Scale (Table 412-3), which is frequently used as a screening tool for identifying excessive daytime sleepiness and generally correlates with other measures of sleep propensity. A score higher than 11 suggests a high probability of a sleep problem. This scale may be limited by its lack of sensitivity in that there may be a striking discrepancy between self-perceived sleepiness and the physiologic sleepiness that can be documented by formal sleep studies.

Objective

Polysomnography

Polysomnography (Chapter 100) determines states of sleep and wakefulness by recording eye movements, submental EMG activity, and the EEG. If sleep-disordered breathing is suspected, additional monitoring such as oral/nasal airflow, chest/abdominal movement, hemoglobin oxygen saturation, and transcutaneous or end-tidal CO_2 is used. A full EEG helps evaluate disorders of arousal, REM sleep behavior disorder, and nocturnal seizures.

Multiple Sleep Latency Test

The multiple sleep latency test, which assesses the tendency to fall asleep during normal waking hours, consists of five 20-minute nap opportunities at 2-hour intervals. An all-night polysomnograph is generally performed the night before to determine the quality and quantity of the preceding night's sleep. Normal, fully rested adults do not usually fall asleep in less than 10 minutes and uncommonly display REM sleep during daytime naps. Patients with narcolepsy typically fall asleep in 5 minutes or less and often display REM sleep during at least two of the daytime naps. This test is not generally performed in patients with obstructive sleep apnea because an explanation for the hypersomnia should have been identified by the preceding all-night polysomnograph.

Actigraphy

Analysis of sleep diaries may be insufficient to verify a tentative diagnosis in patients with reported insomnia or suspected abnormalities in the wake-sleep cycle. In such cases, definitive objective data may be obtained by actigraphy,

in which a small, wrist-mounted device records activity plotted against time—usually over a period of 1 to 3 weeks. There is direct correlation between the rest/activity recorded by the actigraph and the wake-sleep pattern as determined by polysomnography.

SPECIFIC SLEEP DISORDERS

Obstructive Sleep Apnea

Obstructive sleep apnea (Chapter 100), which is the most common medical disorder causing hypersomnia, affects more than 2% of adult women and 4% of adult men. It is seen primarily in overweight people who are loud snorers, but it may also occur in children and thin individuals.

Obstructive sleep apnea is characterized by collapse of the upper airway during sleep. This upper airway collapse may be associated with a fall in the blood oxygen level and results in repetitive arousal (up to 100 per hour of sleep) to re-establish upper airway airflow. These brief arousals are not perceived by the individual but result in excessive daytime sleepiness. Obstructive sleep apnea is described in detail in Chapter 100.

Narcolepsy

EPIDEMIOLOGY AND PATHOBIOLOGY

Narcolepsy affects 1 in 2000 individuals. It has a clear genetic component, with more than 90% of affected individuals carrying the HLA-DR2/DQ1 (under current nomenclature, HLA-DR15 and HLA-DQ6) gene, which is found in less than 30% of the general population. Despite a genetic component, the risk in a first-degree relative is only 1 to 2%, but this risk represents a 10- to 40-fold increase over that in the general population. Thus, the genetic component is neither necessary nor sufficient to cause narcolepsy.

Hypocretin-1 is an excitatory neuropeptide found in a very circumscribed group of neurons confined to the hypothalamic region. Patients with narcolepsy have lost hypocretin cells, possibly by an immune-mediated phenomenon.

CLINICAL MANIFESTATIONS

Narcolepsy is characterized by the tendency to fall asleep inappropriately during the daytime, particularly during sedentary or nonstimulating activities, despite having obtained an adequate amount of sleep the preceding night. Other symptoms of narcolepsy include (1) cataplexy (sudden brief spells of muscle weakness), often triggered by emotionally laden events; (2) hypnagogic (occurring at sleep onset) or hypnopompic (occurring at sleep offset) hallucinations; (3) sleep paralysis (awakening to find the entire body paralyzed—with the exception of being able to breathe and move the eyes); (4) automatic behavior; and (5) disrupted nighttime sleep.

Patients with narcolepsy do not sleep more per 24 hours than non-narcoleptics do; instead, they are unable to maintain the normal boundaries of wakefulness, NREM sleep, and REM sleep. The automatic behavior (driving past the desired freeway exit, putting clothing into the refrigerator) represents an admixture of wakefulness and NREM sleep, with enough wakefulness to perform complex behavior but not enough for conscious awareness of the behavior. Sleep paralysis and cataplexy represent the simultaneous occurrence of REM sleep–related muscle paralysis and wakefulness. If the paralysis intrudes into wakefulness, the result is cataplexy; if it persists into wakefulness from a period of REM sleep, sleep paralysis results. The waking hallucinations represent the release of sleep-related dreaming into wakefulness, and the disrupted nighttime sleep is a manifestation of the "state boundary dyscontrol" aspect of narcolepsy. Sleep paralysis and hypnagogic/hypnopompic hallucinations, but not cataplexy, are often experienced by people who do not have narcolepsy—particularly in the setting of sleep deprivation.

DIAGNOSIS

Sleep laboratory evaluation of patients with narcolepsy includes polysomnography and the multiple sleep latency test. Results of the all-night polysomnograph will usually be unremarkable. The multiple sleep latency test will demonstrate objective hypersomnolence, and REM sleep may be present during the daytime naps.

Levels of hypocretin-1 are undetectable in the cerebrospinal fluid (CSF) of most patients with narcolepsy who experience cataplexy and are HLA-DQB1*0602 positive. Absent CSF hypocretin-1 levels are not found in any conditions that could be confused clinically with narcolepsy, thus suggesting that CSF hypocretin determinations could be of value in the diagnosis of narcolepsy in difficult cases.

TABLE 412-4 CLASSIFICATION OF ADULT INSOMNIA

PRIMARY INSOMNIA
Idiopathic insomnia—Insomnia arising in infancy or childhood with a persistent, unremitting course
Psychophysiologic insomnia—Insomnia caused by a maladaptive conditioned response in which the patient learns to associate the bed environment with heightened arousal rather than sleep; its onset is often associated with an event causing acute insomnia, with the sleep disturbance persisting despite resolution of the precipitating factor
Paradoxical insomnia (sleep-state misperception)—Insomnia characterized by a marked mismatch between the patient's description of sleep duration and objective polysomnographic findings
SECONDARY INSOMNIA
Adjustment insomnia—Insomnia associated with active psychosocial stressors
Inadequate sleep hygiene—Insomnia associated with lifestyle habits that impair sleep
Insomnia caused by a psychiatric disorder—Insomnia secondary to an active psychiatric disorder, such as anxiety or depression
Insomnia caused by a medical condition—Insomnia secondary to a condition such as restless legs syndrome, chronic pain, nocturnal cough or dyspnea, or hot flashes
Insomnia caused by a drug or substance—Insomnia secondary to consumption or discontinuation of medications, drugs of abuse, alcohol, or caffeine

Reproduced with permission from *The New England Journal of Medicine*. Silber M. Clinical practice. Chronic insomnia. *N Engl J Med*. 2005;353:803-810.

TREATMENT Rx

Stimulant medications such as methylphenidate (e.g., 10 to 60 mg/day), methamphetamine (e.g., 20 to 60 mg/day), dextroamphetamine (e.g., 5 to 60 mg/day), and modafinil (e.g., 100 to 400 mg/day) are generally effective and well tolerated. Sodium oxybate (20 to 40 mg/kg per night in divided doses), alone or combined with modafinil, can reduce sleep disruption significantly. However, responses to these medications are variable among individuals, and clinical judgment is needed to titrate to an effective dose. Dependency, tolerance, or abuse of stimulant medications is uncommon in patients with narcolepsy, and there is no indication for "drug holidays." Cataplexy is often controlled by tricyclic antidepressants (e.g., imipramine, 25 to 50 mg at bedtime), selective serotonin re-uptake inhibitors (e.g., fluoxetine, 10 to 20 mg/day), or selective norepinephrine re-uptake inhibitors (e.g., venlafaxine, 25 to 37.5 mg/day). γ-Hydroxybutyrate (20 to 40 mg/kg per night in divided doses) has been used in difficult cases.

Insomnia

Insomnia (Table 412-4) is defined not simply by total sleep time but rather by difficulty in initiation and maintenance of sleep, poor quality of sleep, and a insufficient duration of sleep, such that functioning in the awake state is impaired.

EPIDEMIOLOGY

Insomnia, the most prevalent sleep complaint, affects up to 10 to 20% of the adult population and is second only to the complaint of pain as a reason to seek medical attention.

PATHOBIOLOGY

There is growing evidence that some insomniacs may be in a constant state of hyperarousal because many are actually less sleepy during the day than normal subjects are as measured by objective daytime nap studies, and some also have increased 24-hour metabolic activity.

Many people with insomnia have identifiable psychiatric or psychological problems, and untreated insomnia is a risk factor for the future development of psychiatric problems such as depression (Chapter 404) or substance abuse (Chapter 33). Importantly, the relationship between insomnia and psychiatric conditions is bidirectional: depression may cause insomnia, and insomnia may cause depression.

CLINICAL MANIFESTATIONS

Patients with insomnia complain of an inability to sleep long enough or well enough to awaken feeling rested or restored despite having an adequate amount of time to devote to sleep. Sleep deprivation as a result of inadequate time to devote to sleep is not insomnia. Many patients complain of

TABLE 412-5 COGNITIVE BEHAVIORAL THERAPY FOR INSOMNIA

STIMULUS-CONTROL THERAPY
Go to bed only when sleepy
Use the bedroom only for sleeping and sex
Go to another room when unable to sleep in 15 to 20 minutes, read or engage in other quiet activities, and return to bed only when sleepy; repeat if necessary
Have a regular wake time regardless of the duration of sleep
Avoid daytime napping
SLEEP-RESTRICTION THERAPY
Reduce time in bed to the estimated total sleep time (minimum, 5 hr)
Increase time in bed by 15 minutes every week when the estimated sleep efficiency (ratio of time asleep to time in bed) is at least 90%
RELAXATION THERAPY
Physical component: progressive muscle relaxation, biofeedback
Mental component: imagery training, meditation, hypnosis
COGNITIVE THERAPY
Education to alter faulty beliefs and attitudes about sleep, such as that a minimum of 8 hours of sleep per night is required for health
SLEEP-HYGIENE EDUCATION
Correct extrinsic factors affecting sleep, such as environmental disruption (pets or snoring bed partner); bedroom temperature; fixation on the bedside clock; use of alcohol, nicotine, or caffeine; lack of exercise or exercise too close to bedtime

Reproduced with permission from *The New England Journal of Medicine*. Silber M. Clinical practice. Chronic insomnia. *N Engl J Med*. 2005;353:803-810.

nonrestorative sleep. Daytime consequences include feeling tired or fatigued or having trouble concentrating. True excessive daytime sleepiness (inappropriate or uncontrollable sleep episodes during the day) is extremely rare in insomniacs.

DIAGNOSIS

Insomnia is a clinical diagnosis. Sleep diaries and actigraphy may be very helpful in difficult cases. Formal sleep studies are rarely indicated unless there is reason to suspect a coexisting sleep disorder such as obstructive sleep apnea.

TREATMENT

Rx

Behavioral therapy for insomnia (Table 412-5) can be quite effective but may be very time-consuming. Over-the-counter sleep aids are of little, if any benefit.

Although medications used to treat depression are often prescribed to treat insomnia, there is very little evidence that they are effective in the treatment of insomnia not associated with depression. Nevertheless, if patients with insomnia are physiologically hyperaroused, a case may be made for chronic administration of sedative-hypnotic agents. Three classes of medications are approved for the treatment of insomnia: the benzodiazepines (e.g., temazepam, 15 to 30 mg at bedtime; triazolam, 1.25 to 2.5 mg at bedtime; or estazolam, 1 to 2 mg at bedtime), the newer, nonbenzodiazepines (e.g., zolpidem, 5 to 10 mg at bedtime; zolpidem controlled release, 6.25 to 12.5 mg at bedtime; zaleplon, 5 to 10 mg at bedtime; or eszopiclone, 1 to 3 mg at bedtime), and a melatonin agonist (ramelteon, 8 mg at bedtime). Combined behavioral and pharmacologic treatments are often effective. Benzodiazepines may be administered safely and effectively for longer than 3 weeks. Tolerance, abuse, and dependency can be associated with chronic benzodiazepine administration in patients with well-documented sleep disorders, but the incidence of these complications is relatively low. Melatonin is normally secreted by the pineal gland (Chapter 230) in synchronization with the light-dark cycle. Its effect on sleep is variable, and its efficacy in treating insomnia has been disappointing.

Restless Legs Syndrome

Restless legs syndrome, which is one of the most common causes of severe insomnia, is a neurologic sensory/movement disorder that affects 5 to 15% of the general population. It is described in detail in Chapter 417.

Disorders of Circadian Rhythm

DEFINITION

Most living creatures follow a relentless and pervasive daily rhythm of activity and rest that is ultimately linked to the geophysical light-dark cycle. Plants, animals, and even unicellular organisms show daily variations in metabolic activity, locomotion, feeding, and many other functions. The importance of the light-dark cycle on the human biologic clock is underscored by the fact that only a third of totally blind humans will be entrained to the environment, a third will have a 24-hour cycle that is out of phase with the environment, and the remaining third have a free-running pattern that is longer than 24 hours.

EPIDEMIOLOGY

In the absence of blindness, the etiology of primary circadian dysrhythmias is unknown. There is good evidence that genetic factors contribute in some cases.

PATHOBIOLOGY

The function of the biologic clock is to promote wakefulness. Normally, maximal wakefulness occurs during daylight hours. For reasons that are not understood, the biologic clocks of people with circadian dysrhythmias are inexorably out of synchronization with the environment, thus making it difficult or impossible to adjust to demands of the environment.

Exposure to bright light has a potent effect on the biologic clock, and exposure at strategic times during the wake-sleep cycle results in a change in the underlying rhythm. For example, evening light exposure may delay the clock, whereas morning light exposure may advance it.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The primary symptom of disorders of circadian rhythm is an inability to sleep during the desired sleep time. Once asleep, there is no abnormality of sleep per se, only an abnormality of the timing of sleep. The result is often a complaint of insomnia if sleep is attempted during the "wake" cycle of the clock or a complaint of sleepiness if wakefulness is attempted during the clock's sleep period. Wake-sleep schedule disorders fall into two categories: (1) primary malfunction of the biologic clock per se and (2) secondary malfunction as a result of environmental effects on the underlying clock. The primary disorders may be difficult to diagnose because they typically masquerade as other sleep, medical, or psychiatric disorders, such as hypersomnia, insomnia, substance (sedative-hypnotic or stimulant) abuse, or psychiatric conditions.

The diagnosis is made by the history. Most people, if asked what their wake-sleep pattern would be if they had 3 weeks of vacation without any constraints on their wake-sleep activities (meals, work, school, family activities), can provide an accurate estimate of their inherent wake-sleep pattern. Sleep diaries and actigraphy may be helpful in difficult cases. The secondary disorders (such as jet lag and shift work) are usually immediately apparent on simple questioning of the patient.

TREATMENT

Rx

The mainstays of treatment of the primary circadian dysrhythmias are chronotherapy, phototherapy, and pharmacologic therapy.

Chronotherapy

In chronotherapy, the desirable total sleep time is determined by sleep logs during a "free-running" period. The patient then delays or advances the onset of sleep by a few hours every day and sleeps only the predetermined number of hours until the onset of sleep occurs at the desired time, at which point the patient attempts to maintain that time. This method requires several days of free time and can be difficult if sleeping quarters cannot be kept dark and quiet during the several day sleeps required.

Phototherapy

The timing and duration of phototherapy depend on the diagnosis and individual response. The patient sits at a prescribed distance from a bright light that furnishes an illuminance of greater than 2500 lux at that distance. The effect of light on human rhythms varies with the intensity, wavelength, timing, and duration of exposure. This intervention can be performed at home, with the timing of light exposure individualized for a given patient's complaint. Light exposure in the morning will advance the clock, whereas evening

exposure will delay the clock. Once the desired sleep period time has been achieved, continued light exposure must be maintained.

Pharmacologic Therapy

The administration of melatonin, 3 mg 4 to 5 hours before the desired time of sleep onset, may assist in advancing the timing of the biologic clock.

JET LAG, SHIFT WORK, AND PERSISTENT PRIMARY CIRCADIAN DYSRHYTHMIAS

The best way to manage jet lag is to assume the wake-sleep pattern of the destination site immediately. Sedative-hypnotic medication may reduce the sleep-onset insomnia associated with jet lag. Jet lag usually resolves at a rate of 1 day per time zone change.

Management of shift work may be difficult; options include stimulant medications and exposure to bright light at night or sedative-hypnotic medication and protection of the sleep environment during the day (or both). The biologic clocks of night shift workers virtually never completely adjust to the night shift because the drive home in the morning resets the clock every day and workers tend to sleep at conventional times during nights off.

Treatment with medications is justified in patients who have persistent symptoms despite chronotherapy and phototherapy. For example, modafinil, 100 to 200 mg during the night shift, is effective for the excessive sleepiness and loss of attention associated with shift work sleep disorder. Caffeine has modest benefits■ but is no better than napping, bright light, or modafinil.■ The administration of 3 mg of melatonin 4 to 5 hours before the desired onset of sleep may be of benefit, especially in individuals who travel across five or more time zones, particularly in an eastward direction.■

DELAYED SLEEP SYNDROME

In delayed sleep phase syndrome, the patient falls asleep late and rises late. There is a striking inability to fall asleep at an earlier, more desirable time. This syndrome may be manifested as either sleep-onset insomnia or daytime hypersomnia, particularly in the morning. Delayed sleep phase syndrome is the most common of the primary circadian dysrhythmias and may, in part, be the consequence of societal increases in opportunities for nighttime activity. Combinations of chronotherapy, phototherapy, and medications may be effective in "resetting" the clock, as for circadian dysrhythmias. Unfortunately, the treatment regimen must be maintained, or the clock will again become delayed.

ADVANCED SLEEP PHASE SYNDROME

Individuals suffering from advanced sleep phase syndrome fall asleep early and awaken earlier than desired. They are unable to remain awake until the desired time; they fall asleep in the early evening and awaken in the very early hours of the morning. This syndrome may be manifested as hypersomnia, particularly in the evening, or sleep maintenance insomnia. Patients complain of interruption of evening activities by their sleepiness. They may avoid evening social activities for fear of the intrusive sleepiness. The undesirable early morning awakenings in this condition may lead to a misdiagnosis of depression. Exposure to bright light in the evening may delay the clock to a more acceptable pattern.

OTHER ABNORMALITIES OF CIRCADIAN RHYTHM

Other, less common circadian dysrhythmias include a "non–24-hour wake-sleep pattern" in which the wake-sleep period is longer than 24 hours and sleep begins at a later time each cycle, as well as an "irregular wake-sleep pattern" characterized by a completely chaotic and unpredictable wake-sleep pattern.

Parasomnias

Parasomnias are defined as unpleasant or undesirable behavioral or experiential phenomena occurring predominately or exclusively during sleep. Initially attributed to psychiatric disease, it is now clear that parasomnias are the manifestation of a wide variety of completely different conditions, most of which are diagnosable and treatable. The common parasomnias are examples of "dissociated sleep states," which represent the simultaneous admixture of wakefulness with either NREM sleep (disorders of arousal such as confusional arousal, sleepwalking, or sleep terrors) or REM sleep (REM sleep behavior disorder). The parasomnias, like narcolepsy, support the concept that wake and sleep are not mutually exclusive states and that sleep is not necessarily a global brain phenomenon.

Isolated, often bizarre sleep-related events may be experienced by perfectly normal individuals, and most do not warrant further extensive or expensive evaluation. However, serious attention should be paid to complaints of sleep-related behavior that is potentially violent or injurious. In these cases, formal sleep studies using a full EEG montage with continuous audiovisual monitoring is indicated to establish a correct diagnosis and treatment plan.

DISORDERS OF AROUSAL

Disorders of arousal tend to arise from NREM sleep and usually occur in the first third of the sleep cycle and rarely during naps. They are common in childhood and usually decrease in frequency with increasing age.

Disorders of arousal may be triggered by febrile illness, prior sleep deprivation, physical activity, emotional stress, or medications. They are not caused by significant underlying psychiatric problems.

Clinical manifestations vary across a broad spectrum ranging from confusional arousal to somnambulism (sleepwalking) to sleep terrors. Some patients perform more specialized behavior, such as sleep-related eating and sleep-related sexual activity, without conscious awareness. Such behavior may have forensic implications.

TREATMENT Rx

Most disorders of arousal, such as simple sleepwalking or sleep terrors, require no treatment other than reassurance of their benign nature. If the behavior is bothersome or potentially injurious, medical management with benzodiazepines (e.g., clonazepam, 0.5 to 1.0 mg 30 minutes before bedtime) or tricyclic antidepressant medications (e.g., imipramine, 25 to 50 mg 30 minutes before bedtime) or behavioral treatment in the form of self-taught relaxation exercises is often effective.

RAPID EYE MOVEMENT SLEEP BEHAVIOR DISORDER

The most common and best-studied REM sleep parasomnia is the REM sleep behavior disorder.

EPIDEMIOLOGY AND PATHOBIOLOGY

REM sleep behavior disorder predominately affects males (about 90%) and usually begins after the age of 50 years. Acute REM sleep behavior disorder is often due to undesirable side effects of prescribed medications, most commonly antidepressant medications and particularly the selective serotonin re-uptake inhibitors. Chronic REM sleep behavior disorder, which may be preceded by a lengthy prodrome of REM sleep behavior disorder, can be idiopathic or associated with neurodegenerative disorders, particularly the synucleinopathies (Parkinson's disease, multiple system atrophy, or dementia with Lewy bodies), in which it may be the first symptom and precede other manifestations of the underlying process by more than 10 years (Chapter 416). There is also a higher incidence of REM sleep behavior disorder in patients with narcolepsy, in whom this tendency may be aggravated by the tricyclic antidepressants or selective serotonin re-uptake inhibitors prescribed to treat cataplexy.

CLINICAL MANIFESTATIONS

In these patients, somatic muscle atonia—one of the defining features of REM sleep—is absent, thereby permitting the acting out of dream mentation, often with violent or injurious results. The initial complaint is vigorous sleep behavior usually accompanying vivid dreams. Such behavior may result in repeated injury, including ecchymoses, lacerations, and fractures.

DIAGNOSIS

The diagnosis may be suspected by the clinical history, but formal sleep studies are indicated. Patients with REM sleep behavior disorder will demonstrate increased EMG activity during REM sleep, thus confirming the clinical suspicion.

TREATMENT Rx

The benzodiazepine clonazepam (0.5 to 2.0 mg 30 minutes before bedtime) is a highly effective treatment of REM sleep behavior disorder, with a sustained response rate of nearly 90%, although its mechanism of action is unknown. Melatonin, 6 to 12 mg at bedtime, may also be effective.

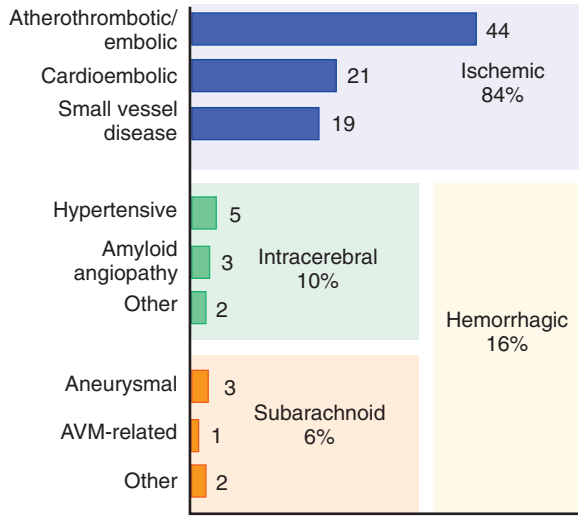

FIGURE 413-1. Classification of cerebrovascular disease. AVM = arteriovenous malformation.

413 APPROACH TO CEREBROVASCULAR DISEASES

JUSTIN A. ZIVIN

DEFINITION

Stroke is the generally preferred term for a group of diseases that are of abrupt onset and cause neurologic damage (Fig. 413-1). Approximately 85% of strokes are caused by a sudden onset of inadequacy of blood flow to some or all of the brain (Chapter 414). The remaining strokes are divided between hemorrhage (Chapter 415) into brain tissue (parenchymatous hemorrhage) and hemorrhage into the spaces surrounding the brain, most frequently the subarachnoid space. A commonly used synonym for stroke was *cerebrovascular accident*, but this term has lost favor because strokes are not really accidents. Well-established prophylactic and acute therapies are now available, and diagnostic tools have improved markedly. Management of stroke has become much more rational and successful.

EPIDEMIOLOGY

Stroke is the second leading cause of mortality worldwide and the third most common cause of death in the industrialized world (after heart disease and all types of cancer combined). It is the most common cause of adult disability in the United States. In China and Japan, stroke is the most frequent cause of death.

In the United States, the annual incidence and death rate for stroke declined steadily for most of the 20th century. In more recent years, however, the rate of decline has slowed and the incidence of stroke may be increasing. About 750,000 new strokes reach medical attention per year in the United States, and strokes cause about 150,000 deaths annually. At any given time there are about 3 million stroke survivors in the United States. Incidence rates in Western European countries are slightly higher than those in the United States, and several Eastern European countries, China, and Japan have much higher rates based at least partly on smoking and on environmental and dietary factors.

The rate of stroke approximately doubles with each decade after the age of 55. Blacks and Hispanics have about twice the risk as whites, and men have about a 40% higher incidence of stroke than women do. Hypertension increases the risk by four-fold, smoking nearly doubles the risk, and diabetes increases the risk two- to six-fold. Carotid stenosis and atrial fibrillation are perhaps the strongest risk factors. Other factors that increase risk include obesity, hypercholesterolemia, physical inactivity, alcohol abuse, hyperhomocysteinemia, drug abuse, and use of oral contraceptive agents.

Comm. = posterior communicating artery; SCA = superior cerebellar artery. (Modified from Lord R. *Surgery of Occlusive Cerebrovascular Disease.* St. Louis, MO: CV Mosby; 1986.)

PATHOBIOLOGY

Cerebrovascular Anatomy

Strokes are usually caused by abnormalities in the cerebral circulation. Anatomic variations are frequent, however, and the territory receiving its blood supply from a given artery is not entirely predictable; as a result, stroke syndromes may not correlate well with the location of the vascular injury. Appropriate imaging studies are needed to provide detailed information about each individual patient. In many situations, noninvasive imaging is adequate. For vascular anomalies such as stenosis, malformations, and aneurysms, angiography is crucial for diagnosis because an understanding of the anatomy is necessary to develop treatment plans.

Four major arteries supply the brain: the bilaterally paired internal carotid and vertebral arteries (Fig. 413-2). The left common carotid artery arises directly from the aortic arch, but the right originates from branches of the aorta. The right common carotid artery is a branch of the innominate artery, and the left and right vertebral arteries originate from the subclavian arteries.

Internal Carotid Arteries

In most individuals, each common carotid artery bifurcates into an internal and external carotid artery just below the angle of the jaw and approximately at the level of the thyroid cartilage. The internal carotid artery (ICA) enters the skull through the foramen lacerum and travels a short distance within the petrous portion of the temporal bone. It then enters the cavernous sinus before penetrating the dura and ascends above the clinoid processes to divide into the anterior cerebral artery (ACA) and middle cerebral artery (MCA). The portion of the ICA that lies between the cavernous sinus and the supraclinoid process forms an S shape and is sometimes termed the *carotid siphon*. The ICA gives off its first important branches at the supraclinoid level: the ophthalmic, posterior communicating, and anterior choroidal arteries, usually in that order. In some cases, the ophthalmic artery arises from the ICA within the cavernous sinus.

External Carotid Arteries

Branches of the external carotid artery sometimes form anastomoses that provide collateral circulation to the ICA. These branches include the facial artery and the superficial temporal artery. Both vessels may anastomose with the supratrochlear branches of the ophthalmic artery. In instances of ICA occlusion below the level of the ophthalmic branch, the facial and superficial temporal arteries sometimes supply blood through the ophthalmic branch to the distal ICA.

Vertebral-Basilar Arteries

Anatomic variation is considerably more common in the vertebral artery system than in the ICA. The paired vertebral arteries usually arise from the subclavian arteries, but their origins may be more proximal on the aortic arch, or they may form a common branch of the thyrocervical trunk. The vertebral arteries generally enter the foramina of the sixth cervical vertebra or, much less commonly, the fourth, fifth, or seventh vertebral foramina. The vertebral arteries ascend through the transverse foramina and exit at C1, where they turn nearly 90 degrees posteriorly to pass behind the atlantoaxial joint before penetrating the dura and entering the cranial cavity through the foramen magnum. The portion of the vertebral artery that loops behind the atlantoaxial joint is prone to mechanical deformation, and excessive rotation of the head may cause arterial narrowing and reduction of blood flow to the ipsilateral vertebral artery.

Intracranially, the vertebral arteries are lateral to the medulla oblongata and then course ventrally and medially, where they unite rostrally at the medullopontine junction to form the basilar artery. The basilar artery ultimately bifurcates at the pontomesencephalic junction to form the posterior cerebral arteries (PCAs).

In a few individuals, the right or left vertebral arteries terminate before reaching the basilar artery, which is consequently supplied, proximally, by a single vertebral artery. The vertebral arteries usually have medial branches that turn caudally and unite to form the anterior spinal artery, as well as lateral branches supplying the dorsolateral medulla and posterior cerebellum, called the *posterior inferior cerebellar arteries*.

Circle of Willis

The circle of Willis, which is at the base of the brain, is formed by the union of the right and left ACAs via the anterior communicating artery, the MCAs, and the PCAs via the posterior communicating arteries. Anomalies of the circle of Willis occur frequently; in large autopsy series of normal individuals, more than half show an incomplete circle of Willis. The most common sites for these abnormalities, which are usually manifested as hypoplasia or absence, are the posterior communicating arteries and the ACAs.

Anterior Cerebral Arteries

The ACAs travel medially above the optic chiasm and pass rostrally toward the interhemispheric fissure, where they arch caudally to lie just dorsal to the corpus callosum. In a small fraction of normal individuals, the A1 segment of the ACA (the portion between the origin at the MCA and the first major branch, the anterior communicating artery) is hypoplastic or absent, which leaves its distal portion to be supplied by the opposite ACA via the anterior communicating artery. Branches of the ACA normally supply the frontal poles, the superior surfaces of the cerebral hemispheres where their distal branches anastomose with those of the MCA, and all of the medial surfaces of both cerebral hemispheres with the exception of the calcarine cortex (Figs. 413-3 and 413-4). Cortical areas served by the ACA include the motor and sensory cortex of the legs and feet, the supplementary motor cortex, and the paracentral lobule.

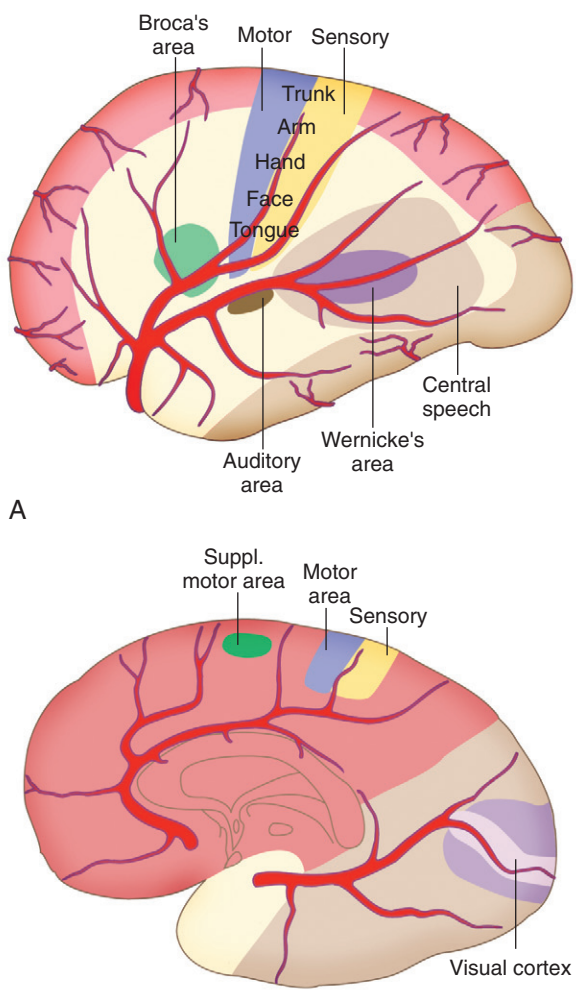

FIGURE 413-3. Surface cerebral arterial anatomy. Lateral (**A**) and medial (**B**) views of the cerebral hemisphere show the surface distributions of the anterior, middle, and posterior cerebral arteries.

The A1 and A2 segments (the portions between the anterior communicating artery and the genu of the corpus callosum) give off many small branches that penetrate the anterior perforated substance of the brain. These small penetrating branches include all of the anterior and some of the medial lenticulostriate arteries. Usually, there is a dominant medial striate vessel called the *recurrent artery of Heubner*, which commonly arises from the A1 segment of the ACA. This artery penetrates the perforated substance of the brain and, along with the other small perforators, supplies the anterior and inferior portions of the anterior limb of the internal capsule, the anterior and inferior head of the caudate nucleus, the anterior globus pallidus and putamen, the anterior hypothalamus, the olfactory bulbs and tracts, and the uncinate fasciculus.

Anterior Choroidal Artery

The anterior choroidal artery arises from the supraclinoid portion of the ICA in most people. It travels caudally and medially over the optic tract, to which it provides a few small branches, and enters the brain via the choroidal fissure. Many important brain structures receive blood flow from the anterior choroidal artery, including portions of the anterior hippocampus, uncus, amygdala, globus pallidus, tail of the caudate nucleus, lateral thalamus, geniculate body, and a large portion of the most inferior, posterior limb of the internal capsule.

Middle Cerebral Artery

The MCA provides flow to most of the lateral surface of the cerebral hemispheres and is the vessel most frequently involved in ischemic stroke. As the

(Modified from De Armond S, Fusco MM, Dewey MM. *Structure of the Human Brain, a Photographic Atlas,* 3rd ed. New York: Oxford University Press; 1989, with permission.)

main MCA trunk passes laterally toward the sylvian fissure, it gives rise to some of the medial and all of the lateral lenticulostriate arteries. These arteries supply the putamen, the head and body of the caudate nucleus, the lateral globus pallidus, the anterior limb of the internal capsule, and the superior portion of the posterior limb of the internal capsule. The MCA extends into the sylvian fissure, where it branches into several smaller arteries grouped into a superior division, which feeds the cortical surface above the fissure, and an inferior division, which supplies the cortical surface of the temporal lobe. The territory of the MCA includes the major motor and sensory areas of the cortex, the areas for contraversive eye and head movement, the optic radiations, the auditory sensory cortex, and in the dominant hemisphere, the motor and sensory areas for language.

Posterior Cerebral Arteries

Blood flow to both PCAs is derived in most people from the basilar artery and infrequently from the ICA. Sometimes the ICA is the origin of one PCA and the other PCA originates from the basilar artery. The PCAs pass dorsal to the third cranial nerves and across the cerebral peduncles and then ascend upward along the medial edge of the tentorium, where they branch into anterior and posterior divisions. The anterior division supplies the inferior surface of the temporal lobe, where its terminal branches form an anastomosis with branches of the MCA. The posterior division supplies the occipital lobe, where its terminal branches anastomose with the ACA and the MCA. In its most proximal course along the base of the brain, the PCA gives off several groups of penetrating arteries commonly called the *thalamogeniculate*, the *thalamoperforating*, and the *posterior choroidal* arteries. The red nucleus, the substantia nigra, medial portions of the cerebral peduncles, the nuclei of the thalamus, the hippocampus, and the posterior hypothalamus receive blood from these penetrating branches.

Brain Stem Blood Supply

The ventral medial portion of the brain stem receives its blood supply from short paramedian vessels, the ventrolateral region receives its blood from short circumferential branches of the vertebral or basilar arteries, and long circumferential branches supply the dorsolateral brain stem and cerebellum (Fig. 413-5). These vessels include the posterior inferior cerebellar arteries, which arise from the vertebral arteries, and the anterior inferior and superior cerebellar arteries, which arise from the basilar artery.

The pyramids, the inferior olives and medial lemnisci, the medial longitudinal fasciculi, and the emerging fibers of the hypoglossal nerve derive blood from the vertebral arteries. Longer branches from the vertebral arteries and posterior ICAs supply the spinothalamic tracts, the vestibular nuclei, the sensory nuclei of the fifth cranial nerve, the descending fibers of the sympathetic nervous system, the restiform body, and the emerging fibers of the vagus and glossopharyngeal nerves. The most cephalad and dorsal segment of the medulla includes the vestibular and cochlear nuclei, which along with the posterior portion of the cerebellum, receive flow from the posterior inferior cerebellar artery.

The basilar artery gives rise to perforating branches as it spans the ventral midline pons and midbrain. These short perpendicular branches distribute blood to the paramedian structures, including the corticospinal tracts, the pontine reticular nuclei, the medial lemnisci, the medial longitudinal fasciculi, and the pontine reticular nuclei. The anterior ICA feeds blood to the lateral pons, including the emerging seventh and eighth cranial nerves, the trigeminal nerve root, the vestibular and cochlear nuclei, and the spinothalamic tracts. It also branches to the most dorsal and lateral of these structures on its dorsal course toward the cerebellum.

At the midbrain level, the basilar artery lies in the midline in the interpeduncular fossa. Short branches pass laterally and dorsally on both sides to supply the cerebral peduncles, the emerging fibers of the third nerve, medial portions of the red nuclei, the medial longitudinal fasciculus, the oculomotor nuclei, and the midbrain reticulum. The superior cerebellar arteries contribute to the dorsal midbrain supply, including that of the colliculi and the superior portion of the cerebellum on each side.

Venous Drainage

The veins in the brain, in contrast to those in many other parts of the body, often do not accompany the arteries. Cortical veins drain into the superior sagittal sinus, which runs between the cerebral hemispheres. Deeper structures drain into the inferior sagittal sinus and great cerebral vein (of Galen), which join at the straight sinus (Fig. 413-6). The straight sinus runs along the attachment of the falx cerebri and tentorium to join with the superior sagittal sinus at the torcular Herophili, from which the two transverse sinuses arise. Each transverse sinus passes laterally toward the petrosal bone to become the sigmoid sinus, which exits the skull into the internal jugular vein. Each cavernous sinus communicates with its contralateral twin and surrounds the ipsilateral carotid artery. Both drain into the petrosal sinuses, which drain into the sigmoid sinus.

Normal Physiology

Cerebral Metabolism and Blood Flow

Although the brain is normally about 2% of body weight in humans, it is supplied with approximately 14% of the resting cardiac output. The energy demands to support normal brain activity in conscious humans are equal, on a per-weight basis, to the demands of the most metabolically active tissues, such as the heart and kidney. Aerobic glucose metabolism in a normal, conscious human brain consumes an average of 140 µmol of oxygen and 24 µmol of glucose per 100 g of brain tissue each minute. Normal brain activities, such as thinking or sleeping, do not alter total blood flow, glucose use, or oxygen uptake in the brain, but they do change the patterns of blood supply and energy use in specific brain areas.

The brain extracts approximately 10% of available blood glucose in a single pass, yet only 80% of this glucose is used to generate energy. About 10 to 15% of the glucose is metabolized to lactate, which may be lost to the circulation; the remainder is used for the synthesis of neurotransmitters, fats, and to a

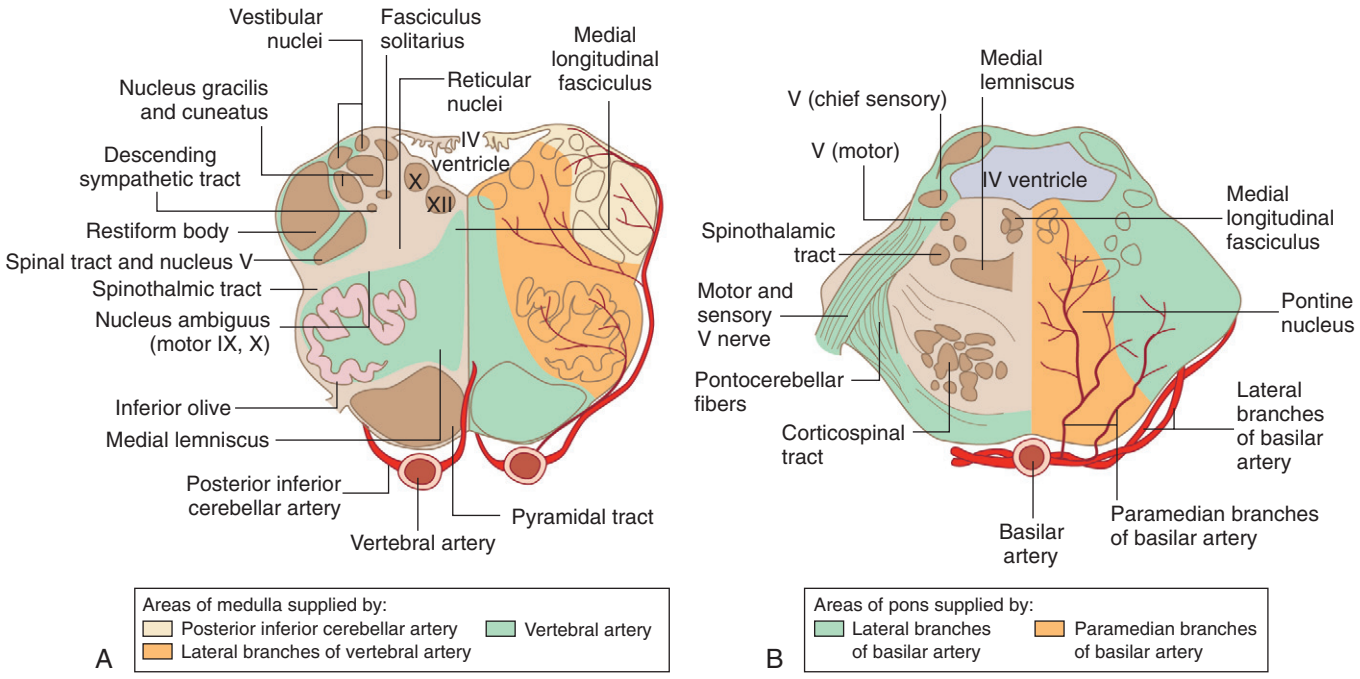

FIGURE 413-5. Brain stem blood supply. A, Cross section of the medulla oblongata at the level of the hypoglossal nuclei (cranial nerve XII). Short branches of the vertebral and anterior spinal arteries supply the medulla. Longer circumferential branches, including the posterior inferior cerebellar artery, supply the lateral portions of the medulla. **B**, Cross section of the midpons region. The medial portion receives blood supply from short, perforating basilar artery branches. More laterally, the blood supply comes from lateral basilar artery branches.

small degree, proteins. Each mole of glucose metabolized by the brain through glycolysis and the mitochondrial respiratory chain yields approximately 30 mol of adenosine triphosphate (ATP) instead of the theoretical maximum of 38 mol.

In contrast to most other tissues, the brain stores little glucose, glycogen, or high-energy phosphates (ATP, phosphocreatine) but instead relies on continuous, well-regulated blood flow to satisfy its needs for energy. Cerebral blood flow (CBF) averages 50 mL/100 g of brain tissue per minute in a normal, conscious human. In the absence of this flow, the brain has sufficient high-energy stores to support its metabolic needs for only a few minutes. The vascular reserves of oxygen and glucose are small, as illustrated by the fact that all changes in synaptic activity, whether related to thinking, talking, or directing muscular activity, are tightly coupled, temporally and anatomically, to an almost instantaneous increase in local CBF. The mechanisms responsible for this coupling of blood flow to metabolic activity have not been fully elucidated, but the relationship is well established, under normal conditions, and provides a basis for the use of imaging methods to assess regional brain activity. Regional CBF can be precisely quantified with positron emission tomography. Other less invasive techniques such as magnetic resonance imaging and single-photon emission computed tomography provide qualitative measurements of local CBF. The brain's functional activities result in a frequently and rapidly changing pattern of regional metabolic and blood flow values that reflect moment-to-moment changes in activity. On a larger scale, the low stores and high metabolic rate of the brain are responsible for the rapid loss of consciousness and subsequent irreversible damage that accompany loss of the critical energy sources of the brain, glucose and oxygen.

The coupling of CBF to regional synaptic and metabolic activity is only one of several mechanisms known to regulate normal CBF. Another is alteration of carbon dioxide. Hypercapnia dilates and hypocapnia constricts cerebral resistance vessels such that CBF shows a linear relationship to $Paco_2$ within the normal range. This physiologic response to $Paco_2$ can be exploited clinically to treat cerebral herniation. Increases in intracranial pressure (ICP) in the absence of adequate intracranial volume may force the hemispheres through the tentorium or the cerebellum through the foramen magnum. Mechanical hyperventilation to a $Paco_2$ of 20 to 25 mm Hg reduces CBF by approximately 40 to 45% and normal adult cerebral blood volume from 50 to approximately 35 mL. Though seemingly small, this reduction sometimes suffices to retard the progression of herniation and is the fastest way to reduce ICP. The response is short-lived, however, and brain and blood HCO_3^- and H^+ ions controlling blood vessel tone re-equilibrate within 30 to 60 minutes. More definitive therapy must be initiated quickly.

A complex system of neural pathways also helps control CBF. Some of these pathways participate in autoregulation, a process that maintains CBF at a constant level despite fluctuations in arterial blood pressure over a fairly wide range (Fig. 413-7). Autoregulation has upper and lower limits; at a mean arterial pressure greater than about 150 mm Hg, blood flow increases and capillary pressure rises, whereas at a mean arterial pressure of less than 50 mm Hg, CBF falls. In patients with chronic hypertension, the upper and lower autoregulatory limits are shifted toward higher systemic pressure. Consequently, a rapid therapeutic reduction in blood pressure to levels that would be normal in most people carries the risk of further lowering CBF in hypertensive patients who have ongoing cerebral ischemia. Long-term treatment with antihypertensive agents readjusts the autoregulatory curve toward more normal values. Conversely, excessive reduction of blood pressure in

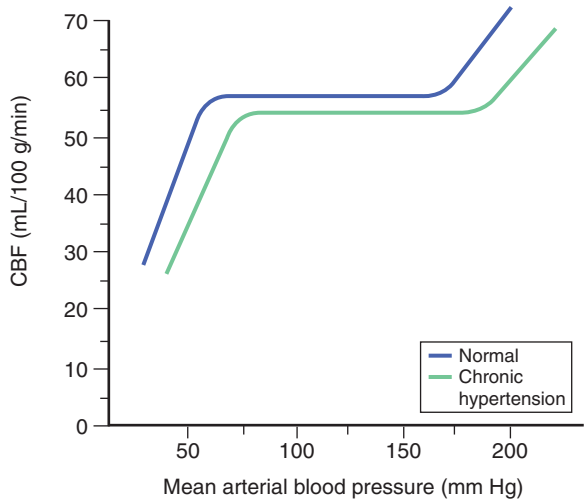

FIGURE 413-7. Autoregulatory cerebral blood flow (CBF) response to changes in mean arterial pressure in normotensive and chronically hypertensive people. Note the shift of the curve toward higher mean pressure with chronic hypertension.

previously normal patients to a mean arterial pressure of less than approximately 50 mm Hg inevitably leads to loss of autoregulation, possible expansion of an ischemic zone, or production of global cerebral ischemia. These injuries are seen in patients who are treated too aggressively with antihypertensive agents in the immediate aftermath of a stroke and in patients who are anesthetized during surgical procedures.

Blood-Brain Barrier

The brain's extracellular ionic and molecular environment is tightly regulated. Small changes in extracellular concentrations of Na^+, K^+, and Ca^{2+} ions or neurotransmitters, including glutamate, acetylcholine, and norepinephrine, alter neuronal function. Intracellular communication within the brain, perhaps its most important basic function, depends on a carefully controlled extracellular space. The blood-brain barrier (BBB), which has evolved to protect this milieu, is composed of unique endothelial cells that lack the usual transendothelial channels and closely abut one another in tight junctions. This anatomy protects the brain against the fluctuating composition of blood and reduces the entry of potentially toxic compounds. A negative consequence is that the BBB prevents the entry of polar molecules into the brain, thus limiting the utility of many drugs, small molecules, and proteins, which cannot gain entry into the brain by the oral or intravenous routes.

The entry of nutrients and egress of metabolic waste across the BBB can occur by simple diffusion, facilitated transport, or active transport. Lipid-soluble compounds can diffuse rapidly across endothelial cell membranes, whereas some polar compounds can be transported by special carrier molecules that are driven either by concentration gradients (facilitated transport) or through the expenditure of energy (active transport). Gas molecules, such as oxygen and carbon dioxide, freely diffuse across plasma membranes and rapidly equilibrate between blood and brain. Glucose, a highly polar molecule, enters the brain on a special glucose transporter. The rate of brain glucose transport is normally two to three times faster than the metabolism of glucose, but because glucose uptake depends so highly on its blood concentration, a reduction in blood glucose level to a third of normal, caused by either ischemia or hypoglycemia, may compromise normal brain energy metabolism.

CEREBRAL ISCHEMIA

Inadequate delivery of oxygen or glucose to the brain initiates a cascade of events that ultimately result in infarction. The severity of the insult, defined by the degree and duration of reduced blood flow, hypoxia, or hypoglycemia, determines whether the brain suffers only temporary dysfunction, such as a transient ischemic attack; irreversible injury to only a few of the most vulnerable neurons (selective necrosis); or cerebral infarction, in which damage occurs to extensive areas involving all cell types (pan-necrosis).

Types of Cerebral Hypoxia-Ischemia

Cerebral hypoxia-ischemia can be divided into focal ischemia caused by vascular occlusion, global ischemia as a result of complete cardiovascular failure, and diffuse hypoperfusion-hypoxia produced by respiratory disease or severely reduced blood pressure.

Focal Ischemia

Focal cerebral ischemia results most frequently from embolic or thrombotic occlusion of extracranial or intracranial blood vessels and the resulting reduction in blood flow within the related vascular territory. Blood flow to the central zone of the ischemic vascular bed is usually severely reduced but rarely reaches zero because of partial supply from collateral blood vessels. The best treatment option for this intensely ischemic region is acute restoration of blood flow. A transition zone may be present between the normally perfused tissue and the more ischemic central core. This rim of moderately deprived tissue has been called the *ischemic penumbra*. It is thought that brain cells in the penumbra remain viable for a longer time than do cells in the ischemic core. This marginally viable tissue may die if inadequate blood flow persists but may be salvaged by restoring flow or, possibly, by neuroprotective therapeutic agents. The size and duration of the penumbra are unknown in any individual patient and poorly defined by current diagnostic techniques. In more recent years, salvage of the penumbra with neuroprotective agents has been the subject of intense basic and clinical research.

Cerebral ischemia sufficient to cause clinical signs or symptoms, if severe, can produce irreversible injury to highly vulnerable neurons in 5 minutes. Progressively longer durations of ischemia increase the probability of permanent damage. If cerebral ischemia persists for more than about 6 hours, infarction of part or all of the involved vascular territory is completed, and the only strategies for therapy entail rehabilitation, such as treatment with neurotrophic factors or neural transplantation. Whether clinical evidence of permanent brain injury from ischemia is detectable depends on the location of the brain tissue involved.

Global Ischemia

Global cerebral ischemia results from cardiac asystole or ventricular fibrillation that reduces the blood flow rate to zero throughout the brain and body. Global ischemia for more than 5 to 10 minutes is generally incompatible with full recovery of consciousness in normothermic humans. If blood flow is restored in time to prevent cardiac death, selective ischemic necrosis usually involves the most vulnerable neurons in the CA1 pyramidal neurons of the hippocampus, the cerebellar Purkinje cells, and the pyramidal neurons in neocortical layers 3, 5, and 6. Anything that prevents adequate oxygen or glucose supply to the brain, such as hypoxemia, carbon monoxide poisoning, and severe and prolonged hypoglycemia, can also produce such injury. Cardiac resuscitation or other causes of prolonged hypotension may cause cerebral infarction, particularly in border zones that lie between the terminal branches of major arterial supplies, often termed *watershed zones*.

Diffuse Hypoxia

Diffuse cerebral hypoxia initially causes cerebral dysfunction but not irreversible brain injury. Individuals with cerebral hypoxia from high altitude, pulmonary disease, or severe anemia can exhibit confusion, cognitive impairment, and lethargy. The onset of coma heralds permanent brain damage. With acute changes in Pao_2 from normal to less than 40 mm Hg or a decrease in the hemoglobin concentration to less than 7 g/dL, compensatory increases in CBF become inadequate, and clinical signs and symptoms of cerebral hypoxia develop. A slower onset of reduced oxygenation, such as caused by moving to high elevations or the gradual development of anemia, permits compensation by a variety of mechanisms; if the hypoxia increases, however, the compensation ultimately fails.

Neuropathology of Cerebral Ischemia

Four general classes of histopathologic damage can occur. Cerebral infarction caused by focal vascular occlusion is characterized by destruction of all cellular elements: neurons, glia, and endothelial cells (pan-necrosis). Cerebral infarcts are initially grossly pale (anemic) or hemorrhagic (showing gross petechial bleeding). Later, necrotic tissue is removed and replaced by a glial scar or a cavity. Transient arrest of the cerebral circulation (global ischemia) can cause selective *ischemic necrosis* of highly vulnerable neurons. Using conventional stains, histologic change begins to outline the margins between living and dying neurons and glia within a few hours, although the full extent of damage may not be evident for several days. The neurologic functionality of the cells is irreversibly lost within the first 6 hours. Newer imaging techniques can reveal abnormal cell function much more rapidly than conventional histology can.

Cerebral *autolysis* is observed most frequently in brain-dead patients who are maintained on mechanical ventilators for more than a few days; it reflects enzymatic autodigestion of brain tissue. *Demyelination* of the central hemispheric white matter is usually a consequence of carbon monoxide poisoning or other prolonged periods of moderately severe hypoxemia or cerebral hypoperfusion. Development of these lesions may take several days, and the onset of neurologic dysfunction may be delayed. Patients may have a lucid interval after such an injury and subsequently manifest neurologic symptoms. Within these lesions, nerve cell axons are demyelinated, and oligodendroglial cells die.

Ischemic Cascade

In severe ischemia, energy-rich compounds become depleted within minutes. As energy-dependent membrane pumps fail, neuronal and glial cell membranes depolarize and allow the influx of Ca^{2+} ions. Elevated intracellular Ca^{2+} and other second messengers activate lipases and proteases, which release membrane-bound free fatty acids that denature proteins. Depolarization of presynaptic terminals releases abnormally high concentrations of excitatory neurotransmitters, such as glutamate, which may elevate metabolic demand at a time when energy supplies are inadequate and thus exacerbate the injury. If blood flow is restored within 5 minutes and there are no other complicating factors such as hyperglycemia, these events are completely reversible. As the duration of ischemia increases, selectively vulnerable neurons die first; if the ischemia persists for hours or longer, cerebral infarction develops. Prompt restoration of blood flow permits full functional recovery and maintenance of tissue integrity. Tissues with partial depletion of ATP and impaired calcium homeostasis may benefit from pharmacologic therapies that reduce calcium movement through voltage- and neurotransmitter-dependent ion channels. Many other neuroprotective strategies have also been shown to be effective in animal models, including prevention of the detrimental actions of excitatory neurotransmitters, inhibition of many biochemical pathways leading to cell death, and therapies that may delay the denaturation of proteins. Thus far, however, none of these therapies has proved useful in clinical trials in stroke patients.

Leukocytes

More recently, the role of leukocytes in ischemic damage has been recognized. Two proposed mechanisms of injury are (1) microvascular occlusion from direct mechanical obstruction and damage to the endothelium and (2) infiltration into central nervous system tissue and cellular cytotoxic injury. The white blood cell–mediated damage may be irreversible even if blood flow is restored.

White blood cells require considerable deformation to pass through capillaries. When activated by chemotactic substances during ischemia, their cytoplasmic stiffness increases, and they adhere to capillary endothelium. Under conditions of reduced perfusion pressure, white blood cells may obstruct the microcirculation. This leukocyte capillary plugging may be the major cause of the *no-reflow phenomenon*, which is defined as incomplete restoration of normal blood flow after a period of ischemia. Areas of parenchyma that might be viable when blood flow returns are inadequately reperfused. This phenomenon was a laboratory curiosity until the advent of thrombolytic therapy; it may now be a cause of apparent stroke in evolution or the development of increased neurologic deficits after apparently successful thrombolysis.

Leukocytes may potentiate injury by toxic damage to vascular endothelium and by transendothelial migration to the parenchyma. Release of leukocyte granule contents, which include reactive oxygen metabolites and membrane phospholipases, can injure the endothelium and is usually responsible for the removal of necrotic tissue after irreversible damage. The resultant effects include increased endothelial permeability, interstitial edema, expansion and injury of individual cells (endothelial, glial, and neuronal), vasoconstriction, and generation of substances that induce further leukocyte adhesion.

Anoxic Encephalopathy

In industrialized countries, out-of-hospital cardiac arrest (Chapter 63) occurs in 0.04 to 0.13% of the total population per year. Only a minority of these patients will survive the arrest and be discharged with a good neurologic outcome, in part because of the risk for anoxic encephalopathy. If brain stem function is preserved but the cerebral hemispheres are destroyed, the patient enters a persistent vegetative state (Chapter 411).

CEREBRAL HEMORRHAGE

Bleeding into the subarachnoid space from a ruptured aneurysm or other vascular malformation produces a chemical (sterile) meningitis and can induce vasospasm, particularly in the vessels constituting the circle of Willis. If the vasospasm is sufficiently severe, it can result in cerebral infarction and death.

Intraparenchymal hemorrhage may be relatively benign. Bleeding into a region of previous infarction, called *hemorrhagic transformation*, causes no additional functional loss. Primary parenchymatous hemorrhage damages tissue in several ways, however. If a large vessel ruptures, the amount of bleeding into the brain can be severe. The portion of the vascular distribution distal to the site of rupture is no longer supplied with blood, and infarction results. At the site of rupture, bleeding into the brain may cause traumatic injury to the exposed tissue, and blood or its breakdown products in the parenchyma damage brain tissue. In addition, the extravascular blood in the brain parenchyma increases total brain volume, and the edema, which forms rapidly in and around the site of bleeding, increases the intracranial contents. Because cranial capacity is fixed, ICP increases rapidly, and cerebral herniation may occur.

The biochemical pathology caused by exposure of brain tissue to blood has not been established. Hypertension is closely associated with intracerebral hemorrhage. Research suggests that the matrix metalloproteinases in vessel walls are activated, thereby leading to degradation of vascular tissue with subsequent bleeding.

CEREBRAL EDEMA

A pathologic increase in the water content of brain tissue (edema) eventually develops in all types of ischemic and hemorrhagic stroke. Brain swelling and raised ICP relate proportionally to the volume of accumulated water; in some instances, edema can cause neurologic deterioration and death by herniation syndromes.

The intracranial space contains the brain, which weighs approximately 1400 g, about 75 mL of blood, and approximately 75 mL of cerebrospinal fluid (CSF). An increase in the volume of any of these contents must be accompanied by a decrease in another component because the intracranial cavity is of relatively fixed size and surrounded by bone. Normally, the brain's tissue volume is constant, whereas intracranial blood and CSF vary reciprocally to maintain normal ICP. A variety of mechanisms can compensate for increased intracranial contents to a limited extent, including displacement of CSF into other cranial compartments, reduction of venous blood volume, reduction of normal cerebral interstitial fluid, and chronic cerebral atrophy. If there is a rapid increase in extravascular blood, reduced venous outflow, blockage or resorption of CSF, or cerebral edema, ICP increases markedly.

Brain edema is categorized on the basis of pathophysiologic and anatomic criteria as intracellular or interstitial. Intracellular edema, also called *cytotoxic edema*, develops as energy-dependent membrane ion pumps fail; as a result, Na^+ and other osmoles enter the cell and draw water in from the interstitial and vascular compartments. This process can begin within a few hours after the onset of ischemia. Cell swelling occurs predominantly in astrocytes, but neurons, oligodendroglial cells, and endothelial cells are also involved.

Interstitial edema, also called *vasogenic edema*, occurs later than the intracellular form. Damage to endothelial cells of the BBB allows macromolecules, such as plasma proteins, to enter the cerebral interstitial space accompanied by osmotically bound water. Interstitial edema after cerebral infarction progressively worsens for about 3 days after a stroke. Fluid accumulation within the vicinity of damaged endothelial cells and the zone of infarction can raise the local water content of brain by 10%. The osmolality of ischemic brain increases from 310 to approximately 350 mOsm. The intracellular accumulation of water increases from a normal value of approximately 79 to 81% of brain weight.

If the cerebral circulation is re-established before permanent brain injury develops, the intracellular edema resolves without permanent sequelae. A large increase in the brain's volume can, however, lead to transtentorial herniation of the cerebral hemispheres or to cerebellar herniation. These syndromes can result in irreversible global ischemia of the hemispheres or crushing of the brain stem, loss of cerebral control of the circulation, and death from respiratory arrest. The edema-induced increase in ICP usually reaches a maximum about 3 days after the onset of a stroke. If a patient has a large stroke and survives after the third day, the patient is unlikely to die as a result of that stroke.

ISCHEMIC CEREBROVASCULAR DISEASE

JUSTIN A. ZIVIN

DEFINITION

Ischemic stroke is caused by insufficient blood flow to part or all of the brain. *Focal stroke* is defined as an infarction in a part of the brain as the result of reduced blood flow in an artery that supplies that part of the brain. During the early phases of a stroke, when acute therapy is potentially beneficial, it is impossible to predict whether an individual patient will recover because the treatment is effective only if given before it is known whether the symptoms will resolve spontaneously.

The important distinction between a transient ischemic attack (TIA) and a stroke is whether the ischemia has caused brain infarction, a difference that may not be possible to distinguish within the first few hours after the onset of symptoms but commonly becomes apparent retrospectively. With a stroke, symptoms usually persist for more than 24 hours, but clinical deficits that persist for more that 1 to 2 hours commonly are associated with permanent brain damage, often demonstrable by computed tomography (CT) or magnetic resonance imaging (MRI), despite complete recovery. Many events that were defined as TIAs in the era before neuroimaging were actually infarcts. By comparison, the symptoms of TIAs usually do not persist for more than 1 to 2 hours and do not cause permanent damage on neuroimaging studies. Patients with TIAs are at considerably increased risk of having a stroke within hours to days after a TIA.

Ischemic strokes are differentiated from hemorrhagic strokes (Chapter 415) by the lack of extravasated blood in the brain parenchyma. There are two main classifications of ischemic stroke. *Thrombosis* and *embolism,* which are caused by arterial occlusion with either a thrombus that forms locally at the site of an atherosclerotic plaque or an embolic clot, are responsible for 65% of all strokes. Emboli are produced when a piece of a larger clot breaks off from a mural thrombus in the heart or a more proximal artery and lodges downstream at a point where the diameter of the vessel has decreased in size so that the clot can no longer pass through the arterial lumen. It is often impossible to distinguish a thrombus from an embolus by imaging methods or histopathologic material, so the two processes are classified together. *Small vessel strokes,* commonly called *lacunes,* are caused by occlusion of small arterioles and account for about 20% of strokes. The histologic lesion in blood vessels in these strokes is classically called lipohyalinosis, which does not help in identifying the cause of these strokes. Some of these strokes are caused by local vascular abnormalities, but others are almost certainly caused by small emboli. The other 15% or so of strokes are caused by hemorrhage (Chapter 415).

EPIDEMIOLOGY

Hypertension is the most important risk factor for ischemic and hemorrhagic stroke (Chapter 67). The incidence of stroke increases directly in relation to the degree of elevation of systolic and diastolic arterial blood pressure above threshold values. More important, there has been conclusive evidence for more than 30 years that control of hypertension prevents strokes. Meta-analyses of randomized controlled trials confirm an approximate 30 to 40% reduction in stroke risk with lowering of blood pressure.

Approximately 7 to 10% of men and 5 to 7% of women older than 65 years have asymptomatic carotid stenosis of greater than 50%. Epidemiologic studies suggest that the rate of unheralded stroke ipsilateral to a stenosis is about 1 to 2% annually.

Nonvalvular atrial fibrillation (Chapter 64) carries a 3 to 5% annual risk for stroke, with the risk becoming even higher in the presence of advanced age, previous TIA or stroke, hypertension, impaired left ventricular function, and diabetes mellitus.

In epidemiologic studies, the risk for stroke in smokers is almost double that in nonsmokers, but the risk becomes essentially identical to that of nonsmokers by 2 to 5 years after quitting. The relative risk for stroke is two to six times greater for patients with insulin-dependent diabetes (Chapter 236). Patients with sickle cell disease (Chapter 166) have a markedly increased risk for stroke. Hyperlipidemia also increases the risk for stroke, and reduction of low-density lipoprotein (LDL) cholesterol levels with statins reduces this risk. Some evidence suggests that abdominal obesity in men and obesity and weight gain in women are independent risk factors for stroke. Weight reduction in overweight people is recommended, but weight loss has not been proved to reduce the risk for stroke.

Epidemiologic studies have found that consumption of fruits and vegetables is associated with a lower risk for stroke, but no randomized trials have proved the value of changing dietary habits. Heavy alcohol consumption may be a risk factor for ischemic and hemorrhagic stroke.

Postmenopausal hormone replacement therapy has been shown to increase the risk for stroke. The absolute risk for stroke remains low, however, in otherwise healthy, low-risk patients. Meta-analysis suggests an increase in the relative risk for stroke in women taking oral contraceptives, but the absolute risk for stroke is small. Women who smoke, are hypertensive or diabetic, have migraine headaches, or have previously suffered thromboembolic events may be at increased risk for stroke when taking oral contraceptives.

PATHOBIOLOGY

The precise signs and symptoms of ischemic stroke depend primarily on the region deprived of blood flow. The tempo with which deficits develop has important clinical implications.

Pattern of Development of Strokes

Shortly after the onset of vascular occlusion, it is common for symptoms and signs to fluctuate and either to improve or to deteriorate, often rapidly. Some patients may be in denial and anticipate that their symptoms will resolve, thereby resulting in delay in seeking medical care until sufficient time has elapsed that acute therapy is useless.

If the symptoms resolve completely in 1 or 2 hours, the patient has had a TIA. The basis for this resolution is unclear. Possibilities include dissolution of an embolus with subsequent restoration of normal regional blood flow, decrease in vasospasm, and improvement in perfusion secondary to increased collateral flow.

Ischemic episodes that ultimately develop into infarction often fluctuate for several hours after onset. Early in the course it is impossible to predict what will happen. Recovery may stop suddenly, and deficits may plateau or increase. Persistence of any neurologic deficit beyond 2 hours, even if the patient subsequently recovers fully, is nearly always accompanied by some degree of tissue destruction.

Hours to days after the abnormality becomes stable, increased neurologic deficits may develop, a deterioration termed *stroke in evolution.* Probable reasons include reperfusion injury, clot extension, or a new stroke in the same vascular distribution. Compromised cardiac output and systemic hypotension resulting from myocardial ischemia, cardiac arrhythmias, or heart failure may also contribute in some cases. Patients may appear to have stroke in evolution because of systemic disorders, such as electrolyte imbalances or glucose abnormalities that initially appear to be exacerbations of a stroke but are really comorbid problems that do not cause extension of the infarct. Cerebral edema may increase neurologic deterioration in large strokes by causing herniation syndromes. Secondary bleeding into an infarct can occur; ordinarily, this process does not increase neurologic deficits unless the blood extends into an area outside the initial boundaries of the infarction or causes a mass effect and increased intracranial pressure. The term *stroke in evolution* describes a clinical picture rather than a specific pathologic process.

Common Causes and Pathogenesis of Stroke

Atherosclerosis

Atherosclerosis (Chapter 70) is the most common disorder that leads to stroke. Atherosclerotic plaques are thought to cause stroke in three ways: (1) mural thrombosis forms at the site of an atherosclerotic lesion, and the clot obstructs the artery at that location; (2) ulceration or rupture of a plaque leads to formation of a clot and distal embolization; and (3) hemorrhage into a plaque obstructs the artery. The clinical manifestations of a stroke depend on the rate of occlusion. If occlusion occurs slowly, there may be time for collateral blood supply to develop, and a stroke is avoided. If the occlusion is abrupt, a stroke ensues, and the degree of damage depends on the extent of collateral supply that is available to the territory of the brain supplied by the occluded vessel. If collateral supply is marginal, just enough blood may pass through the stenotic region to maintain minimally adequate blood flow. In these circumstances, neurologic function may become critically dependent on changes in blood pressure, and small decreases can cause a stroke or recurrent TIAs.

More frequently, a platelet-fibrin thrombus forms on the roughened surface of an atherosclerotic plaque. The thrombus can break off and float distally in the blood stream, eventually becoming lodged in a distal, smaller branch; this process is termed *artery-to-artery embolization.* These embolic occlusions are more likely to be symptomatic because the more distal end vessels have no collateral supply. The amount of territory that is deprived of blood is smaller, however, and symptoms are usually less severe than with occlusion of the main stem of a vessel. The most common locations for an intravascular thrombus to form are the base of the aorta, the bifurcation of the common carotid artery, or the point at which the vertebral arteries originate from the subclavian arteries.

Emboli of Cardiac Origin

Emboli originating from the heart may lodge in any part of the body; however, because about 20% of the normal cardiac output goes to the brain, it is a common site of cardioembolism. Thrombus formation and release of emboli from the heart are promoted by arrhythmias and by structural abnormalities of the valves and chambers. The frequency of the various types of stroke produced by cardioembolism can only be estimated. Although some strokes are clearly embolic in origin, and others are unquestionably thrombotic, it is generally impossible to distinguish them pathologically. There is no diagnostic test to prove that a thrombus or embolus is of cardiac origin.

Mural Thrombi

Myocardial infarction may produce a region of dyskinetic myocardium that predisposes to the formation of mural thrombi (Chapter 73). Anterior wall myocardial infarction is associated with the highest frequency of thromboembolic stroke. Cardiomyopathies (Chapter 60), such as those caused by alcohol abuse or viral infections, also produce dyskinesia that promotes mural thrombi and can result in cerebral embolization, as can any cause of severe heart failure (Chapter 59). In some instances, a cardiac mural thrombus may release numerous pieces that produce a shower of emboli and cause several simultaneous strokes at various locations in the brain.

Valvular Heart Disease

Rheumatic heart disease (Chapter 298), which is now rare in industrialized countries, is associated with systemic emboli, especially in patients who have mitral stenosis (Chapter 75). Acute or subacute infectious endocarditis (Chapter 76) produces vegetations on heart valves, and these vegetations can embolize to the cerebral circulation. Endocarditis caused by staphylococci, fungi, or yeast is often extensive enough to occlude large intracranial arteries. Infective endocarditis is associated with other forms of cerebrovascular disease, including intracerebral hemorrhage, subarachnoid hemorrhage, and mycotic aneurysm (Chapter 415). Strokes can occur during the acute phases of the disease, and the combination of fever, a new murmur, and petechiae should prompt collection of blood for culture and consideration of empirical treatment with antibiotics. Anticoagulants may increase the risk for intracerebral hemorrhage in patients with bacterial endocarditis.

Nonbacterial endocarditis (Chapter 60), which is usually associated with various types of cancer, can also give rise to vegetations that produce cerebral embolization and cause focal strokes or diffuse encephalopathy, sometimes in the form of disseminated intravascular coagulopathy. Systemic lupus erythematosus (Chapter 274) is associated with atypical verrucous (Libman-Sacks) endocarditis in which friable vegetations form on the leaflets of any of the heart valves and can rarely produce cerebral embolization.

In patients with prosthetic heart valves, the incidence of stroke is 1 to 5% per year despite oral anticoagulation (Chapter 75). Mechanical valves have a higher risk than biologic valves. Many studies have suggested that anticoagulants reduce but do not completely eliminate cerebral embolization in these patients.

Arrhythmias

Atrial fibrillation, independent of the presence or absence of valvular disease, is a proven cause of embolic stroke and increases the relative risk, compared with age-matched controls, to about 5% per year (Chapter 64). Approximately 15% of all ischemic strokes are associated with nonvalvular atrial fibrillation. Most patients with atrial fibrillation never have a stroke, however. The strokes are often large and disabling, but minor strokes, silent strokes, and TIAs can occur. Most ischemic strokes in patients with atrial fibrillation are due to embolism from left atrial mural thrombi. The risk for atrial fibrillation–associated strokes is increased in patients who have chronic hypertension. The risk for embolic stroke is highest shortly after the development of atrial fibrillation, but embolism can also accompany cardioversion to normal sinus rhythm regardless of whether the conversion is spontaneous, induced by medication, or electrical.

Paradoxical Emboli

Embolic occlusion of intracranial vessels can be of venous origin. The embolic material gains access to the arterial circulation through various cardiac defects, such as a patent foramen ovale, atrial septal defect (Chapter 69), or arteriovenous malformation. When venous emboli enter the heart, a right-to-left shunt allows the emboli to enter the arterial circulation. A patent foramen ovale has been detected in 40% of patients with acute ischemic stroke of uncertain origin, and it is often assumed that paradoxical embolization is the cause of the stroke. Patients with an atrial septal aneurysm and a patent foramen ovale are at highest risk.

CLINICAL MANIFESTATIONS

The clinical manifestations are summarized in Table 414-1.

Internal Carotid Artery

The common carotid artery bifurcation, at the origin of the internal carotid artery (ICA), is the most frequent site of atherosclerotic lesions of the cerebral vasculature. Occlusion of the ICA is often clinically silent if the circle of Willis is complete. It is often impossible to distinguish ICA occlusion from similar damage to the middle cerebral artery (MCA) on clinical examination (see later). Because the ophthalmic artery originates from the ICA, however, TIAs of the ICA may be manifested as transient monocular blindness (also called *amaurosis fugax*). Severe stenosis of the ICA, particularly if bilateral, can cause hypoperfusion of the cerebral hemispheres and symptoms in border zones between the MCA and other major vascular territories (watershed areas), especially if superimposed on generalized hypoperfusion secondary to severe hypotension.

Anterior Cerebral Artery

Isolated occlusion of the anterior cerebral artery (ACA), which is relatively rare in comparison to strokes in other major branches of the circle of Willis, accounts for about 2% of all cerebral infarcts. The principal symptoms associated with occlusion of an ACA distal to the anterior communicating artery are upper motor neuron weakness and cortical sensory deficits (neglect) in the contralateral leg. Other manifestations of ACA occlusion can include urinary incontinence, generalized depression of psychomotor activity (abulia), and transcortical motor aphasia manifested as loss of verbal fluency with preserved ability to repeat. Bilateral occlusion may occur because the origins of the two ACAs are separated by only a short stretch of anterior communicating artery, and there are frequent anomalies in which both ACAs originate from a common source. Bilateral damage usually causes a patient to be mute, with severe mood disturbances and long-lasting incontinence from bilateral damage to the frontal lobes.

Middle Cerebral Artery

Strokes in the distribution of the MCA are the most common type of focal stroke, and such strokes cause approximately two thirds of all infarcts. Occlusion of the stem of the MCA often results in massive, devastating infarction of much of the hemisphere. Edema during the first 3 to 4 days may lead to

TABLE 414-1 CLINICAL MANIFESTATIONS OF ISCHEMIC STROKE

OCCLUDED BLOOD VESSEL	CLINICAL MANIFESTATIONS
ICA	Ipsilateral blindness (variable) MCA syndrome (see below)
MCA	Contralateral hemiparesis, sensory loss (arm, face worst) Expressive aphasia (dominant) or anosognosia and spatial disorientation (nondominant) Contralateral inferior quadrantanopsia
ACA	Contralateral hemiparesis, sensory loss (worst in leg)
PCA	Contralateral homonymous hemianopia or superior quadrantanopia Memory impairment
Basilar apex	Bilateral blindness Amnesia
Basilar artery	Contralateral hemiparesis, sensory loss Ipsilateral bulbar or cerebellar signs
Vertebral artery or PICA	Ipsilateral loss of facial sensation, ataxia, contralateral hemiparesis, sensory loss
Superior cerebellar artery	Gait ataxia, nausea, dizziness, headache progressing to ipsilateral hemiataxia, dysarthria, gaze paresis, contralateral hemiparesis, somnolence

ACA = anterior cerebral artery; ICA = internal carotid artery; MCA = middle cerebral artery; PCA = posterior cerebral artery; PICA = posterior inferior cerebellar artery.

severely increased intracranial pressure and herniation. The classic picture of occlusion of the MCA stem is contralateral weakness and sensory loss in the face and arm (with relative sparing of the leg) and homonymous hemianopia on the side of the weakness; initially, there may be depressed consciousness and deviation of gaze toward the side of the lesion. There is little chance of substantial recovery. In right-handed people, occlusion of the left MCA produces global aphasia in which the patient can neither understand the speech of others nor produce meaningful speech. In the nondominant hemisphere, unilateral neglect, anosognosia (unawareness of the deficit), and spatial disorientation occur.

Occlusion of branches of the MCA produces partial syndromes. An embolus to the MCA frequently lodges in one of its two main divisions. Occlusion of the superior division can cause dense sensorimotor deficits in the contralateral face and arm without initial impairment of alertness. Later, some neurologic function may recover, and the aphasia may decrease. Strokes of the inferior division in the dominant hemisphere characteristically produce receptive aphasia of the Wernicke type (severe loss of speech comprehension with preserved spoken and written language). Damage to either hemisphere can result in contralateral loss of integrated sensation, such as perception of shapes (stereognosis). Occlusion of more distal branches causes less clinical damage.

Posterior Cerebral Artery

In about three fourths of people, both posterior cerebral arteries (PCAs) arise from the basilar artery; in most others, one PCA arises from the basilar artery and the other arises from the ICA. In a few individuals, both PCAs originate from the ICAs. As a consequence, the syndromes associated with occlusion of the PCA are highly variable. Strokes of the perforating branches most frequently cause complete contralateral hemianesthesia with loss of all sensation and complete hemianopia on that side. Macular (central) vision may be spared because of collateral blood supply from the MCA. Difficulty reading (dyslexia) and performing calculations (dyscalculia) may occur. Recovery is often good, but the initial numbness may be replaced by paresthesias or excruciating pain; this Dejerine-Roussy syndrome is caused by damage to the thalamus. Involvement of the subthalamic nucleus may produce hemiballismus, with wild flinging movements of the limbs on one side of the body. Distal branch occlusions of the PCA cause partial syndromes; occlusion of the terminal branch can produce a variety of incomplete visual field deficits, although the loss is characteristically congruous (superimposable) in both visual fields.

Vertebral and Basilar Arteries

Characteristic of occlusion of the blood supply to the brain stem are "crossed syndromes" (i.e., contralateral loss of strength and selected contralateral and ipsilateral sensory symptoms below the level of the lesion, in addition to ipsilateral motor and sensory deficits localized to the level of the lesion). Weber's syndrome is caused by a mesencephalic lesion that produces an ipsilateral third cranial nerve palsy resulting from damage to the oculomotor nerve as well as contralateral weakness.

The vertebral arteries are the principal blood supply for the medulla. The posterior inferior cerebellar artery is usually a branch of the vertebral artery. The consequences of occlusion of the posterior inferior cerebellar artery are variable, but lateral medullary infarction (Wallenberg's syndrome) is classically produced. In about 80% of cases, occlusion of the vertebral artery causes lateral medullary syndrome, which consists of severe vertigo, nausea, vomiting, nystagmus, ipsilateral ataxia (of the cerebellar type), and ipsilateral Horner's syndrome (ptosis, miosis, and decreased sweating). The syndrome also includes ipsilateral loss of facial pain and temperature sensation and contralateral loss of these sensory modalities in the trunk and limb. Partial syndromes are the rule; a complete lateral medullary syndrome is rare, so it is often misdiagnosed.

The basilar artery supplies most of the brain stem, and occlusion of this artery produces a variety of syndromes. Obstruction of the basilar artery trunk is often fatal because the main motor and sensory pathways between the cerebral hemispheres and the remainder of the body are compact and travel through the brain stem. The findings in occlusion of the basilar artery consist of a combination of bilateral sensory and motor long-tract signs, cerebellar dysfunction, and cranial nerve abnormalities: paralysis or weakness of all extremities and the bulbar muscles, impaired vision with various visual field defects, bilateral cerebellar ataxia, and a variety of sensory disturbances ranging from normal to total anesthesia. Coma may occur, or the locked-in syndrome may develop in which consciousness is preserved but the victims are unable to move anything voluntarily except their eyes or eyelids. It is possible to communicate with these patients and demonstrate normal mental status by codes involving eye movements.

Occlusion of the various branches of the basilar artery produces a large variety of syndromes. Because the pathways are so closely spaced in the brain stem, even small brain infarctions can cause substantial motor and sensory deficits. The characteristic findings are crossed syndromes with motor and sensory dissociation, unless the findings are bilateral. Distinguishing mild vertebrobasilar ischemia from the common causes of dizziness is occasionally difficult (Chapters 50 and 62), but ischemia is rarely a cause of isolated vertigo in the absence of other brain stem signs or symptoms.

DIAGNOSIS

The history gives initial clues about the site and severity of a stroke, and the physical examination helps refine a hypothesis on the location of the lesion. Based on this information, definitive laboratory testing can proceed efficiently.

History

As the name implies, stroke ordinarily starts at a clearly identifiable time. The most important aspect of the history, which must be elicited from a patient or accompanying observers if a stroke is suspected, is the time of onset of symptoms. If abnormalities began within the preceding 3 hours, the patient should be managed as an acute emergency, and thrombolytic therapy may be indicated. Patients may be confused, anxious, or aphasic, and they may not remember the duration of symptoms. It may be necessary to try to associate the onset of symptoms with events that the patient or accompanying persons can identify accurately. Did the patient wake up with symptoms? In this case the symptoms must be assumed, in terms of considering acute treatment, to have started at the time that the patient was last known to be in a premorbid state—usually at the time of going to sleep. Was the patient watching television, and if so, what program was it? Consultation with the program guide can be used to assign a time of onset. Was an ambulance called, and if so, what time was the patient first examined by paramedics? This information is usually available in the ambulance records.

TIAs may not be distinguishable from a stroke during the early phases, but TIAs usually resolve within the first hour or two. Rapid progression of deficits or the presence of headache occurs more often in patients with intracerebral hemorrhage (Chapter 415). Although intracerebral hemorrhage is responsible for only about 15% of strokes, hemorrhages generally produce more

severe symptoms that cannot be denied. By comparison, patients with minor strokes or predominantly sensory symptoms are often in a state of denial and do not seek medical care until long after vessel occlusion. Because ischemic strokes are nearly always painless, they do not awaken patients from sleep and are frequently discovered at the time of normal awakening in the morning. There is some diurnal variation in the onset of stroke, with a peak in the late morning.

Physical Examination

The neurologic examination (Chapter 403) is a cost-effective method for initiating a diagnostic evaluation, and it often helps localize the site of the lesion. The cardiovascular examination (Chapter 50) should focus on measurement of arterial blood pressure, including measurement in both arms to evaluate the possibility of aortic dissection (Chapter 78) or vascular abnormalities that result in reduced blood flow to the brain when the arms are exercised (subclavian steal). The greatest risk factor for stroke is preexisting hypertension. In many patients, transient hypertension develops in the immediate aftermath of a stroke, however, so it is important to determine whether a patient has had sustained hypertension (Chapter 67). Extremely elevated blood pressure at initial evaluation can lead to heart failure, which may have to be managed urgently. If hypertension is a transient manifestation of acute stroke, aggressive reduction may cause hypotension and enlarge the infarct. The pulse may reveal arrhythmias, such as atrial fibrillation, that can result in cerebral embolism. Cardiac murmurs may suggest valvular lesions (Chapter 75) that can cause cerebral embolism. Bruits of the carotid arteries can be produced by atherosclerotic disease of the arteries, and such disease is associated with embolic and thrombotic strokes. Evidence of peripheral vascular disease (Chapter 79) may be a reflection of generalized atherosclerosis.

Ophthalmoscopic visualization of retinal cholesterol or platelet-fibrin emboli suggests more proximal atherosclerotic disease. Examination of the retinal vessels may also reveal signs of chronic hypertension or diabetes (arteriovenous crossing defects or retinal hemorrhages; Chapter 431).

The neurologic examination usually suggests the location and size of the stroke. If the patient's mental status is depressed, bilateral cerebral lesions or a brain stem lesion is suggested. Multiple smaller strokes may lead to dementia. Speech is commonly affected, with various aphasic patterns suggesting the site of the lesion. Testing of strength, sensation, and deep tendon reflexes provides information about the patterns of the deficits and suggests the site of the vascular lesion. Plantar stimulation (Babinski's sign), which is a classic finding in patients with damage to the long tracts, indicates upper motor neuron damage caused by stroke. However, during the early phases of a large stroke, reflexes may be depressed rather than hyperactive.

Laboratory Examination

Hematologic Tests

A complete hemogram, including a platelet count, is essential to evaluate for polycythemia (Chapter 169), thrombocytosis, bacterial endocarditis (Chapter 76), and severe anemia. An erythrocyte sedimentation rate is also a useful screening test because it may be elevated in patients with hypercoagulable states (Chapter 179) and is markedly elevated in patients with giant cell arteritis (Chapter 279). A blood glucose level must be checked because hyperglycemia and hypoglycemia can produce focal and global neurologic deficits, sometimes mimicking stroke. Diabetes (Chapter 236) increases the risk for stroke, and stroke may be the initial symptom of diabetes. A prothrombin time and partial thromboplastin time should be obtained in patients who may have received anticoagulants before the onset of stroke to determine whether they have been taking their medications or the anticoagulation is excessive.

Although moderate hyperlipidemia is not a proven risk factor, extremely high lipid levels are strongly associated with stroke. Antiphospholipid antibodies are elevated in some patients with immune-related diseases. Measurement of protein C, protein S, antithrombin III, blood viscosity, and platelet function (Chapter 179) and tests for homocystinuria, collagen vascular diseases (Chapter 264), amyloidosis (Chapter 194), and syphilis (Chapter 327) should be performed in selected cases.

Cardiovascular Testing

Patients with acute myocardial infarction or a new or chronic atrial arrhythmia may have suffered an embolic stroke. A standard electrocardiogram and rhythm strip should be obtained at initial evaluation to determine whether acute myocardial ischemia or arrhythmia is present. Echocardiography is indicated urgently only in patients with a history of cardiac disease and an abnormal electrocardiogram; if no cause for the stroke is identified, however, particularly if the patient is relatively young, echocardiography is generally indicated.

Noninvasive Brain Imaging

Brain imaging (Chapter 403), which is essential to verify causes of focal neurologic dysfunction, can generally distinguish ischemic stroke from other diseases. The most important disorders to differentiate from acute ischemic stroke are intracerebral hemorrhage (Chapter 415), subarachnoid hemorrhage (Chapter 415), and brain tumors (Chapter 195).

CT is the standard initial imaging study (Fig. 414-1). Non–contrast-enhanced imaging usually detects intracerebral hemorrhage. Signals indicating tissue hypodensity, particularly in the region of the brain appropriate to the neurologic deficits, and loss of the distinction between gray and white matter are often observed 3 to 24 hours after the onset of stroke. These findings cannot predict the size of the infarction, however, and noncontrast CT findings may be normal for 3 to 24 hours after an ischemic stroke. The hypodensity typically becomes progressively more apparent over the first 3 to 24 hours and is usually readily detectable by 24 hours in patients with large infarcts. Small ischemic strokes in the brain stem can produce major neurologic dysfunction and may not be detected by CT. Contrast enhancement of CT scans seldom improves detection of acute stroke, but it may distinguish ischemic lesions from some types of neoplasms.

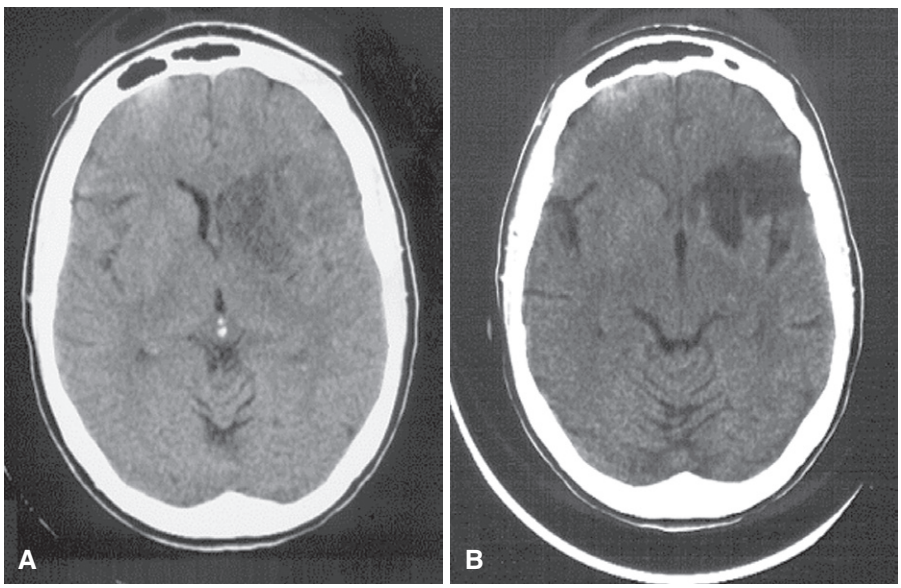

FIGURE 414-1. Computed tomographic imaging. A, A computed tomography (CT) scan of a patient with a left hemisphere infarction 6 to 24 hours after the onset of symptoms shows a hypodense area in the basal ganglia region and compression of the frontal horn of the lateral ventricle. **B,** A CT scan shows the chronic infarction 1 year later; atrophy and loss of tissue volume are visible. (Courtesy of Gregory W. Albers, Stanford University, Stanford, Calif.)

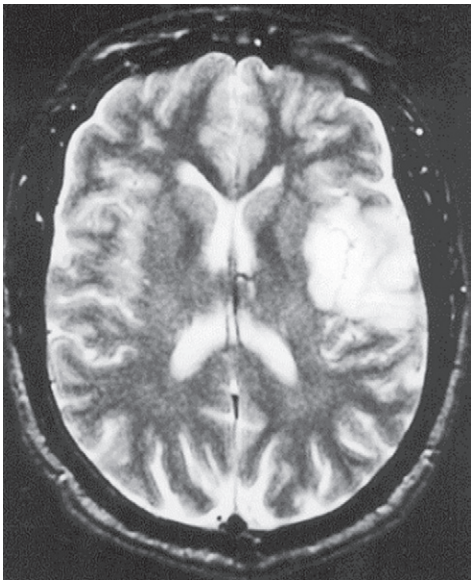

FIGURE 414-2. Magnetic resonance imaging showing early ischemic changes obtained 6 hours after the onset of right-sided weakness in a patient with an occluded left internal carotid artery. (Courtesy of Gregory W. Albers, Stanford University, Stanford, Calif.)

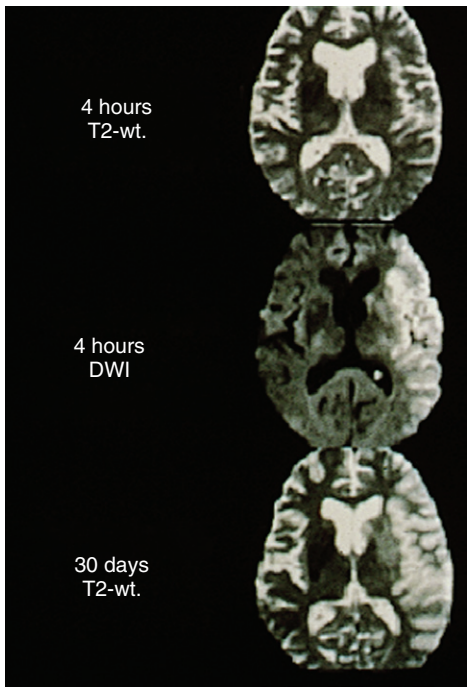

FIGURE 414-3. Magnetic resonance imaging (MRI) showing possible advantages of diffusion-weighted imaging (DWI) relative to conventional MRI at early times after vascular occlusion. *Top,* Conventional T2-weighted MRI 4 hours after symptom onset that appears normal. *Middle,* At the same time, a DWI scan shows abnormalities in the left hemisphere. *Bottom,* Repeat T2-weighted MRI 1 month later showed an infarction in the same location as the initial DWI scan. (Courtesy of Gregory W. Albers, Stanford University, Stanford, Calif.)

CT is currently the only imaging method useful for deciding whether to administer thrombolytic therapy. Detection of hemorrhage in areas of infarction is important because it precludes thrombolytic therapy. Small hemorrhages may be detected by CT scanning during the first few hours but may not have clinical importance. Hemorrhages become more evident with time and appear on repeat scans hours to weeks after infarction. Whether this apparent increase in the detection of hemorrhage is due to a progressive increase in the size of the initial hemorrhage or to alterations in the extravasated blood is not known.

MRI is more sensitive than CT for detecting early ischemia (Fig. 414-2). MRI sequences can identify tissue or blood flow abnormalities within minutes after the onset of ischemia (Fig. 414-3). These early indicators of tissue injury are qualitative and have not been shown to predict the ultimate volume of the lesion or whether the tissue damage is irreversible. MRI cannot be used in patients who have ferromagnetic materials within their bodies, is often impossible to use in critically ill patients, and renders the patient inaccessible for several minutes. No MRI sequences successfully distinguish ischemia from hemorrhage, especially during the early phases of injury, when decisions regarding whether thrombolysis should be administered are needed. CT remains the imaging procedure of choice for acute patient management.

Lumbar Puncture

Lumbar puncture is no longer performed routinely in the evaluation of a patient with stroke because CT detects intracerebral hemorrhage more reliably (Chapter 403). CT can also usually identify blood in the subarachnoid space, although lumbar puncture is more sensitive for this purpose and can give some indication about when the bleeding occurred (Chapter 415). After subarachnoid hemorrhage, erythrocytes hemolyze. As hemoglobin is metabolized, cerebrospinal fluid becomes xanthochromic. Lumbar puncture is required to determine whether a patient has neurosyphilis (Chapter 327), although screening blood testing should be conducted first. Lumbar puncture is also occasionally indicated if there is concern that a patient may have bacterial meningitis (Chapter 420).

Noninvasive Cerebrovascular Examination

Ultrasonography provides an estimate of luminal diameter and the direction and speed of blood flow. B-mode ultrasonography, which produces real-time images of the carotid vessels, and range-gated pulsed Doppler, which is guided visually by the B-mode image, can detect increased blood velocity through a stenotic lumen. The combination of the location of the Doppler frequency signal and the B-mode image provides a noninvasive method for analyzing the condition of the extracranial circulation. Limitations of the technique include (1) access to only the portion of the carotid circulation that lies between the clavicles and the mandible (in approximately 10% of patients, the carotid bifurcation lies above the angle of the jaw, thus making ultrasonography difficult or impossible); (2) absorption of sound waves by calcium within a mural plaque, a process that may "shadow" and obscure a plaque on a distal vessel wall; and (3) echolucency of acute thrombi, which can be indistinguishable from flowing blood. The direction and velocity of blood flow in the intracranial blood vessels originating from the circle of Willis can be examined with low-frequency pulsed transcranial Doppler. Although these methods are useful screening techniques with essentially no risk to the patient, the "gold standard" for defining the status of the cerebral vasculature remains cerebral angiography. Moreover, ultrasound technique is critically dependent on the training and skill of the technician; there is considerable variation among different laboratories, and the clinician must confirm new or suspicious findings with repeat examinations or other tests.

CT and magnetic resonance (MR) angiography can visualize the larger cerebral vessels and detect abnormalities such as stenosis, aneurysms, or arteriovenous malformations. These methods lack sensitivity for small lesions, however, and the degree of stenosis tends to be exaggerated.

Cerebral Angiography

Cerebral angiography is reserved for patients who are suspected to have a surgically correctable lesion. Arterial vessels are displayed initially, and delayed images can outline the venous system. Patients commonly receive anticoagulants during the procedure. The images give high-quality resolution of the vessels but do not provide quantitative information about blood flow. This method is the only one that has been proved useful for selecting patients who can benefit from carotid endarterectomy.

Angiography, particularly in patients with abnormal vasculature, can itself cause stroke and result in permanent neurologic deficits or death. The rate of injury varies in different surveys but is about 0.5% in good facilities. Angiography requires exposure to ionizing radiation, may be associated with adverse reactions to the contrast material, and involves a fluid load that poses a risk to patients with severe cardiac disease.

Other Techniques

Single-photon emission computed tomography provides only qualitative blood flow rates. Positron emission tomography quantitatively measures blood flow or brain metabolism. CT and MRI methods for measurement of cerebral blood flow and metabolism are in development. None of these

techniques has yet been shown to be useful for the management of stroke patients (Chapter 403).

Differential Diagnosis

The characteristic feature of ischemic stroke is the abrupt, painless onset of a neurologic deficit. Blood supply is lost in the distribution of a terminal vessel, and loss of function begins within seconds. The brain does not have pain receptors in its parenchyma, so the symptoms are painless unless the dura mater, which does have pain fibers, is stretched or irritated. One type of stroke that can evolve slowly is subdural hematoma (Chapter 415), which may be distinguishable from ischemic stroke because a hematoma produces deficits more slowly. Focal symptoms and signs of tumors (Chapter 195) of various types typically evolve over a period of weeks or longer, except in uncommon cases in which a tumor erodes a vessel and causes bleeding or crushes it and causes infarction. TIAs cannot initially be distinguished from strokes, but they generally resolve within the first 1 or 2 hours.

Other neurologic disorders can be manifested as an abrupt onset of neurologic abnormalities. Migraine (Chapter 405) with or without aura may simulate stroke or TIA because of its associated hemiparesis or other focal deficits. Migraine is primarily an exquisitely painful, throbbing, unilateral headache that sometimes has an aura (symptoms preceding the headache) of scintillating scotomas (flashing lights). Complicated migraine (migraine accompanied by focal deficits) can rarely evolve into a true ischemic stroke, probably because of the decreased blood flow that often accompanies migraine.

Seizures (Chapter 410) can be confused with TIAs. Many seizures produce tonic (sustained) or clonic (rapid) motor activity or positive sensory phenomena. Strokes and TIAs produce weakness and sensory loss without involuntary motor activity. Seizures can sometimes be associated with these negative symptoms, particularly in the postictal state after (unobserved) seizures. The patient generally returns to the premorbid state after a seizure, however. Serial observations usually permit the differentiation of stroke from seizure, but early differentiation may be difficult and require laboratory testing, particularly an electroencephalogram. In a few patients with stroke, especially with emboli, a seizure occurs at the onset of the stroke.

Hyperglycemia and hypoglycemia can cause focal neurologic deficits. Most patients have a history of diabetes, and the glucose abnormality is substantial at the time of focal neurologic deficits.

Hemorrhagic stroke (Chapter 415) cannot generally be definitively distinguished from ischemic stroke on the basis of the history or clinical examination. Primary hemorrhages are often severe at onset and may result in headache and rapidly evolving deficits. Ischemic strokes are normally painless and characterized by a fixed deficit or a stuttering onset followed by rapid waxing and waning fluctuations. Headaches can occur in conjunction with many ischemic strokes, however, and the only way to distinguish infarct from hemorrhage definitively is with a CT scan.

Brief global cerebral anoxia causes syncope without any permanent sequelae. Prolonged diffuse ischemia, by contrast, can have devastating consequences. The most common causes are cardiac asystole or other forms of overwhelming cardiopulmonary failure. Aortic dissection (Chapter 78), global hypoxia, or carbon monoxide poisoning (Chapter 94) can cause a similar picture. Clinically, these disorders result in unconsciousness. If ischemia persists for more than 4 to 5 minutes, patients often remain in a coma, sometimes evolving into the vegetative state, in which brain stem functions are preserved but the patient has no higher cortical function (Chapter 411). If patients do not regain consciousness within 2 or 3 days, the prognosis for return of independent function is poor. Prompt and aggressive effort to restore cardiovascular circulation is most important. Clinical trials have shown that induced hypothermia within minutes to hours improves outcome in adults who remain comatose after initial resuscitation from out-of-hospital ventricular fibrillation cardiac arrest.[1]

In young patients, hypoxia caused by near-drowning in cold water may result in resistance to prolonged hypoxic-ischemic damage. Therapeutic hypothermia has not yet been proved useful in adults with stroke.

TREATMENT

Acute Stroke

Thrombolytic therapy is the only safe and effective method for acute management of ischemic stroke of typical cause (i.e., atherosclerotic and embolic stroke). Meta-analyses provide support for the efficacy and safety of thrombolysis if patients are treated within 4.5 hours after the onset of symptoms,[2,3] with about a one third increase in the likelihood of a favorable neurologic outcome, directly attributable to the drug, despite the minimal risk for hemorrhage. Obstacles to thrombolytic treatment include the need to redesign and implement acute stroke care systems, delay of patients in reaching medical facilities, and insufficient expertise in the use of thrombolysis by many physicians. Telemedical approaches, whereby physicians can communicate through audio, video, and digital imaging with consultants at referral institutions, can improve the evidence-based use of acute thrombolytic therapy.[4]

The recommended therapy with intravenous tissue plasminogen activator (t-PA) requires adherence to relatively stringent eligibility criteria (Table 414-2 and Fig. 414-4). Therapy must be started within 4.5 hours after the onset of stroke. Before initiating therapy, a non–contrast-enhanced CT scan should be obtained to exclude patients with intracranial hemorrhage. Blood pressure limits are a maximum of 185 mm Hg systolic or 110 mm Hg diastolic. If blood pressure exceeds these limits, it should be lowered with an antihypertensive drug such as labetalol before initiating t-PA. In addition, patients who have had major surgery or serious trauma within the preceding 2 weeks or evidence of gastrointestinal bleeding should not be treated. The recommended dose of intravenous t-PA is 0.9 mg/kg to a maximum of 90 mg, administered as a 10% initial bolus with the remainder given over a 60-minute period.

Treatment should begin as soon as possible, and even patients with mild strokes or rapidly resolving deficits probably merit treatment. Patients with severe strokes, as evidenced by major clinical deficits or early signs of a large infarct by CT scan, do not fare well regardless of whether they are treated. Treatment 3 to 6 hours after the onset of ischemic stroke is not currently recommended, although one study of intra-arterial prourokinase given 3 to 6 hours after the onset of an ischemic stroke showed benefit from such therapy. Streptokinase is not of benefit. Intra-arterial t-PA has been used in patients who are not candidates for intravenous t-PA, but there are no controlled studies of this form of treatment.

Acute anticoagulation with various forms of heparin or warfarin is of no benefit in patients with ischemic stroke. Patients with stroke in evolution, in which deficits increase over the first day after the onset of the stroke, commonly receive anticoagulants, but there is no strong evidence that such therapy is effective. Vital signs and neurologic status should be monitored. After the acute stroke has stabilized and begun to improve, hypertension must be treated.

Blood pressure is often transiently elevated in the initial hours after a stroke and should not be rapidly lowered except as a prelude to t-PA therapy (see earlier). Many stroke patients have markedly elevated blood pressures, even in the absence of a history of hypertension. Until multiple ongoing trials are completed, a reasonable acute blood pressure goal is less than 180 mm Hg systolic in patients who have an intracerebral hemorrhage or are eligible for thrombolysis (<220 mm Hg otherwise), then a goal of 160/100 mm Hg after 24 hours.

If a patient has suffered an acute myocardial infarction, the preferred therapy is primary angioplasty (Chapter 74). It is uncertain what dose of t-PA should be administered if a patient simultaneously has a stroke and myocardial infarction. If a patient is a candidate for coronary artery bypass graft surgery and is found to have surgically correctable carotid stenosis, the more urgent procedure should generally be performed first.

There is an increased risk for pulmonary embolism and deep vein thrombosis in patients with ischemic stroke, particularly those with neurologic deficits that produce immobility. In these patients, prophylactic low-dose subcutaneous heparin or low-molecular-weight heparin (Chapter 37) is recommended unless there are other contraindications to anticoagulation. The use of graduated compression stockings does not significantly reduce deep vein thrombosis after stroke but results in adverse skin effects.[5]

UNUSUAL CAUSES OF STROKE

Atrial Myxoma

Atrial myxomas (Chapter 60) are the most common type of primary cardiac tumor and are found in about 0.05% of autopsies of young adults with ischemic strokes or TIAs. Nonspecific constitutional symptoms are frequent, and less than half of myxomas produce emboli. When these tumors do produce emboli, the danger period usually lasts days to weeks. Metastasis can rarely cause cerebral aneurysms. Other primary and metastatic cardiac tumors can embolize neoplastic tissue or thrombus.

Vasculitis

Vasculitis (Chapters 274, 278, and 279) can produce focal or multifocal cerebral ischemia by means of inflammation and necrosis of extracranial or intracranial blood vessels. Segmental inflammation of cerebral blood vessels is associated with cerebral ischemia acutely at the site of involvement.

Vasculitis of the central nervous system (CNS) is often manifested as cognitive disturbances, headache, and seizures. Because the vascular damage is commonly diffuse, these nonfocal neurologic abnormalities occur more

TABLE 414-2 TISSUE PLASMINOGEN ACTIVATOR THERAPY FOR ACUTE ISCHEMIC STROKE

Clinical manifestation—focal neurologic deficits
Patient selection
Therapy must be started within 3 hr of the onset of acute ischemic stroke symptoms
A baseline CT scan must be obtained before initiation of therapy
Contraindications
Evidence of intracranial hemorrhage on pretreatment evaluation
Suspicion of subarachnoid hemorrhage
Recent intracranial surgery, serious head trauma, or previous stroke
History of intracranial hemorrhage
Uncontrolled hypertension at the time of treatment—≥185 mm Hg systolic or >110 diastolic—that cannot be reduced with acute antihypertensive therapy
Seizure at stroke onset
Active internal bleeding
Intracranial neoplasm, AVM, or aneurysm
Known bleeding diathesis, including but not limited to
Oral anticoagulation with a prothrombin time >15 sec
Heparin administration within the preceding 48 hr and an elevated activated partial thromboplastin time at initial evaluation
Platelet count <100,000/mm^3
Warnings
Patients with a severe neurologic deficit (NIH Stroke Scale >22) at initial evaluation have an increased risk for ICH
Patients with major early infarct signs on CT (edema or mass effect) are probably >3 hr since vessel occlusion
Dosing information for acute ischemic stroke
0.9 mg/kg to a maximal dose of ≤90 mg
10% of the total dose administered as an intravenous bolus over a 1-min period
90% of the remainder infused continuously over a 60-min period
Follow-up
Monitor vital signs and neurologic status
Maintain blood pressure at ≤185/≤110 mm Hg
No anticoagulant or antiplatelet therapy for 24 hr

AVM = arteriovenous malformation; CT = computed tomography; ICH = intracranial hemorrhage; NIH = National Institutes of Health.
Modified from package insert for Activase, Genentech, Inc., South San Francisco, Calif.

frequently with vasculitis than with focal ischemic disorders. The diagnosis is often difficult to make because the signs and symptoms are frequently nonspecific. The angiographic appearance of a beadlike segmental narrowing of cerebral blood vessels, when present, is virtually diagnostic, but cerebral angiograms are often normal in histologically proven cases. Definitive diagnosis requires the demonstration of characteristic inflammatory histopathology in leptomeningeal or cortical biopsy specimens. Because of the segmental and highly focal nature of the inflammatory process, the histopathology may go undetected at biopsy despite a positive angiogram.

Primary CNS vasculitis, Behçet's disease (Chapter 278), Takayasu's arteritis (Chapters 78 and 278), and temporal arteritis (Chapter 279) are notable for their infrequent involvement of the peripheral nervous system. By contrast, hypersensitivity and systemic necrotizing vasculitides frequently produce polyneuropathies. Primary CNS arteritis (Chapter 278), giant cell arteritis (Chapter 279), and vasculitis associated with certain CNS infections may be manifested initially or solely as neurologic abnormalities.

Primary arteritis of the CNS causes headache and other encephalopathy-like symptoms in young or middle-aged individuals. The course is usually insidiously progressive but may wax and wane for periods of several months. A few of these patients initially have a strokelike episode.

Giant cell arteritis (Chapter 279) can affect any medium or large artery in the body. When it is present in the cerebral vasculature, it is called *temporal arteritis* and is characterized by panarteritis, including intimal proliferation, destruction of the internal elastic lamina, and thickening of the media. Luminal obstruction is caused by edema, thickening of the intima, and thrombosis. A prominent inflammatory infiltrate consisting of mononuclear cells, giant cells, and eosinophils with granuloma formation is present with active disease. Giant cell arteritis is the most common angiitis causing ischemic stroke. Temporal arteritis predominantly affects patients older than 55 years. Symptoms include fever, malaise, weight loss, and headache. In many patients, constitutional symptoms consistent with polymyalgia rheumatica may coexist, including jaw, neck, and facial pain and morning stiffness. Pain over the temporal arteries and an erythrocyte sedimentation rate greater than 50 mm/hour are frequently present. Biopsy of the superficial temporal artery provides a definitive diagnosis; because of the segmental nature of the vasculitis, however, serial sections must be examined or the characteristic histology may be missed. The diagnosis is important to establish because early initiation of corticosteroid therapy (e.g., prednisone, 60 mg/day) may decrease the risk for acute ischemic blindness or stroke (Chapter 279). This treatment can be started shortly before performing the biopsy.

Takayasu's arteritis, also called *pulseless disease* (Chapters 78 and 278), is a chronic, idiopathic inflammatory disorder, primarily of young women. It affects mainly the aortic arch, the large brachiocephalic arteries, and the abdominal aorta. Mononuclear infiltrates and fibrous proliferation produce progressive narrowing of the lumen of these vessels and thus reduced flow into the upper extremities and cerebral ischemia. Although initially diagnosed in Japanese families, it has been recognized in Western countries.

Fibromuscular dysplasia is a segmental vasculopathy of unknown etiology (Chapters 78 and 127). Its frequency in large angiographic series is less than 1%. Bilateral extracranial involvement of the ICA is common, but abnormalities of the intracranial carotid or vertebrobasilar artery are rare. Dysplasia of the arterial wall may involve the intima, media, or adventitia. This disorder, which may also affect the renal arteries and is associated with hypertension, can lead to aneurysm formation and cervicocephalic arterial dissection. The diagnosis is made by cerebral angiography. Little information on treatment is available; angioplasty and stenting to open the narrowed lumen are unproven experimental procedures.

Other types of vasculitis are unusual causes of stroke. Such diseases include Wegener's granulomatosis (Chapter 278); sarcoidosis (Chapter 95); bacterial, fungal, and viral infections; meningovascular syphilis (Chapter 327); and lymphomatoid angioendotheliomatosis.

Hemoglobinopathies

In sickle cell anemia (Chapter 166), irreversible sickling results in increased blood viscosity, microvascular sludging, and brain infarction. Sickle cell disease also causes hyperplasia of fibrous tissue and muscle cells of the vascular intima, thereby leading to stenosis and occlusion of some medium to large cerebral arteries.

Estimates of the incidence of stroke vary but are generally reported to be 8 to 17% in patients with hemoglobin SS and about 2% in individuals with hemoglobin SA. The mean age at first stroke is about 8 years in people with hemoglobin SS. Ischemic stroke occurs more frequently in children. In adults, hemorrhagic strokes are more common.

Hyperviscosity Syndrome

Cerebral blood flow decreases with increasing blood viscosity. Blood viscosity increases with increasing levels of red and white blood cells, platelets, and plasma proteins. A hyperviscosity syndrome can occur when any of these blood components is markedly increased and produce focal or multifocal neurologic dysfunction, including headache, encephalopathy, and seizures. Common causes of hyperviscosity include polycythemia vera (Chapter 169) and paraproteinemias (Chapter 193) secondary to macroglobulinemia or multiple myeloma.

Coagulation Disorders

Hereditary

Four circulating proteins that inhibit coagulation are protein C, protein S, antithrombin III, and factor V (Chapters 81 and 179). Deficiencies of these proteins rarely cause arterial strokes but more frequently cause venous thrombosis. Deficiencies of proteins C and S are dominantly inherited. Homozygotes have serious, frequently fatal clotting abnormalities at birth, whereas heterozygotes may show no signs of hypercoagulability. Because of incomplete penetrance, the occurrence of thrombosis and stroke in adults is extremely rare; testing for these abnormalities should be undertaken only in unusual cases. Antithrombin III is vitamin K independent and synthesized in the liver. Deficiency should be suspected in young patients with a history of recurrent deep vein thrombosis or pulmonary embolism, especially if there is a similar family history. Inheritance is autosomal dominant with incomplete penetrance. Arterial stroke is rare.

Acquired

Cancer and pregnancy, including the postpartum period, are associated with hypercoagulable states that predispose to arterial and venous thrombosis (Chapters 81, 179, and 187). Although a variety of clotting abnormalities may be present, no tests have been devised to detect patients at risk for stroke. No treatments have been proved useful for strokes associated with these conditions.

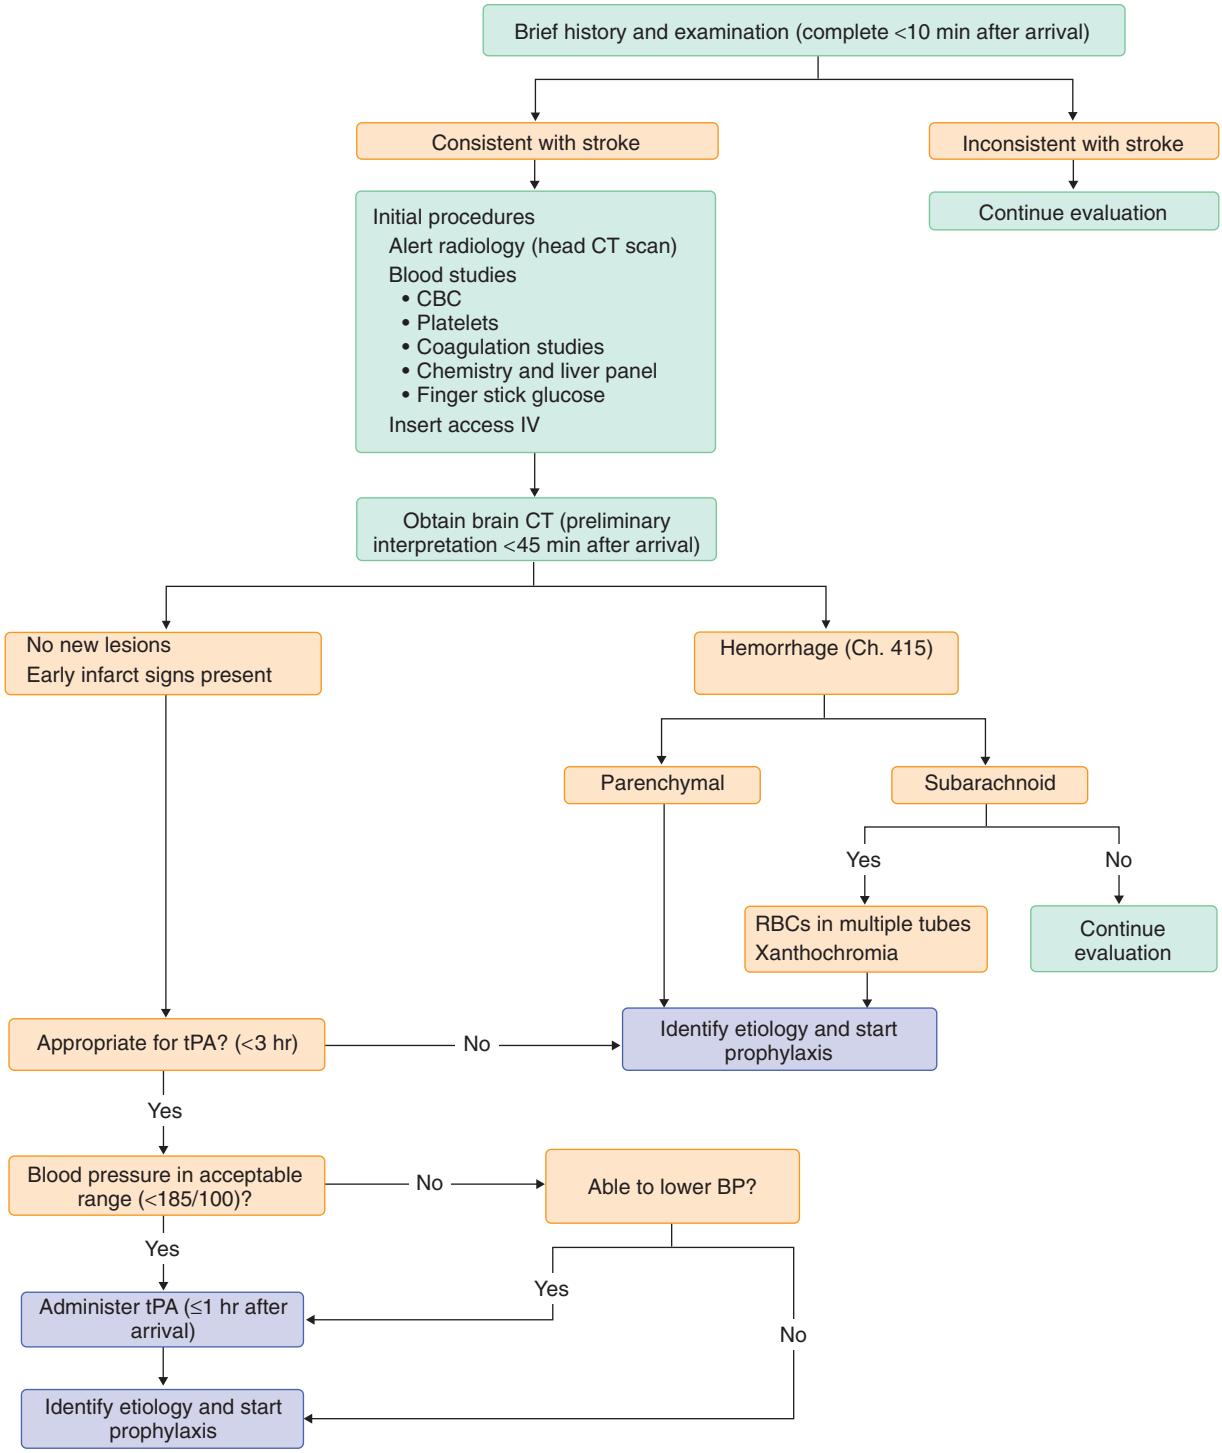

FIGURE 414-4. Algorithm for the emergency evaluation of a patient with suspected stroke. BP = blood pressure; CBC = complete blood count; CT = computed tomography; RBCs = red blood cells; tPA = tissue plasminogen activator.

Antiphospholipid Antibodies

The antiphospholipid antibody syndrome is associated with cerebral arterial and venous infarction, particularly in young adults (Chapter 179). There is no clear relationship between the levels of these antibodies and the risk for stroke. Other laboratory abnormalities include a prolonged activated partial thromboplastin time, biologic false-positive Venereal Disease Research Laboratory results, thrombocytopenia, and a positive antinuclear antibody test. There is an association with atypical migraine, TIA, and ischemic encephalopathy. The reason for the relationship between the antibodies and cerebral thrombosis is unknown.

Drug-Related Causes of Stroke

Numerous legal and illicit drugs have been associated with stroke (Chapter 33). Even the process of drug administration may cause a stroke. Intravenous drug abuse may lead to septicemia and diseases that cause strokes, such as bacterial endocarditis and mycotic aneurysms. Particles of adulterants can be trapped by pulmonary arterioles and cause local arteritis and later arteriovenous shunts that are thought to allow the microemboli to reach the brain. Paradoxical embolization is also possible through structural cardiac defects or arteriovenous malformations.

Some of the drugs that are associated with stroke are potent vasoconstrictors and may initiate cerebral vasospasm. In other instances, cerebral vasculitis is associated with either immune responses to the primary drug or hypersensitivity to contaminating adulterants.

Over-the-counter common cold remedies and nasal decongestants containing sympathomimetic amines, such as ephedrine, phenylpropanolamine, and fenoxazoline, have been associated with ischemic stroke, although hemorrhages are more common (Chapter 415). These drugs are often used in

high doses as appetite suppressants, and case reports suggest that the high doses are especially likely to be related to stroke, often after the first use of these products. Herbs taken as dietary supplements may also include sympathomimetics (e.g., ephedra, also known as *ma huang*) that have been associated with stroke (Chapter 38).

Cervical Artery Dissection

Spontaneous dissection of the cervical or cerebral arteries is produced by subintimal dissection of blood with subsequent longitudinal extension of the intramural hematoma between its layers for various distances. Hemorrhage into the intima can cause luminal stenosis and obstruction, whereas hemorrhage into the media or adventitia produces a pseudoaneurysm that can rupture. Most dissections are spontaneous, but this process is also associated with trauma, including whiplash and other neck-stretching injuries, and chiropractic cervical manipulation. Some cases are associated with fibromuscular dysplasia and others with a variety of inherited conditions, including Ehlers-Danlos and Marfan syndromes (Chapter 268) and tuberous sclerosis (Chapter 426). Recognition of dissection is sometimes difficult, and the physician must probe carefully for recent injuries to the neck. Cerebral angiography can occasionally show a double lumen, although a tapered lumen leading to an obstruction is more common. MRI with attention to vessel cross section may show a crescent-shaped hyperintense mass adjacent to a flow void. Some patients with this condition have been treated by thrombolysis or anticoagulation and surgical repair, but no therapy has been proved to be useful in randomized trials.

Homocystinuria

Homocystinuria (Chapter 216) is associated with a variety of disorders, including dislocated ocular lenses, bone deformities, mental retardation, and accelerated atherosclerosis of large and medium-sized arteries. Strokes commonly occur before 20 years of age. Detection of homocystine in urine is the diagnostic test of choice. Individuals with modest increases in serum homocystine levels may also have an increased risk for stroke. Treatment with a diet low in methionine and supplements of cysteine and pyridoxine (vitamin B_6) can decrease the plasma level of methionine. Folate administration may also be helpful because it is necessary for methylation of homocystine. Vitamin therapy has not been proved to reduce the risk for stroke in patients with homocystinuria, however.

Fat Embolism

Fat embolism (Chapter 98) is mostly a complication of long bone trauma (Chapter 112), intramedullary manipulation during orthopedic procedures, contusions of soft tissues, and severe trauma to large fat deposits. Strokes typically occur several days after the trauma. Clinical features of cerebral embolization depend on the sites within the brain that are affected. Diffuse embolization can produce encephalopathy or seizures, but more discrete lesions can cause focal neurologic deficits. The condition is probably underdiagnosed clinically and at autopsy. Peripheral features that suggest the diagnosis include petechiae and fat emboli visible on ophthalmoscopic examination. Laboratory abnormalities include hypoxemia, anemia, lipuria, and disorders of blood coagulation. The chest radiograph commonly shows bilateral fluffy infiltrates.

Air Embolism

Air embolism can occur with a variety of surgical procedures, particularly cardiac surgery, and as a complication of neurosurgical procedures performed with the patient in the sitting position. Trauma can produce pneumothorax, and air may enter the pulmonary vein and subsequently lodge in the brain. Extended underwater dives and too rapid an ascent can cause the air in the blood to come out of solution and form bubbles that can be pumped into the cerebral circulation (caisson disease). Arterial gas embolism can cause disturbances in cortical function, including seizures and focal deficits. Segmental areas of pallor may be observed on the tongue, marbling of the skin may be seen, and air emboli can be detected on funduscopic examination. When caused by rapid decompression, barotrauma is treated in a decompression chamber.

Moyamoya

Moyamoya disease is a chronic, noninflammatory occlusive vasculopathy of unknown etiology. It is a rare condition that is most common among the Japanese. It has a bimodal age distribution, with peaks in the first and fourth decades. Diagnostic criteria include stenosis or occlusion involving the bifurcation of the ICA and proximal portions of the ACA and MCA, the presence of unusual netlike ("puff of smoke") collateral arteries arising from the circle of Willis, and bilateral occurrence. In adults, the clinical manifestation is usually hemorrhages. Moyamoya is diagnosed by cerebral angiography. No treatment has been proved effective.

Cerebral Venous Sinus Thrombosis

Thrombosis of a cerebral venous sinus may be manifested as headache, focal neurologic deficits, seizures, altered mental status, and papilledema. With obstruction of the superior sagittal sinus, veins draining into the sinus from the superior and medial surfaces of both cerebral convexities are commonly obstructed; in its early stages, the condition can result in bilateral weakness and sensory changes in the legs. The presence of bilateral leg weakness should alert the clinician to the possibility of sinus thrombosis. Seizures occur more often with venous than with arterial occlusion. The most dangerous form of venous disease arises when the superior sagittal sinus is occluded, but obstruction of a transverse sinus or one of the major veins over the cerebral convexity can also produce major damage. These venous occlusions occur most commonly in association with coagulopathies, often in the puerperal period, or in patients with disseminated cancer. The transverse sinus can be occluded as a consequence of inner ear infections, a condition called *otitic hydrocephalus.*

The differential diagnosis of venous obstruction can include an arterial stroke, but the findings more often suggest a diffuse process, such as herpes simplex encephalitis or meningitis. The diagnosis depends on the recognition of impaired venous flow, which can be suspected on routine CT or MRI and confirmed by CT or MR angiography; conventional angiography is rarely needed. Unfractionated dose-adjusted heparin (see Table 81-4 in Chapter 81) and perhaps low-molecular-weight heparin may be safe and effective for cerebral venous sinus thrombosis during the acute phase, even in the presence of hemorrhagic infarction caused by the sinus thrombosis. Oral warfarin anticoagulation is generally continued for 3 to 6 months with the usual target international normalized ratio of 2.0 to 3.0.

Rare Genetic Causes

More than 50 genetic disorders have stroke as at least one of their features, but the prevalence of these abnormalities is low, so strokes produced by monogenetic anomalies are relatively rare. Cerebral autosomal dominant arteriopathy with small subcortical infarcts and leukoencephalopathy (CADASIL) is characterized by recurrent strokes resulting in multiple deep infarcts and dementia, without the usual risk factors for stroke. It has an autosomal dominant pattern of inheritance. The mean age at onset is approximately 40 years, and dementia ensues within 10 to 15 years. Migraine with aura often precedes the strokes by several years. The responsible gene on chromosome 19 results in mutations of the Notch3 receptor protein. As is true of all these genetic causes of stroke, treatment is symptomatic. Antenatal diagnosis is possible in these disorders.

Fabry's disease (angiokeratoma corporis diffusum) (Chapter 215) is an X-linked disease that causes a reduction in α-galactosidase A enzyme activity. Patients have diseases of the skin, eyes, and kidneys as well as frequent neurologic complications that result from either vascular occlusion or, infrequently, intracerebral hemorrhage related to the accumulation of glycolipids in small and medium-sized arteries. The gene encoding this enzyme is located at Xq22. Enzyme replacement therapy is of benefit (Chapter 215).

Neurofibromatosis (Chapter 426) is associated with strokes as a result of occlusion of the internal carotid arteries or the proximal part of the anterior cerebral circulation. Histologically, arterial lesions consist of hyperplasia of the intimal layer with fragmentation and reduplication of the elastic layer. Cerebral aneurysms can also occur. The diagnosis of type I neurofibromatosis is usually based on clinical findings. *DNA-based testing* of the *NF1* gene is available clinically but is infrequently needed for diagnosis.

Marfan syndrome (Chapter 268), which is an autosomal dominant disorder of the fibrillin gene on chromosome 15, affects the skeletal, ocular, cardiovascular, and central nervous systems. Expression is highly variable, and only one system may be involved. Involvement of large arteries, such as the aorta and carotid arteries, is common and may cause death. The most life-threatening problem is dissection of these arteries. Pathologically, the disease results from defective fibrillin, which is an important component of connective tissue.

PREVENTION AND TREATMENT OF STROKE AND TRANSIENT ISCHEMIC ATTACK

Rx

Primary Prevention

Risk factors for stroke fall into two general categories, nonmodifiable and modifiable (Table 414-3). Within the modifiable group are risk factors that are well documented and others that are not. Blood pressure control (Chapter 67) is the most important primary prevention strategy. It is especially important in patients with diabetes, in whom tight control of hypertension with angiotensin-converting enzyme inhibitors substantially reduces the incidence of stroke. Statins are recommended in patients who meet the criteria for treating hyperlipidemia (Chapter 213), in whom they reduce the risk of stroke proportionately to the reductions in the LDL cholesterol levels.[6] Statins also reduce the risk for stroke in patients with an elevated C-reactive protein level even when the LDL level is less than 130 mg/dL.[7] Smoking cessation (Chapter 31) is routinely recommended, but there are no prospective randomized trials to prove that cessation of smoking reduces the risk for stroke. Anticoagulation markedly reduces the risk for stroke in patients with atrial fibrillation (Chapter 64), and blood transfusion is the usual treatment to prevent strokes in patients with sickle cell disease (Chapter 166).

Prophylactic Carotid Interventions

In asymptomatic patients, ipsilateral carotid endarterectomy benefits patients who have a 60% or greater reduction in diameter of the artery without ulceration, provided that the perioperative complication rate is less than 3%,[8] a rate that requires a skilled surgeon. Carotid artery angioplasty and stent placement are not as efficacious as operative endarterectomy, mainly because of their higher risk for stroke.[9]

Secondary Prevention in Patients with Previous Stroke or Transient Ischemic Attack

All the risk factor reductions that are recommended for primary prevention are also recommended in patients who have suffered a previous stroke or TIA and have no contraindication. In addition, specific medical and surgical therapies should be considered.

Medications

Aspirin and other antiplatelet agents reduce the odds of nonfatal stroke by 31% when used in patients with known vascular disease (Chapter 37). All patients who have sustained a stroke and have no contraindication should receive an antiplatelet agent to reduce the risk for recurrent stroke. The optimal dose of aspirin has not yet been established, and doses of 50 to 1300 mg/day have been used. Clopidogrel, 75 mg/day, instead of or in addition to aspirin appears to be no better than aspirin alone[10] but is substantially more expensive. The addition of dipyridamole to aspirin can benefit high-risk patients with prior cerebral ischemia.[11] Warfarin anticoagulation is not superior to antiplatelet agents in preventing recurrent strokes, except in patients with atrial fibrillation or another cardiac source of emboli, because of its risks for cerebral hemorrhage.[12] In patients with previous cerebrovascular disease or high-risk conditions, aggressive cholesterol reduction with 40 mg of simvastatin or 80 mg of atorvastatin reduces the rate of stroke by 25% or more.[13]

Surgery

Carotid endarterectomy reduces the cumulative risk for any ipsilateral stroke at 2 years from 26 to 9% in patients with a 70 to 99% symptomatic (i.e., previous TIA or nondisabling stroke) internal carotid stenosis and from 22 to 16% at 5 years in patients with a 50 to 70% symptomatic stenosis. Patients with less than a 50% symptomatic stenosis do better with medical management alone. In patients with advanced occlusive disease of the carotid arterial system, extracranial-intracranial bypass is no better than medical therapy.[14]

Devices

Carotid artery stents can restore patency to stenotic arteries with an efficacy and safety comparable to that of open endarterectomy in experienced centers. Intra-arterial clots can also be extracted under radiologic guidance with a corkscrew-like device inserted into the common or internal carotid artery for occlusion of the anterior circulation or into the subclavian artery for occlusion of the posterior circulation and then advanced to remove clot located in medium or large intracranial vessels (ICA, MCA, vertebral artery, basilar artery, PCA, or ACA). Using proximal balloon occlusion to arrest flow, the corkscrew device can grab and hold the clot as it is extracted from the patient's artery. Currently, however, outcomes appear to be better with endarterectomy than with stenting, suggesting that stenting should be reserved for selected situations.[9,15]

TABLE 414-3 WELL-DOCUMENTED MODIFIABLE RISK FACTORS FOR STROKE

FACTOR	PREVALENCE (%)	RELATIVE RISK	RISK REDUCTION WITH TREATMENT
Hypertension (by age group)			38%
50 yr	20	4	
60 yr	30	3	
70 yr	40	2	
80 yr	55	1.4	
90 yr	60	1	
Smoking	25	1.8	50% within 1 yr, baseline after 5 yr
Diabetes	20	1.8-6	Reduction of stroke risk in hypertensive diabetics with blood pressure control No demonstrated benefit in stroke reduction with tight glycemic control
Asymptomatic carotid stenosis	2-8	2	50%
Hyperlipidemia			20-30% with statins in patients with known coronary disease
Adults <35 yr	8-9	1.8	
Men >55 yr	25	2.6	
Women >65 yr	40		
Atrial fibrillation (nonvalvular)			68% warfarin 21% aspirin
50-59 yr	0.5	4	
60-69 yr	1.8	2.6	
70-79 yr	4.8	3.3	
80-89 yr	8.8	4.5	

Modified from Goldstein LB, Adams R, Becker K, et al. Primary prevention of ischemic stroke. *Stroke.* 2001;32:280-299.

PROGNOSIS AND REHABILITATION

Patients who receive care in specialized, acute stroke units are less likely to die, more likely to go home, and more likely to be independent 3 months later. In most clinical trials, about 15% of patients with ischemic stroke die within the first 3 months. Immediate causes of death include herniation because of brain swelling or neurologic dysfunction directly related to the stroke. Deaths that occur days after stroke and are not directly related to neurologic dysfunction are commonly produced by pulmonary embolism or pneumonia. Most large population studies report that about 20% of patients who survive a stroke require long-term institutionalization and that 33 to 50% of the others are left with substantial disability. Stroke is the most common cause of adult disability in the United States. Most functional recovery takes place during the first month, but some continued slow improvement is possible for 1 year. The most common long-term cause of death in patients with stroke is myocardial infarction.

415 HEMORRHAGIC CEREBROVASCULAR DISEASE

JUSTIN A. ZIVIN

Approximately 15% of all strokes are due to intracranial hemorrhage. Hemorrhagic stroke can be diffuse (i.e., bleeding into the subarachnoid or intraventricular spaces) or focal (i.e., intraparenchymal hemorrhage). About two thirds of intracranial bleeding cases are predominantly subarachnoid hemorrhages, whereas about one third are intracerebral hemorrhages. Subarachnoid hemorrhage is usually caused by rupture of vessels on or near the surface of the brain or ventricles (e.g., aneurysms, vascular malformations), with bleeding mainly into the cerebrospinal fluid (CSF) spaces. Intracerebral hemorrhage is most frequently caused by the rupture of arteries that are within the brain substance (e.g., hypertensive hemorrhage, vascular malformations) but do not extend to the CSF spaces. Both types of hemorrhagic stroke have high mortality rates, depending on subtype and location. Prevention is the mainstay of management because there are no sufficiently efficacious therapies for hemorrhage-induced cerebral injury.

SUBARACHNOID HEMORRHAGE

EPIDEMIOLOGY

In the United States, about 30,000 new cases of subarachnoid hemorrhage occur each year and predominantly involve young adults. Both genders are equally affected, and the rate may be twice as high in African Americans as in whites. Rupture of aneurysms is by far the most common cause of nontraumatic subarachnoid hemorrhage. Advances in diagnostic imaging have improved the detection of intracranial aneurysms, but most cases are not discovered until after rupture.

Risk factors include cigarette smoking, binge drinking, illicit drugs, phenylpropanolamine, and other sympathomimetic agents. Although hypertension is well established as a risk factor for ischemic stroke, the relationship of nonmalignant hypertension to subarachnoid hemorrhage is less well documented; the decline in hypertension in the general population has not been accompanied by a decrease in the incidence rate of subarachnoid hemorrhage.

PATHOBIOLOGY

The principal causes of subarachnoid hemorrhage are aneurysms and arteriovenous malformations (AVMs), but trauma can also cause subarachnoid bleeding (Chapter 406). Rare causes of subarachnoid hemorrhage include vasculitis, central nervous system neoplasms (Chapter 195), and hematologic disorders such as hemophilia, disseminated intravascular coagulopathy, and thrombocytopenic purpura.

CLINICAL MANIFESTATIONS

The classic symptom of a subarachnoid hemorrhage is a very rapidly developing, severe headache, typically called the "worst headache of my life," that is sometimes accompanied by a stiff neck. Aneurysms may generate prodromal signs and symptoms as they gradually expand or cause sentinel (warning) leaks that produce focal or generalized head pain. Such sentinel headaches are frequently severe, and they may be accompanied by nausea or vomiting and may cause meningeal irritation.

Arterial blood pressure is often elevated, and body temperature usually increases, particularly during the first few days after bleeding as subarachnoid blood products produce chemical meningitis. Transient alterations in mental status occur in nearly half the patients, particularly if intracranial pressure exceeds cerebral mean arterial pressure. Patients can remain in coma for several days, depending on the location of the aneurysm and the amount of bleeding.

Acute subarachnoid hemorrhage causes meningeal irritation; nuchal rigidity and photophobia can require several hours to develop. Ophthalmoscopic observation reveals well-circumscribed, bright red, preretinal hemorrhages, known as subhyaloid hemorrhages and thought to be a result of increased intracranial pressure, raised retinal venous pressure, and dissection of blood along the optic nerve sheath. Focal neurologic dysfunction is not usually a prominent feature unless an aneurysm compresses surrounding brain structures, a jet of blood dissects directly into a clinically eloquent brain region, or vasospasm subsequently develops.

DIAGNOSIS

Laboratory Findings

A complete blood cell count, including platelets, should be obtained, and clotting times should be determined to assess whether the patient has an infection or clotting abnormalities. Blood should also be sent for electrolyte analysis to serve as a baseline for detecting later complications.

Imaging

The patient should then be sent immediately for emergency computed tomography (CT). A scan performed within 24 hours of onset generally reveals an area of high signal attenuation consistent with hemorrhage; if blood is present in the subarachnoid space, it is seen within the basal cisterns in more than 90% of patients. By 48 hours after onset, the sensitivity of CT declines to about 75%. Conventional magnetic resonance imaging (MRI) sequences (T1- or T2-weighted scans) are less sensitive than CT scans.

The location of subarachnoid hemorrhage by CT suggests the source of bleeding. High signal attenuation in the basal cisterns, sylvian fissure, or interhemispheric fissure often indicates rupture of a saccular aneurysm, whereas higher concentrations of blood over the convexities or within the superficial parenchyma of the brain are more consistent with rupture of an AVM or a mycotic aneurysm. A large amount of blood in the subarachnoid space increases the likelihood of subsequent vasospasm. A contrast-enhanced CT scan may aid in the identification of an AVM and some large aneurysms.

An electrocardiogram should be performed to detect peaked or inverted T waves and increased U waves. These abnormalities and subsequent arrhythmias have been attributed to multifocal myocardial necrosis caused by elevated levels of circulating catecholamines.

If the CT findings are normal but the index of suspicion remains high for subarachnoid hemorrhage, a lumbar puncture is usually diagnostic. A traumatic lumbar puncture (i.e., penetration of the needle into a small blood vessel of the venous plexus on the anterior wall of the spinal canal) produces a declining number of red blood cells in subsequent tubes, whereas subarachnoid hemorrhage produces a relatively constant number of red blood cells in each tube. In the presence of bloody fluid, one of the CSF samples should be centrifuged immediately and the supernate examined for the presence of hematin or xanthochromia by visual inspection. Red blood cells in CSF begin to lyse within a few hours, and the centrifuged supernate then appears pink. Later (about 10 hours), as the hemoglobin is converted to bilirubin, the fluid

becomes slightly yellow. Opening CSF pressure is generally elevated and may remain so for many days. CSF samples obtained within the first day may show a white blood cell count consistent with the normal circulating white cell–to–red cell ratio (about 1:1000). Chemical meningitis is produced by the presence of blood or breakdown products within the subarachnoid space, and CSF samples contain increased numbers of polymorphonuclear and mononuclear cells relative to red blood cells. The CSF glucose concentration is usually normal shortly after the onset of bleeding, but as chemical meningitis develops, the glucose level may decline, rarely to less than 40 mg/dL. After a subarachnoid hemorrhage, the protein content of CSF is generally elevated, consistent with contamination by blood (the usual ratio is 1 mg/dL of protein for every 1000 red blood cells).

Cerebral angiography remains the definitive study to identify the source of subarachnoid hemorrhage. When the diagnosis of aneurysmal subarachnoid hemorrhage seems highly probable, the timing and need for a cerebral angiogram should be determined by surgical considerations. If doubt exists, angiography should be performed with minimal delay. Because many patients have multiple cerebral aneurysms, the carotid and vertebral artery systems should be examined angiographically. The initial cerebral angiogram fails to detect the source of bleeding in about 20% of patients; such patients are thought to have a fairly good prognosis, with only a 1 to 2% annual risk for recurrent hemorrhage. Failure to detect the bleeding source can be due to obliteration of the aneurysm because of clot or may be due to the small size of the ruptured aneurysm. A superficial venous angioma, a spinal cord aneurysm, or a spinal AVM also will not be seen on a cerebral angiogram. The presence of back pain or neurologic signs localized to the spinal cord at onset should prompt a search for a spinal source of hemorrhage. If the initial angiogram is negative and no other clues to the bleeding site can be found, repeat cerebral angiography is usually performed within a few weeks; MRI or CT with and without contrast may also be helpful.

TREATMENT

Treatment of Complications

If a patient does not die immediately after a subarachnoid hemorrhage, a number of neurologic complications can occur. Some result from blood in the subarachnoid space, and other concerns include rebleeding from the same aneurysm, cerebral vasospasm and its ischemic consequences, hydrocephalus caused by blockage of CSF outflow pathways, and seizures. Non-neurologic complications include cardiac and electrolyte abnormalities.

Rebleeding

If an aneurysm is not repaired promptly, it can rupture again. A new headache or neurologic worsening suggests repeat rupture, which can be diagnosed only if a repeat CT scan or lumbar puncture shows the presence of new blood in the subarachnoid space. Approximately 30% of patients with aneurysmal subarachnoid hemorrhage rebleed during the first month, and the incidence is highest during the first 2 weeks after the initial episode. Patients with unrepaired aneurysms who survive their initial bleeding for more than 1 month have a 2 to 3% annual risk for rebleeding. Infusion of factor VII can reduce the growth of the hemorrhage but does not improve outcomes.

Vasospasm

A common cause of death and disability in patients with aneurysmal subarachnoid hemorrhage is cerebral vasospasm. The vessels at the base of the brain become narrowed, thereby reducing blood flow; if the vasospasm is severe, it can produce infarction of the brain distal to the site of the spasm. The vessels that go into spasm are often different from the artery that was responsible for the initial bleeding. Vasospasm has been reported in up to 75% of patients after subarachnoid hemorrhage, and delayed neurologic deficits develop in as many as 30% of patients with vasospasm. The onset of vasospasm is typically between days 3 and 14 after bleeding, but this complication can develop as late as 3 weeks after subarachnoid hemorrhage. The arteries of the circle of Willis and their major branches are the usual initial site of spasm, with more distal arteries becoming involved later. The amount and location of blood detected within the basal cisterns on CT correlate with the incidence and location of vasospasm. The pathogenesis of cerebral vasospasm is unknown.

Cerebral angiography, which is the best established method to diagnose vasospasm, shows narrowing of the dye column. However, other methods such as transcranial Doppler ultrasonography and magnetic resonance angiography are increasingly being used. Transcranial Doppler has high specificity, but its sensitivity is not as good as that of angiography.

Hydrocephalus

Acute hydrocephalus occurs in up to two thirds of patients within 3 days after subarachnoid hemorrhage. Hydrocephalus is caused by obstruction of CSF outflow pathways at the level of the fourth ventricle and the pacchionian granulations lining the venous sinuses. Increasing age, a history of hypertension, intraventricular hemorrhage, focal neurologic findings, a decreased level of consciousness, and hyponatremia are associated with risk for the development of hydrocephalus. Chronic ventricular enlargement occurs in as many as 60% of patients within 1 month after subarachnoid hemorrhage and is often asymptomatic. Several forms of treatment have been advocated for the management of hydrocephalus, including repeated lumbar puncture and shunt placement, but their value has not been proved.

Seizures

Seizures may occur shortly after subarachnoid hemorrhage in 15 to 90% of patients. Seizures are thought to be caused by cortical damage from bleeding into the neocortex or from ischemic necrosis related to vasospasm. The development of persistent epilepsy is unusual. Prophylactic anticonvulsant therapy has not been useful.

Non-neurologic Complications

Cardiac complications occur as a consequence of subarachnoid hemorrhage. In the acute phases of subarachnoid hemorrhage, electrocardiographic patterns can mimic acute myocardial infarction (Chapter 73). A pattern of deep inverted T waves across the pericardium is classic. Appropriate biomarker assays and repeat electrocardiograms are needed to document true myocardial damage.

Hyponatremia (Chapter 118) is the most common electrolyte abnormality after subarachnoid hemorrhage. Sodium loss, which is typically mild, may occur in up to 25% of patients. The natriuresis has been attributed to inappropriate levels of antidiuretic hormone (Chapter 232), but this hypothesis has not been proved. Hyponatremia can itself result in a decreased level of consciousness and seizures, but it is often impossible to distinguish the effects of hyponatremia from the other possible causes of these neurologic abnormalities.

SPECIFIC CAUSES AND THEIR TREATMENT AND PROGNOSIS

Saccular Aneurysms

DEFINITION AND EPIDEMIOLOGY

Saccular or "berry" aneurysms, which account for 80 to 90% of all intracranial aneurysms, are thin-walled outpouchings that protrude from the arteries of the circle of Willis or its major branches; 85% are located at branching points (Fig. 415-1). Because of the local weakness and degeneration of the media, the intima bulges outward and is covered only by the adventitia. A saccular aneurysm may be an incidental finding on a scan or may be detected at autopsy in patients who die of other diseases; in symptomatic cases, however, the sack gradually enlarges and ultimately ruptures.

Saccular aneurysms are rarely detected in children, and the incidence of subarachnoid hemorrhage increases with age; therefore, it seems clear that congenital wall defects develop into aneurysms only after some time. Congenital defects in the muscle and elastic tissue of the arterial media are observed at autopsy in up to 80% of normal vessels of the circle of Willis. It is postulated that these defects gradually degenerate over time as they are exposed to pulsatile arterial blood pressure. Multiple aneurysms are found in about 15% of people with at least one aneurysm. Because the incidence of aneurysmal subarachnoid hemorrhage is approximately 1 in 10,000, it is evident that most saccular aneurysms do not rupture.

PATHOBIOLOGY

Approximately 10 to 20% of patients with known aneurysms have a family history. Diseases that are associated with intracranial saccular aneurysms include polycystic kidney disease (Chapter 129), Marfan and Ehlers-Danlos syndromes (Chapter 268), fibromuscular dysplasia (Chapter 78), pseudoxanthoma elasticum (Chapter 268), systemic lupus erythematosus (Chapter 274), and sickle cell anemia (Chapter 166). Screening of other family members is often recommended when two or more members of a family have aneurysms.

TREATMENT

Primary Prevention of Bleeding

Because the natural history of aneurysms may be highly variable and the risk-to-benefit ratio for the various invasive techniques is unknown, expectant waiting may sometimes be the best option. However, an aneurysm may rupture without warning, and the uncertainty is unacceptable to some

patients and physicians. Medical therapies may delay the time of rupture but cannot repair the lesion.

Treatment of Aneurysms that Have Bled

Medical Treatment

Medical management of a ruptured aneurysm aims to reduce the risk for rebleeding and cerebral vasospasm and prevent other medical complications before and after surgical intervention. The only form of medical therapy that has been useful in treating subarachnoid hemorrhage patients is the voltage-regulated calcium-channel antagonist nimodipine. Although it does not reduce the frequency of vasospasm, nimodipine (60 mg orally every 4 hours for 21 days) lowers the incidence of cerebral infarction by about one third.

General support consisting of bed rest, analgesics for headache, and gentle sedation as needed is provided to quiet the patient. Stool softeners can minimize straining. Hypertension should be treated appropriately but not aggressively (Chapter 67) because elevated blood pressure may represent a normal compensatory mechanism, particularly in a chronically hypertensive patient, and excessive reduction may cause extension of the infarct. There is no conclusive evidence that modification of blood pressure in patients with acute subarachnoid hemorrhage is of benefit. Antifibrinolytic drugs, including tranexamic acid and ε-aminocaproic acid, may reduce rebleeding, but any such benefit is outweighed by an increased incidence of infarction.

Interventional Therapies

The objectives of interventional procedures are to exclude the aneurysm from the circulation or relieve pressure on adjacent brain tissue caused by expansion of the sack. The optimal timing of these therapies is uncertain, but many surgeons recommend treatment as soon as possible after the subarachnoid hemorrhage.

An electrical current applied to a detachable coil threaded into an aneurysm by means of percutaneous angiography causes the surrounding blood to clot. The coil is detached and left in place, and the catheter is then removed. This approach is more effective than surgical clipping for achieving disability-free survival in patients who have had ruptured aneurysms.[2] With very large aneurysms, for which use of a coil is not possible, wrapping the sack with various types of material to prevent it from rupturing or growing is sometimes performed. Indirect procedures include various methods of occluding the feeding artery; if there is sufficient collateral supply, the risk for infarction may be less than that of spontaneous rupture of the aneurysm with subsequent extensive subarachnoid hemorrhage.

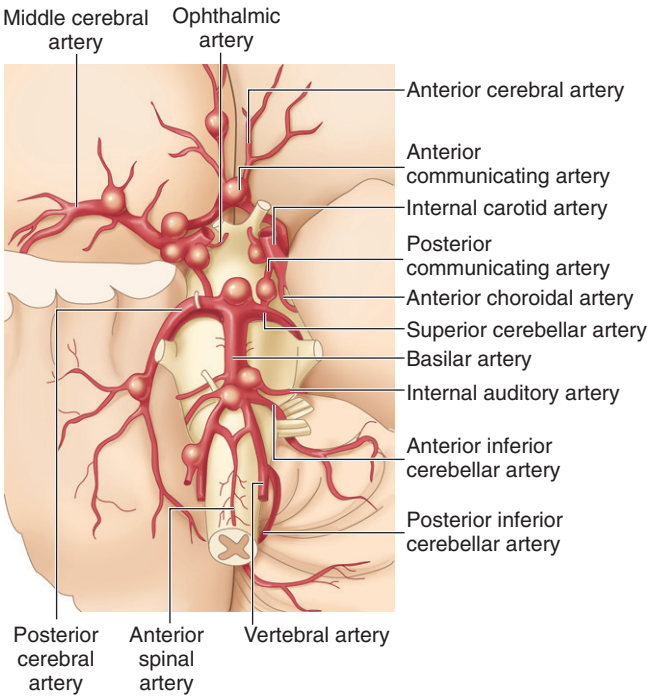

FIGURE 415-1. Saccular aneurysms. Saccular or berry aneurysms typically develop at the bifurcations of arteries on the undersurface of the brain.

PROGNOSIS

Mortality and morbidity rates differ among studies. About 12% of subarachnoid hemorrhage victims die before reaching medical attention. By 30 days, approximately 50% die, but 30-day survivors generally survive for at least a year. An equally high mortality rate accompanies each episode of rebleeding. Approximately 25% of survivors have persistent neurologic deficits.

Fusiform Aneurysms

Fusiform aneurysms are so named because they are elongated dilations (i.e., ectasia) of large arteries associated with atherosclerosis. These aneurysms typically develop in the basilar artery but also may affect the internal, middle, and anterior cerebral arteries of individuals with widespread arteriosclerosis and hypertension. These aneurysms may progressively dilate and become tortuous, thereby producing neurologic dysfunction, most frequently by compressing surrounding structures. Thrombi may form in them and embolize distally to cause ischemic strokes. Typically, ectatic aneurysms of the basilar artery compress cranial nerves and cause facial pain (V), hemifacial spasm (VII), and hearing loss with vertigo (VIII). Fusiform aneurysms may mimic pituitary and suprasellar mass lesions or cerebellopontine angle tumors. Fusiform aneurysms rarely rupture; if they do, they are difficult to treat surgically because their shape and stiff walls generally preclude easy surgical clipping, and total occlusion is usually required.

Mycotic Aneurysms

Infected emboli, usually originating on an infected heart valve (Chapter 76), may lodge in a distal branch of a cerebral artery and cause small areas of infarction or microabscesses. In arteries that do not rupture immediately, focal arteritis and mycotic aneurysms, also known as septic aneurysms, may develop. Mycotic aneurysms are frequently multiple and can be found distally in the cerebral arteries. Rates of rupture of these aneurysms may be as high as 10%. Such lesions may be detected by noninvasive imaging studies, but the definitive test is contrast-enhanced angiography, for which the indications are controversial. Aside from treatment of the underlying infection, other treatments are not established.

Vascular Malformations

EPIDEMIOLOGY

About 1% of all strokes and 10% of intracerebral hemorrhages are caused by vascular malformations. The prevalence of AVM is approximately 0.5%, and the annual incidence of hemorrhage is between 1 and 3 cases per 100,000 people. Familial cases occur but are rare.

PATHOBIOLOGY

Conventional classifications of cerebrovascular malformations are based on the histologic appearance of the vessels and the intervening neural parenchyma. The most frequent type of vascular malformation is an AVM, which has a core of dysplastic vessels (i.e., nidus), feeding arteries, and draining veins. In the nidus, arteries connect directly to veins without intervening capillaries to produce a low-resistance, high-flow shunt that ultimately dilates feeding arteries and thickens the walls of the draining veins. The classic arteriographic appearance includes an early draining vein. Ordinarily, there is no intervening neural tissue in the nidus. The nidus is the usual site of hemorrhage in an AVM.

The next most common lesions are cavernous malformations (i.e., cavernous angiomas or hemangiomas), which are composed of small-caliber sinusoidal vascular channels that are commonly thrombosed. The low flow rate through these vessels makes them difficult to detect by angiography, and they are unlikely to hemorrhage; these malformations also do not contain neural tissue. Cavernous AVMs are often associated with venous malformations, which are composed of small veins separated by normal parenchyma. Smaller venous channels drain into a dilated venous trunk that ultimately drains into a large vein and sinus in the brain. The classic angiographic appearance is a caput medusae in the late venous phase. These anomalies are readily detected by CT, but they rarely hemorrhage.

A cerebral varix is a single dilated vein that seldom causes clinical symptoms. Telangiectasis, also called capillary malformation, is a cluster of enlarged capillaries surrounded by normal parenchyma. These lesions are too small to be detected by conventional imaging methods and are usually noted as petechiae that are found incidentally at autopsy; these benign lesions rarely hemorrhage.

CLINICAL MANIFESTATIONS

Although increasing numbers of probably asymptomatic vascular malformations are being diagnosed by brain imaging as part of the evaluation of nonspecific headaches, about 50% of AVMs are manifested as intracranial

hemorrhage, a lower proportion initially present as seizures, and the remainder cause progressive neurologic disability as the first symptom. Hemorrhage, which is the most feared complication of an AVM, has an associated mortality rate of 10 to 15%. The mortality and morbidity rates associated with AVMs are somewhat less than for aneurysms. The initial hemorrhage tends to occur during the second through fourth decades, and hypertension before the hemorrhage is uncommon. The risk for acute rebleeding averages approximately 6 to 7%. In the next 5 years, the rate is about 2% per year, and it is 1 to 2% per year thereafter. If this rebleeding rate is maintained for life, a young individual who has a hemorrhagic AVM faces a 50 to 60% chance of an incapacitating or fatal subsequent hemorrhage during a normal lifespan.

AVMs can bleed into the subarachnoid space, the brain parenchyma, or the ventricular system. Focal neurologic abnormalities depend on the severity of the bleeding and the location of brain parenchyma that has been affected. The frequency of cerebral vasospasm after hemorrhage from an AVM is less than that for aneurysmal bleeding.

Approximately 30% of patients who have an AVM are initially evaluated for seizures, which often have a focal onset. Focal neurologic deficits independent of seizures can develop, possibly caused by vascular thrombosis and perhaps by shunting of blood through arteriovenous fistulas away from normal brain tissue.

DIAGNOSIS

If a hemorrhage has occurred, unenhanced CT scanning may show evidence of bleeding in an unusual location for primary intracerebral hemorrhage or a ruptured aneurysm. Contrast-enhanced CT scans may demonstrate marked enhancement of the feeding arteries and draining veins. MRI with signal void on T1- or T2-weighted images can also establish the diagnosis. Angiography remains the definitive test to identify the AVM and delineate its size, gross morphology, feeding arteries, and draining veins. Because AVMs are occasionally multiple and may be associated with saccular aneurysms, four-vessel angiography is indicated even if an AVM is found by unilateral carotid injection. Extracranial or contralateral arteries occasionally supply intracranial AVMs and should be considered in the angiographic evaluation.

TREATMENT

Rx

There is uncertainty regarding the prognosis of unruptured AVMs as a result of their various locations, sizes, and morphology. Because the safety and efficacy of the various procedures for treating AVMs have not been established, there are no guiding therapeutic principles.

Conservative treatment is often recommended for unruptured AVMs manifested as seizures or headache, especially in patients older than 55 to 60 years. This approach emphasizes control of hypertension, avoidance of anticoagulants, and use of anticonvulsants to control seizures.

If an AVM has ruptured and the patient has recovered from the initial hemorrhage, the two goals of interventional therapy are to remove the AVM completely and to avoid deterioration of neurologic dysfunction. Removal can be curative, but it is important to eliminate residual abnormal vessels, which may produce hemorrhages, especially if reduction of outflow increases perfusion pressure within the remaining anomalous vasculature. However, it is particularly dangerous to perform these procedures in critical neurologic areas, such as in or near the speech centers.

Therapeutic options include surgical resection of the AVM, embolization of the feeding arteries, and radiation-induced thrombosis. In some cases, combinations of these treatments are used. Selective embolization of the lesion through the transfemoral angiographic approach is commonly the initial procedure, with the goal of reducing blood flow through the AVM. Embolization may be performed in stages to reduce the size of the lesion sequentially, but endovascular treatment seldom obliterates an AVM. A risk for embolization is that embolic material may escape from the AVM and occlude normal vessels.

Stereotactic radiosurgery can eliminate an AVM but is satisfactory only for small lesions. The therapeutic effect of this technique is delayed because the abnormal vessels shrink gradually after the procedure.

Direct surgical intervention involves the use of microsurgical techniques. If the AVM is large, the procedures are often performed in stages to reduce blood flow in an adjacent region and make subsequent surgery easier. Surgery is considered successful if the postoperative angiogram shows no residual AVM. However, long-term occlusion rates are unknown, and recanalization with recurrent hemorrhage is possible.

TABLE 415-1 CAUSES, MEANS OF DIAGNOSIS, AND CHARACTERISTICS OF INTRACEREBRAL HEMORRHAGES

CAUSES	PRIMARY MEANS OF DIAGNOSIS	CHARACTERISTICS
Hypertension	Clinical history	Rupture of small arterioles related to degenerative changes induced by uncontrolled hypertension
Amyloid angiopathy	Clinical history	Rupture of small and medium-sized arteries with deposition of β-amyloid protein; manifested as lobar hemorrhages in people older than 70 years
Arteriovenous malformation	MRI or angiogram	Rupture of abnormal small vessels connecting arteries and veins
Intracranial aneurysm	MRI or angiogram	Rupture of a saccular dilation from a medium-sized artery; usually associated with subarachnoid hemorrhage
Cavernous angioma	MRI or angiogram	Rupture of abnormal capillary-like vessels with intermingled connective tissue
Venous angioma	MRI or angiogram	Rupture of an abnormal dilation of venules
Venous sinus thrombosis	MRI or angiogram	Result of hemorrhagic venous infarction
Intracranial neoplasm	MRI or angiogram	Result of necrosis and bleeding within hypervascular neoplasms
Coagulopathy	Clinical history	Most commonly associated with the use of anticoagulants or thrombolytics
Vasculitis	Serologic and cerebrospinal fluid markers, brain biopsy	Rupture of small or medium-sized arteries with inflammation and degeneration
Cocaine or alcohol abuse	Clinical history	Underlying vascular abnormalities may be present
Hemorrhagic transformation	CT	Hemorrhage in the region of cerebral infarction as a result of ischemic damage to the blood-brain barrier

CT = computed tomography; MRI = magnetic resonance imaging.
Modified from Qureshi AI, Tuhrim S, Broderick JP, et al. Spontaneous intracerebral hemorrhage. *N Engl J Med.* 2001;344:1450-1460.

PRIMARY INTRACEREBRAL HEMORRHAGE

DEFINITION

Primary nontraumatic intracerebral hemorrhage (i.e., hemorrhage that does not result from ischemic injury) occurs predominantly as a consequence of chronic, poorly controlled hypertension (Chapter 67). Less frequently, a ruptured vascular malformation or amyloid angiopathy is responsible. Intracerebral hemorrhage can also be caused by a bleeding diathesis and certain drugs of abuse (Table 415-1).

EPIDEMIOLOGY

In the United States, primary intracerebral hemorrhage is responsible for 10 to 15% of strokes and about 80% of all intracranial hemorrhages. The average annual incidence in the United States is approximately 50,000. Intracerebral hemorrhage has the highest mortality rate of all subtypes of stroke, and almost 60% of affected patients die within the first year. The risk for primary intracerebral hemorrhage in blacks is about 40% higher than in whites. Worldwide, the incidence of intracerebral hemorrhage ranges from 10 to 40 per 1 million people, with the rate in Japan being at the top end of this range. Age-adjusted rates for men are about 50% higher than those for women. As with ischemic stroke, the incidence appears to be declining in the industrialized world, concurrent with the decline in hypertension.

PATHOBIOLOGY

Primary intracerebral hemorrhage typically consists of a large, confluent area of blood that clots (Fig. 415-2). Most bleeding occurs at or near bifurcations

FIGURE 415-2. Pathology specimen showing a large basal ganglia parenchymal hemorrhage in the left hemisphere. (Courtesy of Gregory W. Albers, Stanford University, Stanford, Calif.)

of arteries with prominent degeneration of the media and smooth muscle. Several weeks later, the blood is slowly removed by phagocytosis, and after several months, only a small, collapsed cavity lined by hemosiderin-containing macrophages may remain. Rupture into the ventricles with bleeding into the subarachnoid space commonly occurs with large hemorrhages. Edematous parenchyma rapidly develops around the clot. Although hemorrhage may destroy brain tissue locally, histologic examination suggests that displacement of normal brain tissue and dissection of blood along fiber tracts account for much of the pathology. Viable and salvageable neural tissue may exist in the vicinity of the hematoma.

The most important risk factor for intracerebral hemorrhage is hypertension, particularly in people who are younger than 55 years, smokers, and poorly compliant with antihypertensive medications. Excessive chronic alcohol consumption also increases the risk for intracerebral hemorrhage. A less well established risk factor is a low serum cholesterol concentration (<160 mg/dL).

Hypertension is associated with hemorrhage in various locations throughout the brain, especially in the external capsule–putamen, internal capsule–thalamus, central pons, and cerebellum (Fig. 415-3). A smaller number of hemorrhages occur in the subcortical white matter, especially in the frontal, temporal, and occipital lobes.

Evidence, especially from serial CT scans, shows that hematomas expand for many hours after the onset of bleeding in many patients. Bleeding may cease when the lesion grows to a size sufficient to produce increased tissue pressure with consequent tamponade.

Amyloid (congophilic) angiopathy is a pathologic diagnosis that is more frequently made in people older than 55 years. This condition, which is unrelated to generalized amyloidosis and is occasionally hereditary, commonly produces multiple, small hemorrhages. It often appears in the brains of patients with Alzheimer's disease (Chapter 409) and has been associated with nonhypertensive hemorrhage in unusual lobar locations in the cerebral hemispheres. Amyloid deposits, chemically similar to those in Alzheimer's plaques, are seen in the media and adventitia of small and medium-sized arteries.

Anticoagulation, thrombolysis, and various hematologic abnormalities (Chapters 175 to178) are associated with intracerebral hemorrhages. Warfarin anticoagulation to conventional intensities (i.e., international normalized ratio of 2.0 to 3.0) has been associated with a risk for intracranial hemorrhage of approximately 1% per year in many stroke-prone patients (Chapter 37). This rate is about 7 to 10 times greater than the risk in similar patients who have not undergone anticoagulation. On average, when such hemorrhages occur, the fatality rate is about 60%. Predictors are advanced age, previous ischemic stroke, hypertension, and the intensity of anticoagulation.

The most feared complication of thrombolytic therapy for acute myocardial infarction (Chapter 73) or ischemic stroke (Chapter 414) is intracerebral hemorrhage. When tissue plasminogen activator (t-PA) is administered within 3 hours after the onset of stroke symptoms, the intracerebral hemorrhage rate is 6.5%, compared with 0.5% in placebo patients; 50% of the patients who sustain these hemorrhages die. However, the overall benefit of t-PA therapy in appropriate patients persists because the increased risk for hemorrhage is more than counterbalanced by the improvement in ischemic strokes (Chapter 414).

Cerebral hemorrhages also occur in patients with leukemia (Chapter 189), polycythemia vera (Chapter 169), thrombocytopenia (Chapter 175), hemophilia (Chapter 177) and other clotting abnormalities, infectious and noninfectious vasculitis, intracranial neoplasms, and venous thrombosis. In addition, intracerebral hemorrhage can occur in patients who abuse various sympathomimetic agents and cocaine (Chapter 33).

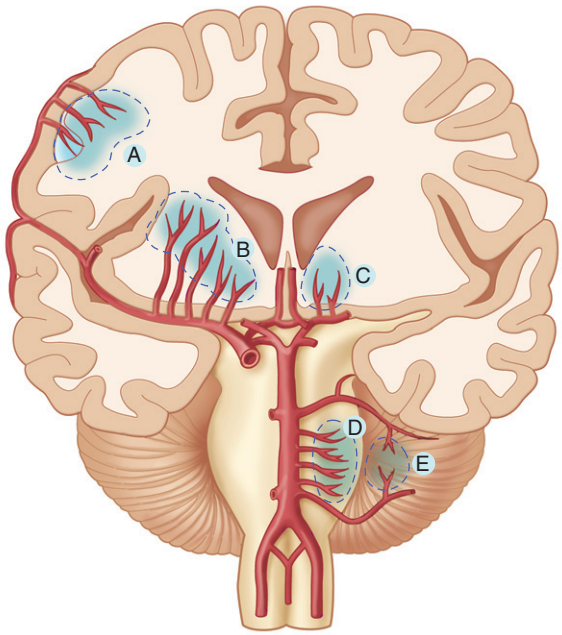

FIGURE 415-3. Typical sites and sources of intracerebral hemorrhage. Intracerebral hemorrhages most commonly involve the cerebral lobes and originate from penetrating cortical branches of the anterior, middle, or posterior cerebral arteries (A); the basal ganglia and originate from ascending lenticulostriate branches of the middle cerebral artery (B); the thalamus and originate from ascending thalamogeniculate branches of the posterior cerebral artery (C); the pons and originate from paramedian branches of the basilar artery (D); and the cerebellum and originate from penetrating branches of the posterior inferior, anterior inferior, or superior cerebellar arteries (E). (From Qureshi AI, Tuhrim S, Broderick JP, et al. Spontaneous intracerebral hemorrhage. *N Engl J Med.* 2001;344:1450-1460.)

CLINICAL MANIFESTATIONS

Neck stiffness, seizures, diastolic blood pressure higher than 110 mm Hg, vomiting, and headache increase the likelihood of a hemorrhagic stroke rather than an ischemic stroke. Otherwise, however, the neurologic abnormalities caused by intracerebral hemorrhage do not differ from those caused by ischemic strokes (Chapter 414) because destruction of neural tissue is the basis of the neurologic dysfunction caused by both entities. The signs and symptoms are related to the location of the lesion. Because the site of intracerebral hemorrhage often differs from that of ischemic strokes, characteristic patterns of neurologic loss may be more frequently associated with intracerebral hemorrhage than with ischemic strokes (Table 415-2). Hemorrhages may grow as the bleeding continues, whereas ischemic lesions usually do not change in size after vascular occlusion; as a result, hemorrhages characteristically cause progressively increasing loss of neurologic function until a plateau is reached, whereas ischemic strokes may fluctuate or remain static after the early phases of the stroke. Subsequent deterioration in the level of consciousness after an intracerebral hemorrhage occurs in about one fourth of patients who are initially alert.

Intracranial hemorrhages in each of the four typical locations produce characteristic findings. Patients with massive *putaminal hemorrhages* become lethargic or comatose within minutes to hours after onset and concurrently experience contralateral weakness (including the face) with contralateral hemianopia and gaze paresis (i.e., eyes deviated toward the side of the hemorrhage). *Cerebellar hemorrhages* initially spare the brain stem, and consciousness is generally preserved in the early stages. Occipital headache may be the first symptom. The usual findings are unsteady gait, ataxia, nausea, and vomiting, which is often severe and repetitive. A variety of eye movement abnormalities may be present. Weakness is not prominent at onset, but with progression and brain stem compression, focal or bilateral weakness and coma develop, often rapidly. Further deterioration can result from herniation of cerebellar tissue downward through the foramen magnum or upward across the tentorium; hydrocephalus may be caused by obstruction of CSF flow. With continued bleeding or tissue swelling, severe brain stem damage ensues and causes rapid demise of the patient. Less frequent are *thalamic*

TABLE 415-2 CLINICAL FEATURES OF COMMON HYPERTENSIVE HEMORRHAGES

	Site of Hemorrhage			
CLINICAL FEATURES	**PUTAMINAL**	**THALAMIC**	**PONTINE**	**CEREBELLAR**
Unconsciousness	Later	Later	Early	Late
Hemiparesis	Yes	Yes	Quadriparesis	Late
Sensory change	Yes	Yes	Yes	Late
Hemianopia	Yes	Yes	No	No
Pupils				
Size	Normal	Small	Small	Normal
Reaction	Yes	Yes or no	Yes or no	Yes
Gaze paresis side	Contralateral, sometimes ipsilateral	Contralateral	Ipsilateral	Ipsilateral
Response to calorics	Yes	Yes	No	Yes or no
Downward eye deviation	Yes	No	No	
Ocular bobbing	No	No	Sometimes	Sometimes
Gait loss	No	No	Yes	Yes
Vomiting	Occasional	Occasional	Often	Severe

hemorrhages, which cause patients to lose consciousness relatively rapidly; those who survive often experience contralateral hemiparesis, sensory deficits, and homonymous hemianopia. *Pontine hemorrhage* was once thought to produce coma invariably, but modern imaging detects smaller hemorrhages that are not fatal. Patients with severe pontine hemorrhages become comatose, usually with very small but detectable reactive pupils. Oculovestibular responses are often lost early, vomiting can occur at onset, and these patients generally have quadriplegia and bilateral extensor posturing. Patients may be "locked-in" (Chapter 411).

Lobar hemorrhages, which are more characteristic of amyloid angiopathy than hypertension, usually originate at the junctions between gray and white matter in the cerebral hemispheres. Such hemorrhages account for about one third of intracerebral hemorrhages and are approximately as common as putaminal hemorrhages. The clinical manifestation depends on the location of the hemorrhage. Most patients are elderly because amyloid angiopathy and hypertension are relatively frequent in this age group. Nonspecific symptoms, including headache, nausea, and vomiting, probably occur with about the same frequency but with less intensity than with deep, hypertensive hemorrhages. Coma and seizures are uncommon, possibly because most of these hemorrhages are comparatively small and located in subcortical white matter.

DIAGNOSIS

Intracerebral hemorrhage often cannot be distinguished from other types of stroke based on clinical findings alone. The test of choice for making the diagnosis is a non–contrast-enhanced CT scan (Fig. 415-4) that shows areas of hemorrhage as zones of increased density, which may or may not have associated regions of decreased density indicating infarction. Primary parenchymal hemorrhages typically display homogeneous areas of increased density and a mass effect (i.e., shift of normal tissue from its usual location), whereas hemorrhagic infarctions are characterized by areas of increased density (i.e., blood) interspersed with areas of decreased density (i.e., infarction).

MRI findings depend on the precise imaging sequence and the age of the hemorrhage. The sensitivity and specificity of MRI for the diagnosis of hemorrhage, particularly in the presence of infarction, are unknown. MRI is able to detect small lesions, particularly in the posterior fossa, better than CT, but how much of the lesion is hemorrhage or hypoperfusion is uncertain. Cerebral angiography is not needed for the acute evaluation of hemorrhages, but it is commonly used later to identify a suspected aneurysm or AVM that may be considered for intervention.

TREATMENT

Rx

General Measures

The usual medical management of acute parenchymal hemorrhage has been supportive, with initial care directed at maintenance of the airway, oxygenation, nutrition, and prevention and treatment of secondary complications. Optimal blood pressure treatment is uncertain, although the general guidelines for excessive hypertension and reduction of cerebral perfusion apply as for ischemic strokes (Chapter 414). There is no accepted protocol for the management of increased intracranial pressure; osmotherapy, hyperventilation, and neuromuscular paralysis rarely are beneficial. Fluid management should maintain euvolemia; fluid restriction or volume expansion is not of proven value. Seizures are particularly harmful in critically ill patients and are treated despite lack of data from randomized trials. Maintenance of normal body temperature is theoretically desirable because fever may accelerate tissue destruction.

Medical Therapy

Intravenous administration of recombinant factor VIIa within 4 hours after onset reduces the volume of hemorrhage and surrounding cerebral edema, as measured by CT, but does not improve clinical outcomes.[1] Larger trials of this promising therapy are in progress. Small clinical trials of corticosteroids, glycerol, and hemodilution have not demonstrated benefit, and corticosteroids may increase the risk for infectious complications.

Surgical Therapy

The goal of surgical treatment of intracerebral hemorrhage is to remove as much blood clot as possible as quickly as possible. Ideally, surgery should remove the underlying cause, such as an AVM, and prevent hydrocephalus. Early surgical intervention to evacuate intracerebral hematomas within 24 hours is no better than medical therapy.[2] However, patients who have cerebellar hemorrhages and are deteriorating because of brain stem compression and hydrocephalus caused by ventricular obstruction are still recommended by some for removal of the clot or amputation of part of the cerebellum, although no proof exists to support this approach.

PROGNOSIS

In recent series, the 30-day case-fatality rate averaged 30 to 50%. Most early deaths result from the direct neurologic consequences of the hemorrhage; the severity of bleeding (e.g., size, extension into ventricles) and level of neurologic function are the best predictors of poor outcomes. Supratentorial hemorrhages smaller than 30 mL rarely lead to death unless they are located in the thalamus. The long-term prognosis for various degrees of recovery is similar or better than that of cerebral infarctions of comparable severity. The risk for recurrent intracerebral hemorrhage has not been well studied, but the risk for at least one rebleeding episode may be as high as 25% over the next several years. The risk for intracerebral hemorrhage can be reduced by appropriate treatment. Control of mild to moderate hypertension decreases the risk for hemorrhagic stroke by one third to one half (Chapter 67).

HYPERTENSIVE ENCEPHALOPATHY

DEFINITION

Hypertensive encephalopathy is usually defined as malignant hypertension associated with central nervous system abnormalities (Chapter 67). Malignant hypertension is commonly defined as sustained, elevated arterial blood pressure, with diastolic levels of 130 mm Hg or greater and systolic pressure in excess of 200 mm Hg. Abnormal funduscopic findings include papilledema, retinal linear hemorrhages, or extravascular cotton-wool exudates. Hypertensive encephalopathy is classically characterized by rapidly evolving severe hypertension associated with headache, nausea, vomiting, visual disturbances, seizures, confusion, stupor, and ultimately coma. Focal neurologic signs are common.

PATHOBIOLOGY

The pathogenesis of hypertensive encephalopathy remains unclear. Pathologic findings include purpura in the brain, retinal hemorrhages, papilledema, and fibrinoid arteriolar lesions of the glomeruli. Diffuse fibrinoid necrosis and thrombotic occlusion of arterioles cause microinfarctions and petechial hemorrhages, and these changes lead to distal ischemia. Ring hemorrhage around a thrombosed precapillary is the characteristic microscopic lesion of hypertensive encephalopathy. Multiple, compacted petechiae can resemble a hematoma.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hypertensive encephalopathy is associated with hypertension of any cause and can occur in patients of any age. Severe headache is the most frequent manifestation. Nausea, vomiting, impaired vision, and dizziness are common. Confusion, stupor, and coma with generalized seizures may develop. Retinal changes characteristic of severe hypertension are common and often include hemorrhages or papilledema, but arteriolar narrowing may be the only abnormality. Because there are no pathognomonic findings in this disorder, it is a diagnosis of exclusion.

Uremic encephalopathy also occurs in patients with renal failure (Chapter 132). Uremia can cause altered mental status and seizures, and differentiation from hypertensive encephalopathy may be difficult. However, uremia is usually accompanied by metabolic acidosis or water intoxication, which may differentiate it from hypertensive encephalopathy, and correction of the uremia by dialysis may help clarify the picture.

Other complications of hypertension to be considered in the differential diagnosis of hypertensive encephalopathy include hemorrhagic and ischemic strokes. Focal neurologic signs predominate in these other conditions, whereas mental status changes are characteristic of hypertensive encephalopathy. Increased intracranial pressure from obstructive hydrocephalus (Chapter 195), brain tumor (Chapter 195), or subdural hematoma (Chapter 406) can elevate blood pressure and slow the pulse, but encephalopathy and markedly elevated blood pressure are absent.

TREATMENT

Rx

Therapy should be initiated immediately, but the rate of decrease in blood pressure should be controlled to avoid hypotension (Chapter 67). Seizures can usually be stopped with intravenous diazepam (10 mg); in eclamptic patients (Chapter 247), fosphenytoin (15 to 20 mg phenytoin equivalent per kilogram intravenously) or magnesium sulfate (4 g intramuscularly every 4 hours as needed) are often used, particularly because they may not depress the respiratory drive of the fetus as much as some other drugs. Prompt delivery of the fetus may be quite helpful.

416 PARKINSONISM

ANTHONY E. LANG

Parkinsonism is a clinical syndrome that consists of four cardinal signs: tremor, rigidity, akinesia, and postural disturbances (TRAP). Parkinson's disease is a common cause of the TRAP syndrome, but there are numerous other causes (Table 416-1).

PARKINSON'S DISEASE

EPIDEMIOLOGY

Parkinson's disease, which is the second most common neurodegenerative disorder after Alzheimer's disease, occurs in approximately 1 in 1000 in the general population and in 1% of persons older than 65 years. Men are affected slightly more often than women (3:2).

PATHOBIOLOGY

The cause of Parkinson's disease is believed to be a variable combination of poorly understood genetic and environmental factors. Both autosomal dominant and recessive genes can cause classic Parkinson's disease. The protein α-synuclein, which is the chief constituent of the hallmark cytoplasmic inclusion, the Lewy body (Chapter 409), is critical in the pathogenesis of Parkinson's disease. Abnormal aggregation of the protein, either from mutations in the α-synuclein gene or as a result of excessive production of the normal protein because of gene duplications or triplications, is associated with varying disease phenotypes. Other defined genetic abnormalities may be associated with classic later-onset Parkinson's disease, including *LRRK2,* which is currently the most common cause of autosomal dominantly inherited Parkinson's disease, or with early-onset parkinsonism, typically found in the autosomal recessive forms associated with *parkin*, *DJ-1*, and *PINK1*. Other genes in which mutations may increase the risk for development of Parkinson's disease include the glucocerebrosidase gene (*GBA*).

Although monogenetic forms of Parkinson's disease are uncommon, knowing that parkin is an E-3 ubiquitin protein ligase has implicated the ubiquitin proteasome system in the pathogenesis of Parkinson's disease. Proteasome inhibitors, which may be present in the environment, are being

studied for their potential to cause parkinsonism in animals. Such findings support the "environmental hypothesis" of sporadic Parkinson's disease, similar to the discovery that the selective neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is oxidized to the active toxin MPP^+, which is a selective inhibitor of complex I of the mitochondrial electron transport chain. This knowledge, combined with recognition of the importance of dopamine (see later), has implicated oxidative stress in the pathogenesis of Parkinson's disease. Other proposed pathogenetic factors include mitochondrial dysfunction, protein misfolding or aggregation, excitotoxicity, and inflammation.

Pathology

Many of the features of Parkinson's disease are due to loss of dopamine in the neostriatum (especially the putamen) secondary to loss of pigmented dopaminergic neurons in the substantia nigra pars compacta (SNc) of the midbrain. Approximately 60% of these dopaminergic neurons will have degenerated before clinical features of the disease develop.

In addition to the prominent degenerative changes in the SNc (cell loss, gliosis, abnormal deposition of aggregated α-synuclein as Lewy bodies and Lewy neurites), pathologic changes are also evident in other brain stem nuclei, in cortical regions, and in peripheral autonomic neurons. Indeed, it has been suggested that Parkinson's disease may begin in the lower brain stem and the olfactory system, where it causes early loss of the sense of smell and only later involves the substantia nigra. Independent of the order of involvement, it is likely that the widespread extranigral neurodegenerative changes account for the many symptoms that do not respond to dopamine replacement and that become increasingly problematic as the disease progresses.

CLINICAL MANIFESTATIONS

Typically, the symptoms begin in one limb. This asymmetry often persists into later stages of the disease.

Motor Symptoms

Tremor

The classic "resting tremor" of Parkinson's disease has characteristic clinical features. The tremor has a frequency of 4 to 6 cycles per second, typically with a "pill-rolling" character when it involves the hand. It is generally present with the limb in complete repose and typically subsides when the limb moves and takes up a new position, although the tremor may reemerge ("reemergent tremor") within a short time after maintaining the new position (Video 416-1). Because resting tremor diminishes or subsides with action, it may not be disabling but can be embarrassing and may be associated with aching or fatigue of the affected limb. Resting tremor is usually accentuated by stress (e.g., by asking the patient to perform mental calculations). It is also characteristically present in the upper limbs while walking. A higher-frequency (e.g., 7 to 10 Hz) postural and kinetic tremor is also common in patients with various causes of parkinsonism.

Rigidity

Rigidity is a form of increased muscle tone appreciated best on slow passive movements. It may be characterized as "cogwheel" when a tremor is superimposed or as "lead pipe" when it is not. Rigidity is "activated" or accentuated on examination by asking the patient to move the limb opposite the one being tested. Patients may complain of stiffness, but the rigidity is not usually disabling.

Akinesia

Akinesia or bradykinesia comprises a variety of disturbances in movement, including slowness, reduced amplitude, fatiguing, and interruptions in ongoing movement. This disabling aspect of parkinsonism interferes with all voluntary activities and accounts for many of the well-known features of parkinsonism: lack of facial expression with reduced blinking (hypomimia or masked facies—the "reptilian stare"), soft monotonous speech (hypophonia), impaired swallowing resulting in drooling (sialorrhea), small handwriting (micrographia), reduced arm swing while walking, shortened stride and shuffling gait, difficulty arising from a low chair, and problems turning over in bed. Arrest in ongoing movement ("motor block") can interfere with a variety of activities, but it is best appreciated as freezing of gait (Video 416-2). Bradykinesia is evident on inspection and elicited by testing rapid repetitive and alternating movements: finger tapping, opening and the closing the fist, pronating and supinating the wrist, and toe and heel tapping.

Postural Disturbances

Postural disturbances include a flexed posture in the limbs and trunk (stooped, simian posture), as well as postural instability resulting in imbalance and falls. Patients may complain of being unable to stop themselves from going forward (propulsion) or backward (retropulsion). Clinical assessment of postural instability includes the "pull test," in which the examiner abruptly pulls the patient off balance while being ready to catch the patient in the event of a fall.

Other Symptoms

In addition to the motor features of parkinsonism, a variety of non–motor-related features are extremely common and include pain and other sensory disturbances; dysautonomic complaints, such as urinary urgency and frequency; orthostatic faintness; constipation; male erectile dysfunction; sleep abnormalities, including rapid eye movement behavioral disorder (Chapter 412); anxiety; fatigue; depression; and cognitive disturbances, including dementia. As the disease progresses, more resistant features develop, including "axial" motor disturbances (speech and swallowing abnormalities, freezing, and postural instability), as well as neurobehavioral and cognitive dysfunction.

TABLE 416-1 DIFFERENTIAL DIAGNOSIS OF PARKINSONISM

PARKINSON'S DISEASE
Sporadic
Genetic
Autosomal dominant (e.g., α-synuclein gene mutations, duplications, triplications; *LRRK2* mutations)
Autosomal recessive (e.g., *parkin, DJ-1, PINK-1*)
SECONDARY PARKINSONISM
Neurodegenerative diseases (sporadic or genetic)
Progressive supranuclear palsy* (Videos 416-3 through 416-6)
Multiple system atrophy* (Videos 416-7 through 416-9)
Corticobasal degeneration* (Videos 416-10 and 416-11)
Dementia with Lewy bodies*
Alzheimer's disease*
ALS-parkinsonism-dementia complex of Guam
Huntington's disease
Rapid-onset dystonia-parkinsonism
Pallidopyramidal degeneration (including PARK9 and PARK15)
Neuroacanthocytosis
Spinocerebellar ataxias (e.g., SCA-3, SCA-2)
Wilson's disease
Pantothenate kinase–associated neurodegeneration (Hallervorden-Spatz syndrome)
Neuroferritinopathy
Calcification of the basal ganglia (Fahr's disease)
Dopa-responsive dystonia (not a degenerative disorder)
Drugs*
Neuroleptics, metoclopramide, prochlorperazine, tetrabenazine, reserpine, cinnarizine, flunarizine, α-methyldopa, lithium
Toxic
MPTP, manganese (including illicit use of ephedrone), carbon monoxide, mercury
Infectious
Encephalitis lethargica

TABLE 416-2 PROBLEMS IN LATE-STAGE PARKINSON'S DISEASE

PROBLEM	SYMPTOMS
LATER TREATMENT-RESISTANT SYMPTOMS	
Motor	Dysarthria Dysphagia Freezing of gait (on-period freezing) Postural instability with falls
Non–motor related*	Dysautonomia, weight loss Sensory symptoms, including pain (some may be responsive to levodopa) Changes in mood or behavior (depression, anxiety), sleep disturbances (excessive daytime sleepiness often caused by or aggravated by dopaminergic medication) Rapid eye movement sleep behavior disorder (may develop before parkinsonism) Fatigue Cognitive dysfunction and dementia
RELATED TO TREATMENT AND DISEASE	
Motor fluctuations	Wearing off of drug effect (predictable end-of-dose deterioration, morning akinesia), increased latency to benefit ("delayed-on"), dose failures ("no-on") On-off phenomenon, more rapid and unpredictable fluctuations Concomitant fluctuations of non–motor-related symptoms that may be as disabling as motor symptoms (or more so)
Dyskinesias (abnormal involuntary movements)	Peak-dose dyskinesias: chorea, athetosis, and less often, more prolonged dystonia, typically worse on the initially affected side (Video 416-12) Diphasic dyskinesia ("beginning-of-dose" and "end-of-dose" dyskinesias): mixtures of choreoathetosis, ballism, dystonia, alternating movements (especially in the legs) Off-period dystonia: most often involving the legs and feet (including morning foot dystonia)
Psychiatric disturbances	Vivid dreams and nightmares Visual hallucinations with a clear sensorium Hallucinations with confusion Mania, hypersexuality, problem gambling, dopaminergic drug addiction Paranoid psychosis

Adapted from Lang AE, Lozano AM. Parkinson's disease—second of two parts. *N Engl J Med.* 1998;339:1130-1143.

Complications

In addition to the manifestations of the disease itself, complications of drug therapy include motor- and non–motor-related fluctuations and psychiatric or behavioral disturbances. Thus, in the later stages of the disease, the clinical picture often fluctuates from hour to hour and even from minute to minute; accordingly, patients exhibit a mixtures of the classic features of parkinsonism, which may improve considerably in response to medication, symptoms that persist despite the peak benefit of medication, and symptoms that occur as a complication of dopaminergic medication (Table 416-2).

DIAGNOSIS

Testing for monogenetic forms of Parkinson's disease (e.g., parkin) is becoming available, but guidelines for its use have not yet been developed. Given the classic clinical manifestations, the diagnostic evaluation focuses largely on ways to exclude other causes of parkinsonism (Table 416-3). Young-onset patients should have Wilson's disease excluded by determination of 24-hour urine copper and serum ceruloplasmin and by slit lamp examination (Chapter 218). Findings on magnetic resonance imaging are generally normal in Parkinson's disease, but it is indicated to exclude other diagnoses (Table 416-4). Positron emission tomography, which can assess the presynaptic and postsynaptic sides of the nigrostriatal dopamine system, is useful for research, but the most common ligand, [^{18}F]fluorodopa, does not reliably distinguish Parkinson's disease from many other neurodegenerative diseases that mimic it. The same limitations apply to evaluation of the dopamine transporter by single-photon emission computed tomography. The finding of increased echogenicity in the SNc of the midbrain on transcranial ultrasound may be more specific in diagnosing Parkinson's disease, but the data are not conclusive.

For evidence-based recommendations on investigation of parkinsonism, see the article by Suchowersky and colleagues in Additional Suggested Readings.

TABLE 416-3 CLINICAL CLUES TO AN ALTERNATIVE (NON-PARKINSON'S DISEASE) CAUSE OF PARKINSONIAN SIGNS AND SYMPTOMS

Extraocular movements—e.g., nystagmus, limitation of vertical gaze, especially with slowing of downward saccadic eye movements (see Video 416-4)
Early and prominent dysarthria/dysphagia
Prominent or early abnormal neck postures: flexion or extension (see Video 416-8)
Ataxia—limb, gait (impaired tandem gait)
Lower body distribution with relative sparing of upper limb function
Early postural instability/falls/freezing (see Video 416-3)
Dysautonomia (early/prominent), prominent hypotensive response to dopaminergic medication
Pyramidal tract signs—very brisk reflexes, clonus, extensor plantar responses
Peripheral nerve dysfunction—loss of reflexes, distal sensory loss, weakness
Apraxia/cortical sensory changes
Early severe dementia
Poor response to levodopa

TREATMENT Rx

Treatment of Parkinson's disease is directed at slowing its progression ("neuroprotective" or "disease-modifying" treatments); improving symptoms, typically by restoring dopaminergic tone medically or by correcting basal ganglia neurophysiology surgically ("symptomatic"); or attempting to restore or regenerate the damaged neurons ("neurorestorative" or "neuroregenerative" therapy).

Medical Treatment

To date, no medical treatment (Table 425-5) has been proved to modify the progressive course of Parkinson's disease. The selective monoamine oxidase B (MAO-B) inhibitors selegiline and rasagiline[1] may exert disease-modifying effects, and the potential effects of agents such as coenzyme Q_{10}, creatine, the calcium-channel blocker isradipine, the pro-urate agent inosine, and the dopamine agonist pramipexole are currently under study.

Early treatment in a patient with little or no disability may entail only education, psychological support, encouragement to remain active and become involved in an exercise program, and ongoing follow-up. There is some evidence that early treatment, even when patients are only mildly symptomatic, may preserve quality of life. A treatment philosophy that still requires evidence-based support involves the early initiation of symptomatic therapy to bolster the brain's compensatory mechanisms that have begun to fail as the physical symptoms of parkinsonism become manifested.

When symptoms begin to interfere with function, mildly effective drugs such as an MAO-B inhibitor, amantadine, and anticholinergics (the latter predominantly for tremor in younger patients) may provide adequate benefit (see Table 425-5). When symptoms are more pronounced or inadequately controlled with these approaches, dopaminergic therapy should be introduced. In patients younger than 65 years who are cognitively intact and lack other major medical problems, initial therapy with a dopamine agonist may delay the development of motor complications.[2] However, these drugs result in more excessive sleepiness, leg edema, "impulse control disorders" (such as pathologic gambling, hypersexuality, binge eating, and shopping), and hallucinations than levodopa does. If a full dose of a dopamine agonist does not provide adequate clinical benefit or has intolerable side effects, levodopa should be initiated. In older patients, in those with cognitive dysfunction (more prone to hallucinations with dopamine agonists), and in circumstances that require more rapid improvement of pronounced disability, levodopa should be the initial drug used.

Alleviating Symptoms

Levodopa is the most effective treatment of Parkinson's disease, but it is associated with a variety of side effects (see Table 416-2). For the first year or

TABLE 416-4 DISEASES THAT MUST BE DISTINGUISHED FROM PARKINSON'S DISEASE

DIAGNOSIS	IMPORTANT DISTINGUISHING CLINICAL FEATURES	RESPONSE TO LEVODOPA/COMMENTS (INCLUDING IMAGING)
Multiple system atrophy (MSA) (includes striatonigral degeneration, sporadic olivopontocerebellar atrophy, and Shy-Drager syndrome)	Early dysautonomia (including orthostatic hypotension and sexual impotence) and bladder dysfunction (with autonomic and nonautonomic components) Cerebellar dysfunction	Good response initially evident in 20% and sustained partial response in ≈15% Dyskinesias or motor fluctuations possible; cranial dystonia may be prominent (see Video 416-7) Patient is wheelchair bound despite response to levodopa (early loss of postural reflexes, with or without ataxia) MRI (including diffusion-weighted imaging and gradient-echo sequences) often shows diagnostic changes in the striatum in MSA-P and "hot cross bun sign" in the pons and hyperintensity in middle cerebellar peduncles in MSA-C
MSA-P = a predominant parkinsonian manifestation	Pyramidal tract signs Stimulus-sensitive myoclonus of the hands and face	
MSA-C = a predominant cerebellar manifestation (mixed features are common)	Extreme forward neck flexion (anterocollis) Mottled, cold hands Inspiratory stridor (see Video 416-9) Prominent dysarthria	
Progressive supranuclear palsy	Supranuclear vertical ophthalmoplegia (see Video 416-4) Other oculomotor and eyelid disturbances (see Video 416-6) Axial rigidity greater than limb rigidity Early falls, speech and swallowing disturbances Nuchal extension Cognitive or behavioral changes Possibly a higher incidence of hypertension than in Parkinson's disease and other neurodegenerative causes of parkinsonism	Good response rarely evident; benefit only for classic parkinsonian features such as limb rigidity, bradykinesia, and rare examples of tremor at rest MRI often demonstrates profound midbrain atrophy ("hummingbird sign" on a midline sagittal view)
Corticobasal (cortical-basal ganglionic) degeneration	Apraxia, cortical sensory loss, alien-limb phenomenon (see Video 416-10) Pronounced asymmetrical rigidity Limb dystonia Stimulus-sensitive myoclonus (see Video 416-11) Aphasia (progressive nonfluent aphasia) Cognitive dysfunction (frontotemporal dementia)	Usually negligible MRI may show pronounced asymmetrical cortical atrophy
Vascular parkinsonism	"Lower-half" parkinsonism with gait disturbances predominating, often with minimal or much milder upper body involvement Additional neurologic deficits (e.g., pyramidal tract signs, pseudobulbar palsy)	Usually poor but some respond well Imaging demonstrates multiple infarcts involving the basal ganglia and subcortical white matter
Dementia with Lewy bodies	Early dementia (cognitive profile somewhat different from that of Alzheimer's disease) Spontaneous hallucinations, fluctuating cognitive status, falls, orthostatic hypotension, RBD Pronounced sensitivity to the extrapyramidal side effects of neuroleptic drugs Parkinsonism may be similar to typical Parkinson's disease, although rigidity may be more prominent than bradykinesia or tremor	Motor features may respond well; psychiatric side effects of dopaminergic drugs are typically dose limiting
Alzheimer's disease	Early dementia (memory loss, apraxia, aphasia) Tremor uncommon Spontaneous hallucinations less common than in dementia with Lewy bodies	Poor
Normal-pressure hydrocephalus	"Lower-half" parkinsonism ("gait apraxia") Urinary complaints (frequency, urgency, incontinence) Cognitive disturbances	Generally poor Imaging demonstrates ventriculomegaly out of proportion to cortical atrophy
Drug-induced parkinsonism	All the classic features of parkinsonism (tremor may be less common than in Parkinson's disease) Usually symmetrical signs and symptoms Other drug-induced movement disorders (e.g., tardive dyskinesia with neuroleptics)	Usually poor because of ongoing dopamine receptor blockade; may aggravate movements of tardive dyskinesia

MRI = magnetic resonance imaging; RBD = rapid eye movement sleep behavior disorder.
Adapted from Lang AE, Lozano AM. Parkinson's disease—first of two parts. *N Engl J Med.* 1998;339:1044-1053.

more the benefit of levodopa lasts throughout the day with little symptomatic variability. However, in time the duration of benefit declines, with worsening of symptoms the first thing in the morning (morning akinesia) and for a variable time before scheduled daytime doses (wearing-off/end-of-dose akinesia). Within 2 to 5 years of initiating treatment, up to 50% of patients may also experience involuntary movements (chorea, athetosis, dystonia), most often at the peak action of the medication. These complications, which are generally more prominent and occur earlier in patients with an onset of disease at a younger age, reflect the short half-life of levodopa combined with the underlying progressive loss of presynaptic dopamine neurons and result in nonphysiologic "pulsatile" stimulation of striatal dopamine receptors, which then induces "neuroplastic" changes in postsynaptic striatal neurons. Initially, these complications rarely cause major disability.

Although initiating therapy with a dopamine agonist rather than levodopa may be associated with a delay in the onset of these motor problems, the clinical benefit is generally less than with levodopa, and all patients eventually require the addition of levodopa to control symptoms. No data support delaying treatment with levodopa, and some data suggest that levodopa could have a neuroprotective effect. Even as Parkinson's disease progresses, most of the classic features continue to respond after 20 or more years of treatment.

TABLE 416-5 DRUGS FOR PARKINSON'S DISEASE

CLASS	DRUG	USUAL STARTING DOSE	USUAL FINAL DOSAGE	IMPORTANT ADVERSE EFFECTS	COMMENTS	INDICATIONS
Anticholinergic	Many (e.g., benztropine, trihexyphenidyl)	Benztropine or trihexyphenidyl, 1-2 mg 2-3 times per day	Varied	Peripheral effects, e.g., dry mouth, blurred vision, constipation, difficulty with urination Central effects, e.g., confusion, memory problems, hallucinations	Relatively contraindicated in the elderly and contraindicated in patients with cognitive disturbances	Early treatment of tremor
Miscellaneous	Amantadine	100 mg once per day	100 mg 2 or 3 times per day	Confusion, visual hallucinations; livedo reticularis, swelling of the ankles; dose reduction or drug withdrawal necessary in patients with renal failure	Previously considered a dopaminergic drug, now thought to act primarily through NMDA antagonist effects	Early treatment; later for dyskinesias
	Memantine	5 mg once daily	10 mg twice daily	Confusion, fatigue, dizziness, headache	NMDA antagonist	Possibly effective for cognitive dysfunction in PDD
Dopamine precursor	Levodopa given with peripheral dopa decarboxylase inhibitor (DDCI) (carbidopa [in 4:1 and 10:1 ratios] or benserazide [4:1]*)	50 (levodopa)/12.5 (DDCI) mg (4:1 preparation) 3 times per day (with meals to reduce nausea and vomiting)	Varied; begin with 3-times-daily schedule (controlled-release levodopa-carbidopa may be given twice daily at first); late in the disease patients may require multiple doses per day (sometimes > 2 g/day). Initially give with meals to reduce GI upset; later avoid meals to improve absorption and reliability of response	Peripheral and central dopaminergic side effects Peripheral: nausea, vomiting, and orthostatic hypotension Central: motor fluctuations, dyskinesias, psychiatric disturbances	Peripheral side effects often controlled by additional carbidopa or the peripheral dopamine receptor blocker domperidone* Controlled-release formulations often less bioavailable with less reliable absorption (more "dose failures" later on)	Formulations: immediate release—for early and later treatment Controlled-release (with carbidopa [4:1] or benserazide [4:1]*)—for predictable motor fluctuations (wearing off) and nighttime akinesia Stalevo (with carbidopa and entacapone)—for wearing off Parcopa (orally disintegrating tablets for faster absorption)—for patients with problematic long latency to benefit with individual doses Duodopa* (used with a pump for duodenal infusions)—for problematic motor fluctuations
Dopamine agonists Ergot derived	Bromocriptine	1.25 mg 3 times per day with meals	30-40 mg/day	Peripheral and central dopaminergic side effects; pedal edema, excessive daytime sleepiness Pleuropulmonary reaction, retroperitoneal fibrosis, erythromelalgia Impulse control disorders probably equally common with all dopamine agonists	Peripheral side effects often well controlled with domperidone* Rare pulmonary, retroperitoneal, and skin effects possibly caused by ergot derivation (drug withdrawal usually required)	Early and adjunctive therapy
	Pergolide	0.05 mg once per day × 2 days, increasing slowly thereafter	3-5 mg/day	As for bromocriptine; cardiac valvulopathy	As for bromocriptine	Not the first agonist because it causes restrictive cardiac valve disease
	Cabergoline*	0.5-1 mg once per day	2-6 mg/day	As for pergolide	As for pergolide Long half-life allows once-daily dosage	As for pergolide, although advantage of a long half-life may outweigh this concern
	Lisuride*	0.1-0.2 mg 1-3 times per day	2-5 mg/day	As for bromocriptine	As for bromocriptine	Uncertain whether cardiac valve abnormalities occur Parenteral formulations allow chronic infusion (pump) therapy

Non–ergot derived	Ropinirole	0.25 mg 3 times per day	Up to 24 mg/day in 3 divided doses Once daily extended/prolonged-release formulation available	Peripheral and central dopaminergic side effects similar to those of ergot-derived dopamine agonists, with the probable exceptions of pleuropulmonary reaction, retroperitoneal fibrosis, erythromelalgia, and cardiac valvulopathy	Effective as first-line and adjunctive therapy; dopamine D_3 agonist effects may contribute to efficacy	De novo therapy shown to be associated with less motor complications than with levodopa Implications of less progressive loss of dopamine terminal function on imaging uncertain
	Pramipexole	0.125 mg 3 times per day	Up to 4.5 mg/day in 3 divided doses Once daily extended/prolonged-release formulation available	As for ropinirole	As for ropinirole, possibly greater "D_3-preferring" effects—may account for antidepressant effect	As for ropinirole
	Rotigotine*	4.5 mg/day (10 cm^2)	Transdermal patch (4.5-27.0 mg/day; 10-60 cm^2)	As for ropinirole Additional adverse effects related to skin patch application (dermatitis)	May be effective for both first-line and adjunctive therapy	Limited availability because of problems with patch formulation
	Apomorphine	3-5 mg SC injection	Parenteral agent given as needed or as continuous infusion	Peripheral and central dopaminergic side effects Local skin reactions, including nodule formation	Concomitant antiemetic (e.g., domperidone,* trimethobenzamide) needed	Late-stage problematic motor fluctuations Long-term use of infusions may reduce dyskinesias, as well as motor fluctuations
Monoamine oxidase B inhibitors	Selegiline	5 mg once per day	5 mg 2 times per day	Dopaminergic effects of other drugs possibly accentuated, insomnia, confusion	Last dose given at midday to avoid insomnia	Early mild disease Some controversial evidence suggesting disease-modifying effects Predictable motor fluctuations (wearing off)
	Zydis selegiline	1.25 mg once per day	1.25 or 2.5 mg/day (wafer formulation)	As for selegiline	As for selegiline Absorbed from the buccal mucosa, thereby avoiding first-pass hepatic metabolism and methamphetamine metabolite of selegiline	As for selegiline
	Rasagiline	1 mg once per day	1-2 mg once per day	As for selegiline		Possible disease-modifying effects As for selegiline
Catechol *O*-methyltransferase (COMT) inhibitors	Tolcapone	100 mg 3 times per day	100 or 200 mg 3 times per day (at 6-hr intervals)	Effects of levodopa accentuated Diarrhea in approximately 5% of patients Hepatotoxicity	Dose of levodopa may have to be reduced by as much as 25%; diarrhea (sometimes explosive) typically forces discontinuation Ongoing monitoring of liver function tests required (second-line COMT inhibitor)	Motor fluctuations, especially wearing off (probably more effective than entacapone)
	Entacapone	200 mg with each dose of levodopa	200 mg 4-10 times per day (given with doses of levodopa)	Effects of levodopa accentuated	As for tolcapone; diarrhea possibly less frequent Liver function monitoring unnecessary	As for tolcapone Available in a combination tablet with levodopa/carbidopa (Stalevo)

TABLE 416-5 DRUGS FOR PARKINSON'S DISEASE—cont'd

CLASS	DRUG	USUAL STARTING DOSE	USUAL FINAL DOSAGE	IMPORTANT ADVERSE EFFECTS	COMMENTS	INDICATIONS
Atypical neuroleptics	Clozapine	12.5 mg hs	Wide range (6.25-150 mg/day), usually <75 mg/day	Agranulocytosis, sedation, hypotension, sialorrhea	Very low risk of worsening parkinsonism; agranulocytosis rare (<1%) and reversible if discovered early (requires regular monitoring of complete blood count)	Drug-induced psychosis Other "off-label" indications include drug-resistant tremor and possibly levodopa-induced dyskinesias Drug-induced psychosis
	Quetiapine	12.5-25 mg hs	25-150 mg/day	Sedation May worsen parkinsonism	Probably less effective than clozapine	
Acetylcholinesterase inhibitors	Donepezil	5 mg once per day	5-10 mg/day	Peripheral cholinergic side effects: nausea, vomiting, diarrhea Increased tremor, worsening of other Parkinson's features		Dementia Possibly effective for psychotic symptoms
	Rivastigmine	1.5 mg twice per day	3-12 mg/day	As for donepezil	Patch formulation available for transdermal administration—tolerability may be improved over oral formulation	As for donepezil

Practice parameter: treatment of Parkinson disease with motor fluctuations and dyskinesia (an evidence-based review): report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology*. 2006;66:983-995; and Miyasaki JM, Shannon K, Voon V, et al. Practice parameter: evaluation and treatment of depression, psychosis, and dementia in Parkinson disease (an evidence-based review): report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology*. 2006;66:996-1002.

It is not clear that delaying motor complications in the first 5 years of treatment by the initial use of a dopamine agonist improves long-term outcome or quality of life; indeed, clinical status, including the incidence of motor complications, may be no different after 10 years of treatment in those initiating therapy with a dopamine agonist and those starting with levodopa.[4]

There is no clear advantage to starting a controlled-release rather than an immediate-release preparation of levodopa or combining levodopa with a catechol *O*-methyltransferase [COMT] inhibitor. The motor fluctuations that develop during levodopa therapy are managed by a number of approaches (see Table 416-5), including increasing the frequency of the dose, using a controlled-release preparation, prolonging the action by blocking metabolism (MAO-B or COMT inhibition), or adding a dopamine agonist. For example, adding rasagiline or entacapone to levodopa provides significant incremental benefits. Dyskinesias improve when doses of dopaminergic medications are reduced, but the parkinsonism often increases to an intolerable level. Amantadine may improve the dyskinesias without worsening the parkinsonism.

Medical management of Parkinson's disease often includes a variety of other agents, for example, drugs directed at the treatment of orthostatic hypotension, depression (Chapter 404), anxiety (Chapter 404), urinary frequency and urgency (Chapters 25 and 125), and male erectile dysfunction (Chapter 242). Management of late-stage Parkinson's disease requires skill in polypharmacy and an understanding of the complicated benefit-risk ratios of the many drugs needed.

Surgical Treatment

Surgical therapy, which involves deep brain stimulation of the subthalamic nucleus, improves the symptoms of Parkinson's disease[5] and permits lower doses of antiparkinson medications to be used, whereas deep brain stimulation of the internal segment of the globus pallidus may provide a less consistent and durable response. Nevertheless, a randomized trial comparing these two approaches found no differences in outcome at 24 months.[6] Bilateral deep brain stimulation of the subthalamic nucleus or globus pallidus is more effective (71%) than medical therapy (32%); it also improves self-reported quality of life despite the adverse events associated with the procedure.[5,7] Thalamic deep brain stimulation is of limited utility because it is effective only for tremor. The best predictor of a good response to deep brain stimulation of the subthalamic nucleus is the patient's ongoing clinical response to levodopa. Apart from tremor, which may be resistant to the highest tolerable dose of levodopa, symptoms that are resistant to the peak effect of levodopa (e.g., dysarthria, postural instability with falls) also fail to respond to deep brain stimulation. The typical good candidate for deep brain stimulation of the subthalamic nucleus is an otherwise healthy, relatively young, cognitively intact, and psychiatrically stable patient who still responds well to levodopa but is suffering from disabling motor fluctuations and dyskinesias.

Double-blind randomized trials of transplantation of fetal substantia nigra into the striatum have not only failed to show significant efficacy but have also been associated with the side effect of transplant-induced off-medication dyskinesias. Postmortem assessments in a small number of patients surviving for more than 10 years following fetal transplants have shown Lewy bodies in the transplanted dopamine neurons, thus suggesting that the pathology can be "transmitted" to neurons placed in the diseased host. Double-blind randomized trials of bilateral intraputamenal infusion of glial-derived neurotrophic factor and gene therapy with AAV-neurturin failed to confirm the benefits found in unblinded studies.

PROGNOSIS

Parkinson's disease progresses inexorably over a period of many years; the speed and course of progression vary considerably from patient to patient. Some patients maintain an excellent response to treatment and seem to change very little over prolonged follow-up, but most note increasing disability, with the development of many symptoms that are poorly responsive to medications. Factors such as poor postural stability, falls, dysarthria, dysphagia, dysautonomia, excessive daytime sleepiness, and dementia contribute to the disability and increased mortality.

FUTURE DIRECTIONS

Gene therapies directed at either modifying neurotransmitter function or inducing neuroregeneration and other cell-based therapies are under development. Future treatments must also address the widespread, multisystemic nature of the disease, especially symptoms that are unrelated to nigrostriatal dopamine deficiency and that fail to respond to current therapies.

OTHER CAUSES OF PARKINSONISM

The numerous causes of parkinsonism (see Table 416-1) are sometimes termed "akinetic-rigid syndrome," "Parkinson's syndrome," "atypical parkinsonism," or even "Parkinson-plus syndrome" to emphasize that these patients commonly demonstrate additional clinical features indicative of the more widespread and particularly more severe pathologic involvement of areas beyond the dopaminergic SNc. These other parkinsonism conditions are generally associated with "postsynaptic" changes that result in a poor or unsustained response to levodopa, and this unresponsiveness serves as one of the most important of several clues that the parkinsonism features are caused by conditions other than Parkinson's disease (see Table 416-4) (i.e., "parkinsonism minus" a levodopa response; see Table 416-3).

417 OTHER MOVEMENT DISORDERS

ANTHONY E. LANG

DEFINITION

Movement disorders are first divided into hypokinetic and hyperkinetic categories. *Hypokinetic disorders,* which are characterized by akinesia, bradykinesia, and rigidity, are parkinsonian syndromes and are discussed elsewhere (Chapter 416). The common *hyperkinetic movement* disorders (Table 417-1) are defined by their specific clinical phenomena.

CLINICAL MANIFESTATIONS AND DIAGNOSTIC APPROACH

The traditional approach to a neurologic symptom is first to address localization within the nervous system (i.e., "Where is the lesion?"), followed by an evaluation of the origin ("What is the lesion?"). The neurologic examination is critical in determining the localization of the lesion, and generally the history, including the nature of onset and the progression of the symptoms, determines the most likely diagnosis. However, when a movement disorder is the predominant problem, the approach is somewhat different. The pathophysiology of most movement disorders is complex and often poorly understood. Many of these disorders are the result of dysfunction of different

TABLE 417-1 HYPERKINETIC MOVEMENT DISORDERS

Athetosis
Tics
Myoclonus
Startle
Stereotypies
Miscellaneous

circuits in the brain, and it is often impossible to ascertain a specific anatomic localization. Instead, an accurate appreciation of the clinical phenomena is the first important step in evaluating these patients. The clinician must observe and examine the patient to define the type of movement disorder that best describes the clinical picture. This accurate characterization then allows the generation of a differential diagnosis for the specific movement disorder. The age and nature of onset, the distribution, the progression of symptoms, a family history of similar or related symptoms, and the presence of systemic signs then help to determine the most likely explanation for that movement disorder.

TREMOR

Tremor, which is a rhythmic, sinusoidal movement of a body part, is caused by regular, either synchronous or alternating, contractions of reciprocally innervated muscles. Tremors are classified based on whether they occur at rest (weight fully supported against gravity) or in action. Resting tremors are typically seen in Parkinson's disease and other parkinsonism syndromes (see Table 416-1 in Chapter 416). Action tremors are further divided into postural, kinetic, or intention tremors. A *postural tremor* is seen with the maintenance of a posture against gravity (e.g., when the arms are outstretched in front of the body). A *kinetic tremor* is seen with a voluntary movement of the limb (e.g., a tremor in an upper limb when performing the finger-to-nose test). An *intention tremor* increases in amplitude on approaching a target.

CLINICAL MANIFESTATIONS

Most action tremors (Table 417-2) combine postural and kinetic components. All tremors worsen with stress, including performing an affected activity in public. Initially, a tremor may be evident only when one attempts fine, dextrous tasks such as threading a needle, soldering, or using a screwdriver. More severe tremors interfere with activities such as handwriting, fastening buttons, shaving, eating soup with a spoon, or drinking from a cup. Patients often adapt or use compensatory measures, such as switching an activity to a less affected hand (e.g., shaving with the nondominant hand), using two hands to drink, drinking only from an incompletely filled glass or cup, or completely avoiding more challenging feeding activities in public. Severe action and intention tremors can cause handwriting to become completely illegible and can result in dependence on others for care.

Head tremors, which may be side to side, up and down, or mixed, are rarely disabling but are often a source of embarrassment. Tremor of the larynx, which causes the voice to quaver, is best appreciated by asking the patient to sustain a note. Action tremor of the lower limbs is assessed by having the patient hold the foot up to a target (e.g., the examiner's hand) and then perform a heel-knee-shin test.

Most upper limb action tremors affect many activities to a similar extent. Less commonly, tremors can affect a single task in isolation (*task-specific tremors*), the most common being a primary writing tremor. *Orthostatic tremor* is apparent in the legs and in antigravity muscles only when the patient is standing in one spot and subsides during walking or leaning against a wall; these patients commonly complain of a tremendous sense of insecurity while standing and a fear of falling. Electrophysiologic assessment demonstrates a very characteristic high-frequency tremor (14 to 16 Hz).

Enhanced Physiologic Tremor

A 7- to 12-Hz tremor is found in everyone on electrophysiologic recording. This physiologic tremor is enhanced and may become symptomatic in a variety of circumstances, including fatigue, anxiety, and excitement. This same tremor may be accentuated by drugs and systemic processes.

Essential Tremor

Essential tremor affects up to 5% of the general population after the age of 60 years. Essential tremor is often inherited in an autosomal dominant fashion, with the phenotype showing genetic heterogeneity from at least three different genes, most recently *LINGO1*, as well as environmental influences. Recent pathology studies have demonstrated microscopic abnormalities of cerebellar Purkinje cells. The age of onset may be as early as the first or second decade of life, but senile tremor may be delayed until the mid-60s. Patients first become aware of a mild postural and action tremor in the hands, which is indistinguishable from an enhanced physiologic tremor and may result in little functional impairment for many years until it gradually interferes with

activities. Older patients with large-amplitude, lower-frequency tremors can have a resting component that is often misdiagnosed as Parkinson's disease (see Table 416-1 in Chapter 416). (Video 417-1).

TREATMENT

Rx

Treatment of essential tremor does not influence the course of the illness and therefore is justified only when the tremor interferes with function. At least 50% of patients note improvement or complete amelioration of tremor following the ingestion of a small amount of ethanol.

First-line drug treatment includes trials of a noncardioselective β-adrenergic blocker (e.g., propranolol, ≤320 mg/day) or primidone (starting in a low dose of 25 to 62.5 mg at night and increasing to 500 to 750 mg/day). Other drugs that have been shown to be effective in double-blind crossover trials include gabapentin (1200 to 1800 mg/day), topiramate (≤400 mg/day), and alprazolam (0.125 to 3 mg/day), but many patients remain resistant to all drugs. If disability is substantial, thalamic deep brain stimulation or thalamotomy can be of major benefit, but a few patients suffer permanent neurologic sequelae owing to intracranial hemorrhage or other postoperative complications.

CHOREA

Chorea (Table 417-3) consists of irregular, random, brief, flowing movements that often flit from one body part to another in an unpredictable and purposeless sequence. Patients may incorporate choreiform movements into a voluntary movement to mask them. The severity varies from the appearance of being slightly fidgety or restless, to striking, continuous movements involving the whole body. Many patients with chorea seem unaware of their movements, whereas others can be very troubled and disabled.

Huntington's Disease

DEFINITION AND EPIDEMIOLOGY

Huntington's disease is a fully penetrant autosomal dominant neurodegenerative disorder caused by an expanded trinucleotide (CAG) repeat in the gene for the protein *huntingtin.* The prevalence is approximately 10 per 100,000.

PATHOBIOLOGY

Huntington's disease is characterized neuropathologically by neuronal loss accompanied by intraneuronal inclusions and gliosis, especially in the caudate nucleus and putamen (the striatum) and the cerebral cortex. Understanding how these changes result from the expanded polyglutamine tract in the mutated huntingtin protein is the goal of current research.

CLINICAL MANIFESTATIONS

Symptoms typically begin between the ages of 30 and 55 years, but 5 to 10% of patients have an onset before the age of 20 years (juvenile Huntington's disease), and a few patients begin to have symptoms quite late in life. Symptoms include a combination of a movement disorder, psychiatric disturbances, and cognitive dysfunction. Early on, the movement disorder is predominantly chorea, but parkinsonism and dystonia develop later (Video 417-2). Some patients, especially those with juvenile onset, have a more rapidly progressive akinetic-rigid and dystonic form (the Westphal variant). Psychiatric manifestations, which are universal but widely variable, include personality changes, impulsiveness, aggressive behavior, depression, and paranoid psychosis. These psychiatric symptoms may precede the motor manifestations, and psychotropic drug therapy may be incorrectly blamed for the subsequent development of the movement disorder. Cognitive changes result in progressive "subcortical dementia" with disturbed attention, concentration, judgment, and problem-solving that differs from the typical "cortical dementia" of Alzheimer's disease. Oculomotor dysfunction, most often manifested by difficulties with refixating the gaze and a resulting tendency to use blinks and head thrusts, is another common feature.

DIAGNOSIS

The diagnosis is confirmed by genetic testing. Normal alleles of the *IT15* gene have fewer than 30 CAG repeats, whereas 40 or more repeats invariably result in clinical illness. An earlier age of onset correlates with larger numbers of CAG repeats.

TABLE 417-3 DIFFERENTIAL DIAGNOSIS OF CHOREA

GENETIC DISORDERS
Benign hereditary chorea
Huntington's disease
Huntington-like conditions
Neuroferritinopathy
Neuroacanthocytosis including McLeod's syndrome

TREATMENT AND PROGNOSIS

Rx

Current care for patients with Huntington's disease involves a multidisciplinary team of clinical geneticists, neurologists, psychiatrists, psychologists, social workers, occupational and physical therapists, speech therapists, nutritionists, and nurses. Genetic counseling for patients and family members is critical. Chorea may be extremely responsive to drugs that reduce central dopamine activity, especially tetrabenazine, starting at 12.5 mg two or three times daily and gradually increasing to up to 200 mg per day. Other potential agents include haloperidol (3 to 30 mg/day), pimozide (0.5 to 10 mg/day), fluphenazine (0.5 to 20 mg/day), and reserpine (0.75 to 5 mg/day). These agents should be reserved for patients with disabling chorea because they may be associated with increased parkinsonism, postural instability, depression, sedation, and other adverse effects. Unfortunately, physical function may not improve significantly even when the chorea is controlled. Psychiatric symptoms (e.g., anxiety, psychosis, depression) can be managed effectively with the same strategies as in other psychiatric diseases (Chapter 404). The disease progresses to institutionalization and death over the course of approximately 15 years.

TABLE 417-4 DIFFERENTIAL DIAGNOSIS OF BALLISM

Focal lesions in basal ganglia
Vascular: stroke (including infarction and hemorrhage), cavernous angioma, postsurgical complications
Neoplastic: metastases; primary central nervous system tumors
Infections: cryptococcosis; toxoplasmosis; tuberculoma
Inflammatory: multiple sclerosis
Iatrogenic: subthalamotomy; thalamotomy
Immunologic: systemic lupus erythematosus; scleroderma; Behçet's disease
Nonketotic hyperglycemia (high intensity lesions in striatum on T1 MRI)
Hypoglycemia
Sydenham's chorea
Head injury
Drugs
Anticonvulsants
Oral contraceptives
Levodopa

Other Choreas

Most of the non-neurodegenerative causes of chorea (see Table 417-3) can be excluded by a careful history (including a detailed drug history) and a focused set of investigations, including, in appropriate circumstances, wet preparation of peripheral blood for acanthocytes, immunologic studies (including anticardiolipin antibodies), endocrine assessment (hyperthyroidism, pregnancy), and neuroimaging. *Sydenham's chorea,* which is a late component of rheumatic fever (Chapter 298), is presumably the result of immunologic cross-reactivity between the causative group A β-hemolytic streptococcus and the basal ganglia. This disorder is infrequently seen in North America but is more common in developing countries. Sydenham's chorea usually affects children and young adults, and it is more common in girls before puberty. Adults with a past history of Sydenham's chorea in childhood may develop chorea during pregnancy or in response to taking oral contraceptive agents or estrogen preparations. Drugs that can cause chorea should be withdrawn if possible.

Ballism

Ballism, which is considered an extreme form of chorea, involves large-amplitude, random, often violent flinging movements of the proximal limbs (Table 417-4). It is most often a consequence of an acute cerebral insult, such as a stroke, and it usually involves one side of the body, particularly the arm, hence the term *hemiballism* (Video 417-3). When a causative lesion can be demonstrated, it typically involves the region of the subthalamic nucleus or the striatum. When the condition is caused by a stroke, movements usually subside spontaneously over days to weeks, although they may persist indefinitely in some patients. Treatment often requires the use of medication that antagonizes the effects of dopamine in the brain, including dopamine receptor blockers (neuroleptics such as haloperidol, 3 to 30 mg/day) or dopamine depleters (e.g., tetrabenazine, 50 to 200 mg/day). Functional neurosurgery (e.g., pallidotomy, deep brain stimulation) can be considered in patients with refractory, persistent symptoms.

DYSTONIA

DEFINITION AND PATHOBIOLOGY

In *dystonia,* sustained muscle contractions result in twisting and repetitive movements and abnormal postures. Dystonia can be classified according to its origin (Table 417-5). *Primary dystonia* includes syndromes in which the only phenotypic expressions are dystonia and tremor. These diseases can be hereditary or sporadic. *Dystonia-plus* is characterized by a combination of dystonia with other neurologic signs resulting from a known or presumed genetic defect without an underlying progressive neurodegenerative process; *dopa-responsive dystonia* and *myoclonus dystonia* are examples of such diseases. *Secondary dystonias* are the result of acquired injury to the central nervous system. *Heredodegenerative dystonias* include a large number of genetic as well as idiopathic neurodegenerative diseases.

CLINICAL MANIFESTATIONS

Common forms of dystonia include eyelid closure (blepharospasm), jaw opening or closing (oromandibular dystonia), pulling or turning of the neck in any one or combination of directions (cervical dystonia: rotatory torticollis, laterocollis, retrocollis, anterocollis), hyperadduction and less often excessive abduction of the vocal cords (laryngeal dystonia or spasmodic dysphonia), abnormal posturing and tightness of the hand while writing or using the hand for other tasks (writer's cramp, manual dystonia), abnormal posturing of the trunk or pelvis (axial dystonia), or abnormal posturing of the lower limb, including plantar flexion and inversion of the foot (Videos 417-4 through 417-7). The movements are often slow and sustained, although they may also be rapid (*dystonic spasms*). Slower, sinuous writhing dystonic movements, particularly present in the distal limbs, are referred to as *athetosis*. Dystonia is often made worse by activity (*action dystonia*), and a unique aspect of dystonia is that only selected acts may be affected, with complete sparing of all other activities in the same limb *(task-specific dystonia,* including *writer's cramp* and *musician's cramp)* (Video 417-8). In some patients, dystonia remains isolated and action specific over many years, whereas in others, it progresses to involve adjacent muscles (*overflow dystonia*) and may eventually be present at rest, in which case joint contractures may result. Another common feature of dystonia is its transient improvement with the use of a sensory trick (*geste antagoniste*), such as lightly touching the chin to relieve severe cervical dystonia or the lid to relieve disabling blepharospasm (Video 417-9). Patients with dystonia, independent of cause, often have additional postural and action tremors, phenotypically similar to essential tremor. Some patients also demonstrate more irregular, coarse, lower-frequency rhythmic movements called *dystonic tremor*.

Dystonia is often classified according to the site of involvement: focal, only one body part (e.g., blepharospasm, cervical dystonia, writer's cramp); segmental, two or more contiguous body parts; multifocal, two or more noncontiguous body parts; generalized, legs and other body areas; and hemidystonia, unilateral (generally a causative focal brain lesion is found most often involving the putamen).

DIAGNOSIS AND PROGNOSIS

For diagnostic and prognostic purposes, dystonia also may be distinguished by age of onset as childhood-onset, adolescent-onset, or adult-onset dystonia. The younger the age of onset, the more likely that a cause can be defined. Conversely, isolated dystonia beginning in adult life is most often an idiopathic disorder; further investigations are typically unrewarding and are usually not indicated. Likewise, independent of the cause, dystonia beginning in childhood commonly progresses to segmental or generalized involvement, whereas adult-onset dystonia usually remains focal or segmental.

Specific Dystonias

PRIMARY (IDIOPATHIC) DYSTONIAS

Primary dystonia accounts for up to 90% of patients with a pure dystonic syndrome. To date, no consistent neuropathologic changes have been found in the small numbers of brains affected by primary dystonia that have been studied.

When symptoms begin in *childhood,* a definable genetic cause is often identified, the most common being DYT1 resulting from the autosomal dominant inheritance of a GAG deletion in the *torsin A* gene (*Oppenheim's dystonia*). This disorder is more common in persons of Ashkenazi Jewish descent. The dystonia often begins in the first decade of life and can progress to severe disability, although the spectrum of disease, even within the same family, can be quite varied, and penetrance is relatively low (~40%) (Video 417-10). Genetic testing is available but is recommended only when the age of onset in the patient or another affected family member is less than 26 years. Increasing numbers of other genetic forms of primary dystonia, most recently *THAP1* for DYT6, are being defined, but genetic testing is not yet available for most of them.

ADULT-ONSET IDIOPATHIC DYSTONIA

Adult-onset idiopathic dystonia is the most common type of dystonia seen in general neurologic practice. The dystonia typically begins in the face, neck, or arm and may remain focal and nonprogressive or spread only to contiguous muscles after many years. The cause of this disorder is not known, although a positive family history may be noted if multiple family members can be examined.

DYSTONIA-PLUS

Dopa-responsive dystonia, which usually results in dystonia beginning in the first decade of life, most often in the lower limbs, sometimes can be mistaken for hereditary spastic paraplegia or cerebral palsy. Most patients with

dopa-responsive dystonia have a mutation in the *GCH1* gene, which results in reduced production of dopamine. Approximately 75% of patients have notable worsening of dystonia as the day progresses (*diurnal variation*). Exercise often aggravates the dystonia. Patients commonly demonstrate some degree of bradykinesia (especially in the legs) and postural instability. Rare adult-onset disease may result in a pure parkinsonian phenotype. Dopa-responsive dystonia should be considered in all children with dystonia. Symptoms are exquisitely sensitive to low doses of levodopa (typically as little as 50 mg/day of levodopa), and this treatment allows patients to live a normal life without the usual complications seen in Parkinson's disease (Chapter 416).

Myoclonus dystonia, which usually begins within the first decade of life, combines dystonia with separate multifocal myoclonic jerks. Myoclonus dystonia is genetically heterogeneous; the most common definable cause is a mutation in the *e-sarcoglycan* gene. The dystonia in these patients most often involves the neck or upper limbs, is mild, and is often overlooked. The disorder can also include psychopathology, such as obsessive-compulsive behavior. A characteristic feature of this disorder is the marked ameliorative effect of ethanol on both the myoclonus and the dystonia, a feature that sometimes results in alcohol abuse.

OTHER DYSTONIAS

Dystonia may be a symptom of many diseases. The nature and extent of the investigations undertaken depend on such factors as age of onset, clues provided on the history, and additional neurologic or systemic features on examination. *Wilson's disease* (Chapter 218) is an important consideration in the diagnosis of dystonia beginning in children and young adults.

Some patients with dystonia, chorea, or a mixture of the two ("choreoathetosis") have intermittent symptoms (*paroxysmal dyskinesias*) and may be normal between episodes. The duration of symptoms can be as brief as a few seconds to a few minutes or persist for several hours. Symptoms triggered by sudden movement, which are termed *kinesigenic*, are typically brief; prolonged episodes are commonly triggered by exercise, stress, fatigue, caffeine, or alcohol. These paroxysmal dyskinesias may be genetically determined, idiopathic, the manifestation of another disorder (e.g., head injury, brain tumor, or stroke), or even psychologically based.

TREATMENT

Rx

Ideally, treatment is directed at the underlying cause, such as dopa-responsive dystonia, which is treated with levodopa (usually up to 300 mg per day) or Wilson's disease (Chapter 218). Unfortunately, cause-specific treatment usually is not possible, so a variety of symptomatic treatments may be tried, often unsuccessfully, in an attempt to reduce disability.

Focal injections of botulinum toxin are now usually the first choice for treatment of focal and segmental dystonias. This approach can improve the condition of patients with cranial (blepharospasm, oromandibular dystonia) and cervical dystonia. Patients with task-specific limb dystonias (e.g., writer's cramp) often benefit less because weakness of the treated muscles, which is the most common side effect of this therapy, can impair other important upper limb functions.

Young patients in particular can tolerate and benefit from high doses of anticholinergic drugs such as trihexyphenidyl (6 to 40 mg/day, but sometimes as much as 100 mg/day). Muscle relaxants, including benzodiazepines (diazepam, 5 to as much as 100 mg/day) and baclofen (40 to 120 mg/day), may provide some benefit. Dopamine-depleting (e.g., tetrabenazine, 50 to 200 mg/

day) and dopamine-blocking (e.g., haloperidol, 3 to 30 mg/day) agents are occasionally helpful (more often effective in tardive dystonia than in other types). Neurosurgical treatments, particularly deep brain stimulation of the internal segment of the globus pallidus,[4] can be considered in medically refractory, disabling dystonia, especially in patients with idiopathic dystonia (e.g., DYT1, adult-onset cervical dystonia).

TICS

EPIDEMIOLOGY AND PATHOBIOLOGY

Tics are repetitive, stereotyped movements (motor tics) or vocalizations (vocal tics). Transient tics are extremely common in childhood, and simple tics may begin in childhood and persist throughout adult life. Most tics (Table 417-6) are primary or idiopathic and have no identifiable cause. Secondary tics are caused by a defined underlying brain disease or environmental factor.

CLINICAL MANIFESTATIONS

Tics vary in terms of complexity, from abrupt, brief, meaningless movements or sounds (*simple motor tics* such as eye blinking, nose wrinkling, or head jerking; *simple vocal-phonic tics* such as sniffing, throat clearing, or grunting) to more sustained, more deliberate, almost meaningful gestures or utterances (*complex motor tics* such as touching, hand shaking, and jumping; *complex vocal tics* such as echolalia [repeating others], palilalia [repeating oneself], and coprolalia [uttering profanities]). The frequency of the tics in an individual patient varies markedly over minutes, hours, days, weeks, and years.

Adapted from Cloutier M, Lang AE. Movement disorders: an overview. In: Factor SA, Lang AE, Weiner WJ, eds. *Drug Induced Movement Disorders*. Malden, Mass: Blackwell; 2005:3-19.

DIAGNOSIS

Various characteristics help to differentiate tics from other abnormal movements. Tics are often described by patients as being "semivoluntary" in response to an inner, irresistible urge. Premonitory sensory symptoms occasionally precede the tic, generally in the same general anatomic area as the tic itself. Relief is often associated with the production of the tic. Tics can be partially or completely voluntarily suppressed for variable periods, but often at the expense of mounting inner tension and psychological discomfort. Performing the tic or sometimes even substituting another more acceptable behavior for the socially inappropriate tic alleviates the tension. Many patients report that some tics occur in response to a typical urge, whereas the same or different tics may be unexpected and totally involuntary.

Tourette's Syndrome

EPIDEMIOLOGY AND PATHOBIOLOGY

The exact relationship between childhood tics and Gilles de la Tourette's syndrome remains uncertain. Tourette's syndrome is a common disorder, with prevalence estimates varying from 10 to 700 per 100,000. There is a male preponderance of 3:1 for the classic syndrome, but female patients manifest obsessive-compulsive features more often than tics. A functional mutation in the *HDC* gene encoding L-histidine decarboxylase can result in Tourette's syndrome, thereby suggesting a role for histaminic neurotransmission in its pathogenesis (Video 417-11).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The criteria for this disorder include the presence of multiple motor and at least one vocal tic beginning before the age of 21 years (typically between ages 2 and 10 years) and lasting for more than 1 year, waxing and waning symptoms over time (new tics replacing old ones; previous tics sometimes recurring years after they had originally resolved), and the absence of other explanatory medical conditions. Involuntary swearing (coprolalia), a highly publicized feature of the syndrome, is present in fewer than 10% of patients and is usually manifested by aborted forms such as "fu" and "shi." Patients commonly exhibit a variety of comorbid disorders including obsessive-compulsive disorder, attention-deficit disorder (with or without hyperactivity), impulse control problems, and other behavioral disturbances.

TREATMENT

Most patients who fulfill diagnostic criteria for Tourette's syndrome have mild symptoms that do not require treatment; education, reassurance, behavioral therapy,[5] and follow-up are often sufficient. When tics (isolated or as part of Tourette's syndrome) interfere with social and physical function, low-dose clonazepam (0.5 to 4 mg/day) may be effective. Clonidine (0.05 to 0.5 mg/day) is variably effective in controlling tics and may be useful for impulse control and symptoms of attention-deficit/hyperactivity disorder (ADHD); alternatively, guanfacine (0.5 to 4 mg/day) can be used. The most effective treatments for disabling tics are the dopamine receptor blockers such as risperidone (0.5 to 16 mg/day), haloperidol (0.5 to 20 mg/day), pimozide (0.5 to 10 mg/day), fluphenazine (0.5 to 20 mg/day), and aripiprazole (5 to 15 mg/day), but caution is required in view of the potential for important side effects, including tardive dyskinesia, with long-term use. An alternative without this complication is the dopamine depleter tetrabenazine (50 to 200 mg/day dopamine). Injected botulinum toxin may be effective for simple motor tics of the face and neck and may also reduce the urge to perform the tic. Comorbid ADHD can be treated safely with stimulant therapy (e.g., methylphenidate, 2.5 to 60 mg/day) without a significant risk for increasing the severity of tics. Obsessive-compulsive symptoms may respond well to selective serotonin reuptake inhibitors (e.g., clomipramine, 25 to 250 mg/day; paroxetine, 10 to 60 mg/day; or citalopram, 10 to 40 mg/day). Behavioral disorders, which remain a major therapeutic challenge, may require a variety of psychotherapeutic or behavioral modification approaches. Promising preliminary reports of deep brain stimulation require confirmation in controlled clinical trials.

PROGNOSIS

The natural history of Tourette's syndrome is to stabilize and often improve in adolescence. Approximately 50% of patients have a complete or partial remission at this time.

MYOCLONUS

DEFINITION

Myoclonus (or myoclonic jerks) consists of sudden, brief, shocklike, involuntary movements that result from both active muscle contraction (positive myoclonic jerks) and brief inhibition of ongoing muscle activity (negative myoclonic jerks). The most common form of negative myoclonic jerk is *asterixis.*

PATHOBIOLOGY

Myoclonus generally arises in the central nervous system, although rare peripheral causes are described, and it is distinct from abnormal muscle activity associated with peripheral nervous system diseases, such as fasciculations or myokymia. Myoclonus can be classified according to origin (Table 417-7), including physiologic, essential, epileptic, and symptomatic forms. Physiologic myoclonus, such as hypnic (sleep) jerks and hiccups, occurs in normal healthy subjects. Patients with essential myoclonus, which may be sporadic or inherited, often have additional postural tremor or dystonia, and this disorder is probably the same as what is now referred to as *myoclonus dystonia* (see Dystonias, earlier). Epileptic myoclonus arises in the context of seizures (Chapter 410), including many inherited generalized epileptic syndromes and the progressive myoclonic epilepsies. Symptomatic myoclonus occurs in association with a large number of encephalopathic states.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Myoclonic jerks are very short, typically lasting less then 150 milliseconds. Myoclonus can be spontaneous, action induced, or reflex (induced by various sensory stimuli), or a combination. Spontaneous myoclonus occurs at rest, without any provocation. Action myoclonus occurs during purposeful movement and is often very disabling owing to its interference with volitional activity. Reflex myoclonus can be triggered by visual, auditory, or somesthetic stimuli. The distribution of myoclonus may be focal, segmental, multifocal, or generalized. When myoclonus involves more than one body area, the movements may be synchronous or asynchronous. Myoclonus can be intermittent or repetitive, and it sometimes is rhythmic (e.g., usually originating in the brain stem or spinal cord). *Palatal myoclonus,* recently redesignated as *palatal tremor,* is a rhythmic movement disorder originating in the brain stem and involving the soft palate as well as the eyes, facial muscles, neck, and limbs; it is commonly the result of a focal lesion (e.g., stroke, demyelination) in the connections between the dentate nucleus of the cerebellum and the inferior olives of the medulla (*symptomatic palatal tremor*).

DIAGNOSIS

Myoclonus can be classified according to the anatomic site of origin, usually with the assistance of detailed electrophysiologic assessments. These sites may be cortical, subcortical (e.g., thalamus; lower brain stem [reticular myoclonus]), or spinal (two types: spinal segmental and propriospinal).

TREATMENT

Rx

Management of myoclonus, when possible, should be directed specifically at the underlying cause. Drug treatment includes a variety of anticonvulsant medications, most notably clonazepam (1.5 to 15 mg/day), valproic acid (10 to 15 mg/kg/day), carbamazepine (600 to 1200 mg/day), and levetiracetam (1000 to 4000 mg/day). Postanoxic action myoclonus (the Lance-Adams syndrome) in some patients who survive severe cerebral anoxia may also respond to 5-hydroxytryptophan (400 to 2800 mg/day) given with carbidopa (75 to 300 mg/day). Acetazolamide (250 to 1000 mg/day) may be useful for patients with action myoclonus.

HYPEREXPLEXIA

A disorder related to myoclonus, known as *hyperexplexia,* manifests as excessive response to startle. It may be inherited (startle disease, most often caused by a mutation in the α_1-subunit of the glycine receptor gene). Some patients demonstrate only generalized body jerking or an exaggerated startle response that habituates poorly after repeated stimuli. Others also experience disabling stiffness in response to sudden unexpected stimuli such as loud sound. The disorder responds well to clonazepam (1.5 to 15 mg/day) therapy.

OTHER MOVEMENT DISORDERS

Drug-Induced Movement Disorders

All the movements listed in Table 417-1 can be induced by medications. Neuroleptic drugs, which block postsynaptic dopamine receptors, particularly the D2 subtype, can result in a variety of movement disorder syndromes, including acute dystonic reactions, akathisia, drug-induced parkinsonism (including "the rabbit syndrome" with perinasal and perioral rest tremor), the neuroleptic malignant syndrome, and a variety of later-onset, often persistent, movements referred to as *tardive dyskinesia.*

ACUTE DYSTONIC REACTIONS

*Acute dystonic reaction*s are most often seen in young patients who are receiving potent antipsychotic agents (e.g., young male patients receiving high doses of haloperidol for acute psychosis), but they also occur in patients receiving dopamine receptor blockers, including metoclopramide as antiemetic therapy. Symptoms range from overt dystonic postures of the face and neck, to involuntary prolonged deviation of the eyes (oculogyric crises), to simple slurring of speech and difficulty coordinating the tongue. Symptoms often vary from moment to moment and can increase with anxiety and improve with relaxation or reassurance. Acute dystonic reactions are self-limited and respond rapidly to a parenteral injection of an anticholinergic drug such as benztropine (2 mg intravenously followed by 2 mg three times daily orally for a variable duration depending on neuroleptic use) or an antihistaminic such as diphenhydramine (50 mg intravenously followed by oral benztropine).

AKATHISIA

Akathisia refers to a sense of restlessness and a need to move. Typically, the patient performs a variety of purposeful or semipurposeful, often complex, movements in response to an uncomfortable subjective restlessness, including pacing when standing, marching in place, rocking, shifting weight, moving legs when sitting, picking at clothing or hair, rubbing body parts with hands, and other similar movements. Akathisia is most often a side effect of medications, especially neuroleptic drugs and selective serotonin reuptake inhibitors (Chapter 404). Symptoms occur in a dose-related fashion and usually resolve on drug withdrawal. Akathisia is a common reason for psychiatric patients to comply poorly with their medications; management includes adjustment of the dose or type of antipsychotic agent and trials of β-blockers (e.g., propranolol, 80 mg/day) or antiparkinson agents, such as anticholinergics (e.g., benztropine (6 mg/day) or amantadine (200 to 300 mg/day). Rare patients experience a very disabling and persistent form referred to as *tardive akathisia.* Akathisia is also sometimes seen in patients with Parkinson's disease.

NEUROLEPTIC MALIGNANT SYNDROME

The *neuroleptic malignant syndrome* (Chapters 440 and 442) is an uncommon but severe, sometimes fatal, complication of neuroleptic therapy. Patients usually manifest a combination of features including fever, marked rigidity, changes in level of arousal, and autonomic instability. Laboratory abnormalities include a marked increase in the serum creatine kinase level and the blood leukocyte count. Management involves early recognition, withdrawal of the causative agent, systemic supportive therapy, a dopamine agonist (most experience has been with the older agent bromocriptine, ≤60 mg/day), and, when necessary, dantrolene sodium (50 to 600 mg/day orally or ≤10 mg/kg/day intravenously) to reduce muscle contraction.

TARDIVE DYSKINESIA

EPIDEMIOLOGY AND PATHOBIOLOGY

The term *tardive dyskinesia* encompasses a wide variety of abnormal movements caused by chronic neuroleptic therapy. The cumulative 5-year incidence rate in patients taking classic neuroleptics is approximately 25%, and the incidence may continue to increase almost linearly beyond that point. The propensity to develop tardive dyskinesia on newer atypical neuroleptics appears to be much lower (Video 417-12).

CLINICAL MANIFESTATIONS

Tardive dyskinesia generally begins after a minimum of 6 weeks of treatment. One of the most common forms involves the lower facial muscles and has been given a variety of names, including *orobuccolinguomasticatory dyskinesia.* The movements generally include repetitive chewing and smacking movements with the tongue either protruding between the lips (fly-catching movements) or pushing into the cheek (bonbon sign). Although the movements are somewhat choreic, they are not as random as true chorea. The more stereotypical, repetitive nature of the movements, involving not only face but also the limbs (e.g., piano playing movements of the fingers, rocking or thrusting of the pelvis), has encouraged the more recent term *tardive stereotypies.* Many patients with classic orofacial tardive dyskinesia seem unaware of the presence of the movements and are not disabled by them, but others are embarrassed or otherwise impaired.

Tardive akathisia and tardive dystonia are less common but particularly disabling subtypes of tardive dyskinesia. Rarer forms include tardive tics (tourettism), tardive tremor, tardive myoclonus, and even tardive oral or genital pain.

TREATMENT AND PROGNOSIS

Rx

Treatment is often unsatisfactory, but the dopamine depleter tetrabenazine (50 to 200 mg/day) can be very effective. Prevention is the most important consideration. The physician must regularly reassess the need for ongoing neuroleptic therapy, consider switching to an atypical agent when possible (particularly quetiapine and clozapine; Chapter 404), and routinely evaluate the patient for the presence of early subtle clinical features, such as mild pursing of the lips or rolling movements of the tongue in the mouth. Unfortunately, tardive dyskinesia may persist for many years despite withdrawal of neuroleptic treatment in up to 50% of patients. Several atypical neuroleptics, such as risperidone and olanzapine, nevertheless block dopamine D2 receptors sufficiently to cause drug-induced parkinsonism and tardive dyskinesias.

Restless Legs Syndrome

EPIDEMIOLOGY

Restless legs syndrome (Chapter 412) is now recognized as an extremely common disorder affecting between 3 and 29% of the general population. Women are affected more frequently than men. Although the incidence increases with age, it can also affect children, in whom it may be confused with "growing pains" or ADHD.

PATHOBIOLOGY

Restless legs syndrome is most often primary or idiopathic, in which case it is frequently inherited in an autosomal dominant fashion. Five genetic loci associated with restless legs syndrome by recent genome-wide studies are variants in MEIS1, BTBD9, MAP2K5/LBXCOR1, and PTPRD. Restless legs syndrome also may be secondary to other causes, including peripheral neuropathy, uremia, pregnancy, and iron deficiency, and it may occur more commonly than by chance in some neurodegenerative disorders such as Parkinson's disease. The pathophysiology of restless legs syndrome is uncertain, but central iron dysregulation may somehow alter central dopamine. Serum ferritin levels are often low, even in the presence of normal values of hemoglobin, hematocrit, iron, and iron-binding capacity.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In restless legs syndrome, as in akathisia, movements occur because of the subjective need to move. However, unlike in akathisia, the patient typically complains of a variety of sensory disturbances in the legs, including pins and needles, creeping or crawling sensations, aching, itching, stabbing, heaviness, tension, burning, or coldness. Occasionally, similar symptoms are appreciated in the upper limbs. These symptoms are usually experienced during periods of prolonged inactivity, especially with recumbency in the evening, and are often associated with insomnia (Chapter 412). The discomfort appears particularly during the transition from wake to sleep in the evening and often follows a circadian pattern, peaking between midnight and 4 AM. Symptoms are typically relieved only by movement or stimulation of the legs; although these maneuvers are effective while they are being performed, the discomfort usually returns as soon as the individual becomes inactive or returns to bed to try to sleep. Patients often have significant problems with immobility during long automobile drives or plane flights.

In approximately 80% of patients, this condition is associated with another movement disorder, periodic leg movements in sleep, sometimes inappropriately called nocturnal myoclonus. These periodic, slow, sustained (1 to 2 seconds) movements range from synchronous or asynchronous dorsiflexion of the toes and feet to triple flexion of one or both legs. In 15% of patients, more rapid myoclonic movements or slower, prolonged dystonic-like movements of the feet and legs are present while patients are awake. In the absence of evidence of a secondary cause of restless legs syndrome, the only useful routine test is a serum ferritin level.

TREATMENT Rx

Dopamine agonists (e.g., pramipexole, 0.125 to 1.5 mg at bedtime) and ropinirole (1 to 4 mg at bedtime) are the treatments of choice in moderate to severe restless legs syndrome and can be very effective.■ Levodopa preparations (100 to 300 mg of levodopa at bedtime; consider controlled-release preparation) are also effective but are more often associated with disabling rebound symptoms early in the morning or during the day (*augmentation*). A new nondopaminergic agent, XP13512, is also effective, but is not yet approved in the United States.■ Patients with milder symptoms may respond to gabapentin (300 to 2400 mg/day). Opiate agonists (e.g., oxycodone, 5 mg at bedtime; codeine, 30 mg at bedtime; propoxyphene, 65 mg or N-100 mg at bedtime) and less often benzodiazepines (e.g., clonazepam, 0.5 to 2 mg at bedtime) may also be effective. Tolerance or loss of original benefit may occur with all these treatments. Iron replacement is indicated in patients with reduced serum ferritin levels (325 mg ferrous sulfate two to three times per day for 3 to 4 months until ferritin levels exceed 50 mg/L and iron saturations surpass 20%).

Painful Legs and Moving Toes

Another uncommon but well-defined movement disorder of the lower limbs has been termed *painful legs and moving toes.* Patients typically complain of a deep pulling or searing pain in the lower limbs, associated with continuous involuntary wriggling or writhing of the toes. Occasionally, the ankle and less commonly more proximal muscles of the legs are involved. Rarely, a similar problem is seen in the upper limbs as well. Various treatments have been tried without much benefit to the pain, which is typically the major concern of the patient.

Other Abnormal Movements

Numerous abnormal movements are caused by dysfunction of the peripheral nerves (e.g., fasciculations, myokymia); these movements are usually easily separated from the movement disorders described earlier. *Hemifacial spasm* is a common disorder in which irregular clonic and tonic movements involve the muscles innervated by the facial nerve, usually owing to compression of the seventh nerve as it exits the brain stem, most often by a normal small artery or vein and less often by a mass lesion or inflammatory process. Eyelid twitching is usually the first symptom, followed at variable intervals by lower facial muscle involvement. A magnetic resonance image with careful assessment of the posterior fossa is necessary to exclude secondary causes. Treatment usually involves injections of botulinum toxin into selected facial muscles, although surgical decompression can be curative (Video 417-13).

Hereditary Cerebellar Ataxias and Spastic Paraplegias

CEREBELLAR ATAXIAS

The hereditary cerebellar ataxias, which may begin in childhood or adulthood, can progress at widely varying rates. These ataxias are divided into early-onset ataxias, which are usually inherited as autosomal recessive disorders, and adult-onset ataxias, which are usually autosomal dominant. A small number are X-linked. Because most of these ataxias are untreatable, it is important to recognize the rare causes of treatable or preventable progressive ataxias.

Friedreich's Ataxia

EPIDEMIOLOGY AND PATHOBIOLOGY

The most common progressive inherited ataxia in children is Friedreich's ataxia. Friedreich's ataxia is a trinucleotide-repeat disorder that affects the central and peripheral nervous systems, the heart, and many other organs. Friedreich's ataxia is an autosomal recessive disorder with no anticipation. It has an estimated carrier frequency in the population of about 1 in 100 and a resulting disease prevalence of about 1 per 50,000.

The normal length of the GAA repeat on the long arm of chromosome 9 (9q13-q21) is 10 to 21 copies, but expansion in individuals with Friedreich's ataxia results in 200 to 900 copies and disrupts the expression of the protein frataxin. GAA unstable expansion, which occurs on an intron, leads to gene silencing rather than to the production of an abnormal protein. Higher numbers of copies correlate with more severe neurologic deficits. Frataxin appears to be critical for iron export and mitochondrial function. Because accumulation of mitochondrial iron affects the production of oxygen radicals, loss of frataxin may lead to oxidative mitochondrial damage. The pathology of Friedreich's ataxia includes spinal cord atrophy, which often is evident on magnetic resonance imaging, with loss of neurons in Clarke's columns and the dorsal root ganglia. Degeneration occurs in spinocerebellar tracts, pyramidal tracts, dorsal column tracts, and peripheral nerves, with minor cell loss in the brain stem and cerebellum. Cardiomyopathy is associated with ventricular hypertrophy and chronic interstitial myocardial fibrosis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Typical Friedreich's ataxia first presents clinically during puberty with progressive ataxia, loss of lower extremity deep tendon reflexes, and extensor plantar responses (i.e., Babinski's signs). Other common clinical features include nystagmus, dysarthria, stocking-glove sensory loss, and weakness in the lower extremities. Patients frequently have kyphosis, scoliosis, and pes cavus. Interstitial myocardial disease may cause a typical hypertrophic cardiomyopathy (Chapter 60). A small number of patients have a later onset and less severely progressive course.

The diagnosis is made by genetic testing for the trinucleotide repeat expansion, which usually is present on at least one allele. Point mutations are sometimes present in the other allele and are more difficult to detect. Potentially treatable conditions with similar clinical manifestations include vitamin B_{12} deficiency (Chapter 225), abetalipoproteinemia (Chapter 142), and a selective defect in vitamin E absorption (Chapter 225).

TREATMENT AND PROGNOSIS Rx

Treatment consists of supportive measures. A randomized trial using idebenone showed no benefit. The disorder is progressive, and patients usually are wheelchair bound by their mid-20s. The average age at death is 37 years, and the major cause of death is hypertrophic cardiomyopathy (Chapter 60).

Other Spinocerebellar Ataxias

The hereditary spinocerebellar ataxias are routinely classified by their specific molecular diagnosis. At least 10 autosomal recessive and nearly 30 autosomal dominant cerebellar ataxias have been identified. Clinical features, ethnic origin, and family history may suggest an autosomal recessive, autosomal dominant, or X-linked inheritance and often narrow the search for the genetic mutation. As the molecular pathogenesis of many of the hereditary ataxias is unraveled, the current numerical classification, which largely reflects the chronology of the identification of causative mutations, is likely to be replaced

by a more pathophysiologic approach. Spinocerebellar ataxias 1, 2, 3, 6, 7, and 17 are caused by trinucleotide expansions in or adjacent to a protein-coding region of a gene. These expansions result in polyglutamine expansions in the protein product, which likely results in a toxic gain of function in a manner analogous to the pathogenesis of Huntington's disease.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The predominant clinical features of the spinocerebellar ataxias are ataxia and dysarthria. Other cerebellar signs include titubation, dysdiadochokinesia, and dysmetria. With increasing ataxia, patients can become wheelchair bound. Additional clinical signs include ophthalmoplegia, dementia, optic atrophy, retinal pigmentary degeneration, deafness, dysphagia, and peripheral neuropathy. Extrapyramidal features include masked facies, cogwheel rigidity, dystonia, athetosis, and chorea. Levodopa-responsive parkinsonism (Chapter 416) may be seen in some patients, particularly in spinocerebellar ataxia 2 and spinocerebellar ataxia 3. Pyramidal dysfunction includes spastic limbs, especially legs; hyperreflexia; and Babinski's response. Diagnosis is based on genetic testing.

TREATMENT AND PROGNOSIS

Rx

No treatment is currently available. The spinocerebellar ataxias are progressive, with worsening gait, hand coordination, speech, and eye movements, but with preserved mental function. Pneumonia is a common cause of death.

HEREDITARY SPASTIC PARAPLEGIAS

Hereditary spastic paraplegia, also known as Strümpell's disease, can be an autosomal dominant disorder (70 to 80%), an autosomal recessive disorder, or an X-linked disorder. The prevalence of hereditary spastic paraplegia is about 1 per 10,000 in the population. At least 14 loci have been identified for autosomal dominant hereditary spastic paraplegias; 15 loci for autosomal recessive hereditary spastic paraplegias; and 3 loci for X-linked hereditary spastic paraplegias. The autosomal dominant spastic gait genes include *SPG4*, which encodes for spastin, and the less common *SPG3A* (atlastin) and *SPG31* (*REEP1*) genes.

At autopsy, patients with hereditary spastic paraplegia have axonal degeneration of the pyramidal tracts and dorsal column tracts with lesser involvement of the spinocerebellar tracts. The neurons of origin are intact. The peripheral nervous system is unaffected.

CLINICAL MANIFESTATIONS

Patients with hereditary spastic paraplegia have a progressive gait disturbance with spasticity of lower extremities, hyperreflexia, clonus, and extensor plantar responses. Cranial nerves, speech, swallowing, and upper extremities remain normal. Although patients can experience weakness of their lower extremities, spasticity is usually the disabling component. The progressively increased leg spasticity results in tripping and an inability to run. Strength is generally preserved, and pain is infrequent. Sensation is normal. Pure hereditary spastic paraplegia is limited to symptoms and signs of spasticity, whereas complex or complicated hereditary spastic paraplegia includes additional neurologic or other abnormalities. Other clinical features include pes cavus (30 to 50%), decreased vibratory sensation, and urinary frequency, urgency, and hesitancy.

DIAGNOSIS

Hereditary spastic paraplegia is diagnosed when patients meet clinical criteria and when other causes of spasticity are excluded. Magnetic resonance imaging may show spinal cord atrophy, but cerebrospinal fluid analysis and nerve conduction studies are normal. The differential diagnosis includes other genetic conditions, spinal cord disease from structural lesions, multiple sclerosis, and vitamin deficiencies or retroviral infections (Table 417-8). Even a positive family history does not obviate the need to exclude potentially treatable alternative diagnoses.

TREATMENT AND PROGNOSIS

Rx

No specific treatment is available. Symptomatic therapy is aimed at decreasing disability and preventing complications, such as contractures. Antispastic agents, such as oral baclofen (usually 10 to 20 mg three times daily), improve spasticity but should be used with caution because they may worsen weakness. Some reports suggested an improved therapeutic response to intrathecal baclofen, but no controlled trials have addressed this issue. Preliminary data also raise the possible utility of injected botulinum neurotoxin type A injections for improving spasticity. Most patients become nonambulatory between 60 and 70 years of age. Patients with complicated hereditary spastic paraplegia often have other disabling features.

TABLE 417-8 DIFFERENTIAL DIAGNOSIS OF HEREDITARY SPASTIC PARAPLEGIAS

Hereditary
Dopa-responsive dystonia
Spinocerebellar ataxias
Adult-onset adrenoleukodystrophy
Structural lesions of the spinal cord
Cervical spondylosis
Tumor
Arteriovenous malformation
Syringomyelia
Multiple sclerosis
Primary lateral sclerosis
Vitamin B_{12} deficiency
Copper deficiency
Infections
Human immunodeficiency virus
Human T-lymphotropic virus type 1
Tertiary syphilis

418 AMYOTROPHIC LATERAL SCLEROSIS AND OTHER MOTOR NEURON DISEASES

PAMELA J. SHAW

DEFINITION

The motor neuron diseases (Table 418-1) are a heterogeneous group of disorders in which selective loss of function of upper motor neurons, lower motor neurons, or both results in impairment of the nervous system's control of voluntary movement. The most common acquired motor neuron disease, amyotrophic lateral sclerosis (ALS), is a combined upper and lower motor neuron disorder. The features of lower motor neuron involvement are muscle wasting, fasciculations, and flaccid weakness, with normal or depressed tendon reflexes. Upper motor neuron dysfunction may cause increased muscle tone, clonus, weakness in the pyramidal distribution, and extensor plantar responses. Recent advances in the molecular genetics of hereditary motor neuron diseases have improved their classification and enhanced the careful diagnosis that is essential for genetic counseling, guidance, treatment, and advising patients about prognosis.

TABLE 418-1 CLASSIFICATION OF THE MAJOR MOTOR NEURON DISEASES

COMBINED UPPER AND LOWER MOTOR NEURON DISORDERS
Amyotrophic lateral sclerosis
Familial adult onset
Familial juvenile onset
Sporadic
ALS-plus syndromes
ALS with frontotemporal dementia
Western Pacific ALS–parkinsonism-dementia complex
UPPER MOTOR NEURON DISORDERS
Primary lateral sclerosis
Hereditary spastic paraplegias
Neurolathyrism
Konzo
LOWER MOTOR NEURON DISORDERS
Hereditary
Spinal muscular atrophies (SMAs)
Proximal autosomal recessive SMA (associated with *SMN* mutations) types I to IV
Other forms of SMA not associated with *SMN* mutations
Distal spinal muscular atrophies/hereditary motor neuronopathies
Kennedy's disease (X-linked spinobulbar neuronopathy)
Hexosaminidase deficiency (GM2 gangliosidosis)
Acquired
Monomelic focal and segmental spinal muscular atrophies
Multifocal motor neuropathies
Acute motor axonal neuropathy (AMAN)
Postpolio syndrome
Postirradiation syndrome
Infective disorders
Acute poliomyelitis
West Nile fever
Other viral infections, e.g., enterovirus 71 and rabies virus
Human immunodeficiency virus–associated motor neuron disorder
Lyme disease
Creutzfeldt-Jacob disease (amyotrophic forms)
DISORDERS OF THE BULBAR MOTOR SYSTEM
Kennedy's disease (X-linked bulbospinal neuronopathy)
Brown-Vialetto-Van Laere syndrome
Fazio-Londe disease
TOXIC DISORDERS OF THE MOTOR NEURON
Neurolathyrism
Konzo
Heavy metal toxicity (lead, mercury)
Western Pacific ALS–parkinsonism-dementia complex
Postirradiation motor neuron injury
DISORDERS OF MOTOR NEURON OVERACTIVITY
Neuromyotonia
Stiff person syndrome
MISCELLANEOUS MOTOR NEURON DISORDERS
Endocrinopathies, e.g., hyperthyroidism, hyperparathyroidism, hypoglycemia
Copper deficiency syndrome
Benign cramp-fasciculation syndrome

AMYOTROPHIC LATERAL SCLEROSIS

EPIDEMIOLOGY

ALS is a neurodegenerative disorder that causes progressive injury and cell death of lower motor neurons in the brain stem and spinal cord, as well as upper motor neurons in the motor cortex. ALS has an incidence of about 2 per 100,000 and a prevalence of 6 to 8 per 100,000. The global incidence is fairly uniform, with the exception of a few high-incidence foci such as the Western Pacific island of Guam. The disease affects predominantly middle-aged and elderly individuals, with a mean age at onset of 55 to 60 years, although younger individuals can also be affected. Increasing age, male sex (male-to-female ratio ≈1.6:1), and genetic susceptibility are the only proven risk factors, although ongoing research is assessing the effects of athleticism/physical exercise and other potential environmental risk factors. Approximately 90% of cases of ALS occur sporadically, but 5 to 10% are familial, usually with an autosomal dominant mode of inheritance.

PATHOBIOLOGY

The process of neuronal degeneration in ALS is complex. The subtype of disease caused by *SOD1* mutations accounts for 20% of familial ALS cases and 2% of ALS overall. Mutant *SOD1* appears to trigger a complex interplay of multiple pathogenic processes, including oxidative stress, protein aggregation, mitochondrial dysfunction, excitotoxicity, and impaired axonal transport. Non-neuronal cells in the vicinity of motor neurons may contribute importantly to neuronal injury. Genetically engineered mouse models of *SOD1*-related ALS have shown that normal astrocytes can protect motor neurons expressing mutant *SOD1* and that removing the expression of mutant *SOD1* from microglia or astrocytes has a significant effect in slowing the progression of disease in these murine models. Astrocytes expressing mutant *SOD1* exert toxic effects on neighboring motor neurons through as yet undefined mechanisms.

Familial motor neuron disease has been linked to mutations in *SOD1,* alsin, senataxin, angiogenin, VAPB, dynactin, TDP-43, and FUS/TLS, with a suggestion that defective RNA processing may play a key role in the pathogenesis of ALS. In the sporadic disease, associations have been reported with alterations in at least eight other genes.

Pathology

At autopsy, the gross pathologic features of ALS consist of atrophy of the cerebral precentral gyrus, as well as sclerosis and pallor of the corticospinal tracts of the spinal cord. Thinning of the hypoglossal nerves and ventral spinal roots may be observed, and muscle atrophy is obvious. Microscopically, ALS patients will typically have lost 50% of their spinal motor neurons and have diffuse astrocytic gliosis in the spinal gray matter. By comparison, motor neurons in Onuf's nucleus in the sacral spinal cord, which innervate the pelvic floor muscles, and the motor nuclei of cranial nerves III, IV, and VI, which control eye movements, are relatively preserved. A cardinal feature in residual motor neurons is the presence of ubiquitinated proteinaceous inclusions, which may be compact or skeinlike. TDP-43 has recently been recognized as a major protein constituent of these aggregates. In the motor cortex, there is variable loss of upper motor neurons and astrocytic gliosis. In the descending corticospinal tracts, axonal loss, myelin pallor, and gliosis are seen. The atrophied skeletal muscle shows clusters of angular atrophic fibers and fiber-type grouping, which results from serial denervation and reinnervation. The selectivity of the disease process for the motor system is now recognized to be relative, and involvement of extramotor parts of the central nervous system can be found, especially in the sensory and spinocerebellar

pathways, substantia nigra neurons, and dentate granule cells in the hippocampus.

CLINICAL MANIFESTATIONS

ALS is characterized by a combination of upper and lower motor neuron degeneration. Lower motor neuron degeneration causes weakness, atrophy, and fasciculation of the limb and bulbar musculature. Features of upper motor neuron dysfunction include the incongruous presence of active or brisk tendon reflexes in a wasted limb, increased muscle tone, and sometimes the presence of Babinski's sign. Upper motor neuron bulbar disease causes pseudobulbar palsy, with emotional lability, a brisk jaw jerk, slowing of repetitive tongue movements, and strained effortful speech. Fatigue and weight loss are also common symptoms. With end-stage disease, most patients will have features of upper and lower motor neuron dysfunction affecting all four limbs and the bulbar musculature.

In approximately 75% of patients, the disease starts distally, focally, and asymmetrically in the upper limb, lower limb (Video 418-1), or bulbar territories, followed by progressive spread of injury in an anatomically logical progression to contiguous groups of motor neurons. Affected individuals may notice weakness, wasting or clumsiness of one hand, or unilateral footdrop. Muscle cramps may precede other clinical features, and fasciculations are most noticeable in the large proximal limb muscles. In the upper limbs, the thenar and intrinsic hand muscles tend to be severely affected, whereas the triceps and finger flexors are relatively spared until late in the disease. In the lower limbs, the pattern of weakness is often in a pyramidal distribution (flexors weaker than extensors), with early weakness of hip flexion and ankle dorsiflexion and severe involvement of the distal muscles.

Bulbar symptoms, which are the initial feature in approximately 25% of patients, are especially common in elderly women with ALS (Video 418-2). The first problem is usually slurring of speech, initially apparent only when the individual is tired. Patients often have a mixed spastic/flaccid dysarthria, in which speech develops a tight, strangled quality because of the upper motor neuron component, with a superimposed nasal quality as a result of the flaccid lower motor neuron weakness of the palate and nasopharynx. In patients with bulbar disease, examination often reveals weakness of the facial muscles; a spastic, weak, wasted, and fasciculating tongue; and a brisk jaw jerk. Dysphagia, initially more pronounced for liquids than for solids, usually follows the dysarthria within a few weeks or months (Video 418-3). Complications include weight loss and prolonged and arduous meal times with frequent episodes of coughing, drooling of saliva, and aspiration pneumonia.

Respiratory muscle weakness is rarely the initial feature of ALS. More commonly, respiratory muscle weakness develops insidiously and causes dyspnea and orthopnea. Diaphragmatic weakness may be apparent from the paradoxical movement of the abdominal wall during inspiration and a marked decline in forced vital capacity in the supine position. Symptoms of nocturnal carbon dioxide retention may develop, including morning headaches, anorexia, and daytime somnolence.

Neck muscle weakness, which is common later in the course of disease, causes difficulty holding the head upright (dropped head syndrome). Eye movements tend to be spared even in advanced disease, thereby permitting limited communication by movements of the eyes. Similarly, the strength of the pelvic floor muscles is relatively preserved, so patients with ALS usually remain continent throughout the course of the disease.

Overt features of frontotemporal dementia (Chapter 409), with progressive deterioration in personality and behavior, will develop in approximately 5% of patients with ALS. Cognitive dysfunction may precede, follow, or coincide with the features of motor dysfunction. Up to 50% of ALS patients without overt dementia may show more subtle features of frontal lobe dysfunction.

About 5 to 10% of ALS patients have the progressive muscular atrophy variant with clinical features reflecting only degeneration of lower motor neuron groups in the spinal cord. In primary lateral sclerosis, patients have pure upper motor neuron degeneration. Although severe spastic spinobulbar paresis ultimately develops in these patients, the duration of survival is commonly 10 to 15 years after the onset of symptoms. The progressive bulbar palsy variant usually progresses to involve the limbs, although limb signs may not be present initially.

Several ALS variants follow a more segmental pattern than is typical in ALS. Up to 10% of patients with ALS have flail arm syndrome, which is more common in men and is associated with a longer median survival than seen in those with typical ALS. A similar focal manifestation in the lower limbs, flail leg syndrome, is another recognized variant.

TABLE 418-2 REVISED EL ESCORIAL DIAGNOSTIC CRITERIA FOR AMYOTROPHIC LATERAL SCLEROSIS

The diagnosis of ALS requires:
- [A:1] Evidence of LMN degeneration by clinical, electrophysiologic, or neuropathologic examination
- [A:2] Evidence of UMN degeneration by clinical examination and
- [A:3] Progressive spread of symptoms or signs within a region or to other regions, as determined by history or examination

Together with the absence of:
- [B:1] Electrophysiologic and pathologic evidence of another disease that might explain the signs of LMN and/or UMN degeneration and
- [B:2] Neuroimaging evidence of other disease processes that might explain the observed clinical and electrophysiologic signs

Levels of diagnostic certainty:

Definite ALS
- UMN signs and LMN signs in 3 regions

Probable ALS
- UMN signs and LMN signs in 2 regions with UMN signs rostral to LMN signs

Probable ALS—laboratory supported
- UMN signs in 1 or more regions *and* LMN signs defined by EMG in at least 2 regions

Possible ALS
- UMN signs and LMN signs in 1 region (together) or
- UMN signs in 2 or more regions
- UMN and LMN signs in 2 regions with *no* UMN signs rostral to LMN signs

UMN signs: clonus, Babinski's sign, absent abdominal reflexes, hypertonia, loss of dexterity.
LMN signs: atrophy, weakness. If only fasciculation, search with EMG for active denervation.
Regions reflect segmental motor neuron pools: bulbar, cervical, thoracic, and lumbosacral.
EMG = electromyography; LMN = lower motor neuron; UMN = upper motor neuron.

DIAGNOSIS

The diagnosis of ALS is essentially clinical, and there is no specific diagnostic test. Diagnosis requires evidence of *lower motor neuron degeneration* by clinical, electrophysiologic (Chapter 403), or neuropathologic examination; upper motor neuron degeneration by clinical examination; and progressive spread of symptoms or signs within a region or to other regions, as determined by the history or examination. The diagnosis also requires the absence of other disease processes as determined by electrophysiologic testing, neuroimaging, and if performed, biopsy. Generally accepted criteria (Table 418-2) classify patients as having definite, probable, or possible ALS. However, a number of other conditions may mimic ALS (Table 418-3), and about 8% of patients in whom ALS is initially diagnosed have other lower motor neuron syndromes such as multifocal motor neuropathy with conduction block, Kennedy's disease, or mixed spinal cord and root compression. Conversely, 10 to 15% of patients in whom ALS is ultimately diagnosed may first undergo inappropriate surgery for presumed spinal cord or root compression abnormalities.

Blood tests that may be helpful in distinguishing ALS from mimic syndromes (see Table 418-3) include a complete blood count and serum calcium level, thyroid function tests, serum protein electrophoresis, Venereal Disease Research Laboratory test, creatine kinase level, inflammatory markers (erythrocyte sedimentation rate and C-reactive protein), and levels of anti-GM1 ganglioside and anti–myelin-associated glycoprotein (MAG) antibodies. Further testing, which is guided by the patient's clinical findings, might include acetylcholine receptor antibody; mutation screening in patients with familial disease, suspected Kennedy's disease, or spinal muscular atrophy (SMA); heavy metal screening; urinary porphyrins; serum hexosaminidase A and B levels; *Borrelia* titers; and testing for human immunodeficiency virus.

Typical features of ALS on electromyography (EMG) include evidence of active denervation (i.e., positive sharp waves, fibrillation, and fasciculation potentials) and chronic denervation, as evidenced by large motor unit potentials that cannot be explained by a single nerve, root, or plexus lesion. Neuroimaging of the brain and spinal cord is often needed to exclude structural pathology.

Baseline respiratory function tests should be performed on all patients. Muscle biopsy is indicated only in rare or atypical cases, when diagnostic uncertainty persists.

TABLE 418-3 DISORDERS THAT CAN MIMIC AMYOTROPHIC LATERAL SCLEROSIS/MOTOR NEURON DISEASE

FORM OF MOTOR NEURON DISEASE	MIMIC SYNDROMES	CLINICAL CLUES
Progressive muscular atrophy (PMA)/LMN-predominant phenotype	Multifocal motor neuropathy	Weakness out of proportion to wasting. Neurophysiology identifies conduction block. Anti-GM1 antibodies may be raised
	Kennedy's disease	Gynecomastia, distal sensory features, perioral fasciculation, indolent progression
	Spinal muscular atrophy	SMA can be adult onset. Pure LMN syndrome. Slower progression than PMA. Probably no family history
	Chronic idiopathic demyelinating polyneuropathy	Electrophysiology identifies peripheral nerve demyelination
	Benign cramp-fasciculation syndrome	Predominantly middle-aged men. Largely calf involvement. Failure to progress. No active denervation on EMG
	Postpolio syndrome	Pure LMN syndrome. Past history of an illness compatible with poliomyelitis. Indolent progression
	Lead poisoning	Extramotor clinical features, e.g., constipation, nail and buccal signs
	Acute motor axonal neuropathy (AMAN—a Guillain-Barré syndrome variant)	Acute onset, with progression ceasing after a few weeks. Nerve conduction studies show features of motor axonopathy
	Hereditary motor neuropathies	Pure LMN syndrome. Family history, clinical signs indicating chronicity, slower rate of progression
	Porphyria	Extramotor clinical features, family history, episodic exacerbations
	Compressive focal motor neuropathies	Pure motor disorders can result from compression of the deep palmar branch of the ulnar nerve and posterior interosseous branch of the radial nerve. Failure to extend beyond territory of one nerve. Electrophysiology with or without imaging helpful
Amyotrophic lateral sclerosis	Multilevel spinal cord and root compression by discs, osteophytes, or tumor	Sensory symptoms and pain are common. UMN signs often caudal to LMN signs
	Thyrotoxicosis	Systemic symptoms and signs
	Combined peripheral neuropathy and cervical myelopathy	MRI of the spine and electrophysiology will differentiate
	Inclusion body myositis	Rarer than ALS. Characteristic pattern of weakness with early involvement of the long finger flexors and quadriceps
	Paraneoplastic syndromes, especially lymphoma	History of malignancy or systemic features
	Sjögren's syndrome	Non–motor-related symptoms
	Radiation myelopathy	History of radiotherapy
	Structural lesions of the bulbar region, e.g., tumor of the tongue base	Pain, failure of features to extend outside the bulbar territory
Primary lateral sclerosis	Hereditary spastic paraplegia	Family history. Symptoms rarely extend beyond the lower limb territory. Prominent bladder dysfunction
	Multiple sclerosis	Non–motor-related symptoms and signs, e.g., eye, bladder, cerebellar, and sensory involvement
	Spinal cord compression by disc or tumor	Pain and sensory involvement usually present

ALS = amyotrophic lateral sclerosis; EMG = electromyography; LMN = lower motor neuron; MRI = magnetic resonance imaging; SMA = spinal muscular atrophy; UMN = upper motor neuron.

TREATMENT AND PROGNOSIS

Rx

ALS is best managed in specialized centers that offer multidisciplinary care. Teams typically include a neurologist, nurse specialist, occupational therapist, physical therapist, speech and language therapist, and dietitian. During the course of the disease, patients frequently require referral for placement of a gastrostomy tube and to provide respiratory support.

No therapy currently has a dramatic effect in slowing the progression of ALS. Riluzole, which is a sodium-channel blocker whose primary mechanism of action is to reduce excitotoxicity through inhibition of presynaptic glutamate release, prolongs survival by approximately 3 months when given at 50 mg twice daily.■ It may cause fatigue, nausea, and dizziness, but these effects are frequently transient. Liver function tests should be performed at baseline and monthly for the first 3 months of therapy.

Management must focus on symptoms and preservation of independence and quality of life. In patients with progressive bulbar problems, optimal positioning, attention to food and fluid consistency, and protective swallowing techniques are helpful. If weight loss continues, high-calorie nutritional supplements are added between meals. Placement of a gastrostomy tube via endoscopy or under radiologic guidance is recommended in patients in whom dehydration, weight loss of 10 to 15%, frequent distressing choking episodes, prolonged and tiring mealtimes, or aspiration pneumonia develops. Tube placement is higher risk in patients with respiratory insufficiency. Tubes should ideally be placed before the patient's forced vital capacity falls below 50% of expected.

Respiratory muscle weakness, which can develop insidiously during the course of ALS, causes breathlessness, orthopnea, daytime somnolence, morning headaches, and interrupted sleep. Management must emphasize detection and prevention of aspiration pneumonia, assistance in clearing of secretions by providing a suction machine, use of a mucolytic agent such as carbocysteine (in a dose of up to 750 mg three times daily), adoption of a semiupright position for sleep, and aggressive antibiotic therapy for bronchitis (Chapter 96) or pneumonia (Chapter 97). A small dose of sublingual lorazepam (0.5 to 1 mg) may be useful if the dyspnea is accompanied by extreme anxiety; opiate therapy (such as morphine, diamorphine, or fentanyl; see Table 29-4) may be given orally, transdermally, or by subcutaneous infusion to relieve respiratory distress during the later stages of the disease.

As respiratory function worsens, noninvasive ventilation can alleviate symptoms of chronic hypoventilation, significantly improve quality of life, and prolong survival,■ especially in patients with orthopnea, daytime hypercapnia, and nocturnal oxygen desaturation. Full 24-hour ventilation via a tracheostomy is an option that is chosen uncommonly by fully informed patients. Palliative care teams and hospices can contribute substantially to the care of ALS patients in the later stages of the disease. In the absence of ventilatory support, ALS patients will almost always die in their sleep from hypercapnic coma. In the terminal phases (Chapter 3), the aim of treatment is to ensure comfort by prescribing opiates and anxiolytic medications as required to alleviate discomfort or distress.

PROGNOSIS

Clinical features associated with a worse prognosis include older age at onset of symptoms, early compromise of respiratory function, bulbar symptoms, and more rapid need for medical attention. The mean duration from the onset of symptoms to death in patients with sporadic ALS ranges from 27 to 43 months. The average 5-year survival rate is 25%, and approximately 5% of patients will survive for more than 10 years. The usual cause of death is respiratory failure, which may be accompanied by bronchopneumonia.

SPINAL MUSCULAR ATROPHIES

DEFINITION

The term *spinal muscular atrophy* encompasses a group of pure lower motor neuron disorders that cause progressive, symmetrical muscle weakness and

wasting. Because the bulbar musculature may be affected, an alternative term, "hereditary motor neuronopathy," has been proposed. The time of onset is variable and ranges from in utero to adult life.

EPIDEMIOLOGY AND PATHOBIOLOGY

The most common type of SMA is caused by mutations in the survival motor neuron (*SMN*) gene and is inherited as an autosomal recessive disorder. The estimated carrier frequency of an *SMN* mutation is 1 in 50. Type 1 SMA (Werdnig-Hoffmann disease) has an incidence of 1 in 8000 births. SMA is divided into subtypes I to IV according to age at onset and severity of the phenotype.

The human *SMN* gene on chromosome 5q13 exists in two forms with 5–base pair differences between *SMN1* and its centromeric homologue *SMN2*. A change in exon 7 of *SMN2* leads to skipping of exon 7, and as a result, 80% of the protein encoded by *SMN2* is truncated and nonfunctional rather than full length. The majority of patients with SMA have homozygous absence of *SMN1* exon 7, but *SMN1* may be replaced by a copy of *SMN2* during DNA replication by a process known as gene conversion. An individual may have one to four copies of *SMN2*, with a proportional increase in the amount of full-length SMN protein. A molecular basis for the wide variation in the phenotypic severity of SMA, which can range from in utero onset (SMA type I) to adult onset (SMA type IV), is the number of copies of *SMN2* and the SMN protein levels, although other disease-modifying factors have also been implicated.

The SMN protein oligomerizes and associates with other proteins to form the SMN complex, which in turn has an important role in the assembly of spliceosomal small nuclear ribonucleoproteins that have a function in pre-mRNA splicing in the nucleus. These cellular processes are ubiquitous, so either the clinical features of SMA may be caused by a particular susceptibility of lower motor neurons to defects in RNA processing or SMN may have functions that are specific to the motor neuron, including axonal transport of mRNA molecules essential for the health of the distal axon.

At autopsy, patients with SMA have atrophic spinal cords with loss of α-motor neurons and evidence of motor neuron degeneration and gliosis. The ventral roots are atrophic, and muscle atrophy is apparent with microscopic evidence of denervation and reinnervation.

CLINICAL MANIFESTATIONS

Type I SMA (Werdnig-Hoffman disease) is characterized by severe generalized muscle weakness and hypotonia at birth or by the age of 6 months; affected children never sit or walk. Type II is an intermediate form with an onset of muscle weakness before the age of 18 months; patients can sit but are never able to walk unaided. Type III SMA (Wohlfart-Kugelberg-Welander disease) appears after 18 months of age; patients acquire the ability to stand and walk but often become wheelchair dependent in adolescence or adult life, although life expectancy is normal. Patients with type IV SMA have an onset of muscle weakness in adult life.

DIAGNOSIS

The diagnosis of SMA caused by changes in *SMN* can be made by genetic testing in a patient with appropriate clinical signs and symptoms. Ninety-five percent of affected individuals have *SMN* deletions. Prenatal diagnosis is available. Electrophysiology and muscle biopsy reveal evidence of denervation.

Other disorders that may be manifested in infancy or childhood as hypotonia and a pattern of weakness similar to *SMN*-related SMA can be distinguished by associated clinical features, such as early respiratory distress or vocal cord paralysis or an atypical distribution of motor features, such as upper limb– or lower limb–predominant or scapuloperoneal involvement. The etiologic relationship of these disorders to classic SMA can be clarified by testing for *SMN* mutations.

It is important to distinguish SMA type I from infantile botulism, which can have a similar initial clinical picture. EMG with high-frequency repetitive nerve stimulation shows a decrement in botulism, and testing for the presence of botulinum toxin can confirm the diagnosis. SMA II and SMA III can be distinguished from chronic inflammatory demyelinating polyneuropathy (Chapter 428) by the presence of normal cerebrospinal fluid protein and normal nerve conduction studies in SMA. Patients with SMA III can have clinical features that are similar to those of the hereditary motor and sensory neuropathies, but it can be distinguished by neurophysiologic assessment and genetic testing.

TREATMENT AND PROGNOSIS

Rx

No disease-modifying treatment of SMA is currently available, although experimental approaches to upregulate expression of the SMN protein are being explored. In SMA II and SMA III, children may benefit from passive and active physical therapy, lightweight braces, surgical correction of scoliosis, and respiratory support measures.

Patients with type I SMA usually die by the age of 18 months, patients with type II typically survive into adolescence, and patients with type III and type IV have a normal life expectancy.

SPINOBULBAR MUSCULAR ATROPHY/ KENNEDY'S DISEASE

EPIDEMIOLOGY

Kennedy's disease, or spinobulbar muscular atrophy (SBMA), is an X-linked degenerative disorder of the lower motor neurons. Though rare, it is important not to miss the diagnosis because of the genetic implications for the family and a more benign course than occurs with ALS. The diagnosis should be considered in any male patient with a pure lower motor neuron disorder, particularly when the disease course is relatively indolent, gynecomastia is present, or there is evidence of a mild accompanying sensory neuropathy.

PATHOBIOLOGY

SBMA is a trinucleotide repeat disorder in which a CAG expansion encodes for a polyglutamine tract in the first exon of the androgen receptor gene on chromosome Xq11-12. The androgen receptor, which contains three functional domains, is transported to the nucleus, where it binds to DNA and acts as a transcription factor. Expansion of the polyglutamine tract results in reduced target gene transactivation, and neurodegeneration occurs when the polyglutamine tract reaches a critical length of approximately 40 repeats. The neurodegeneration in patients with SBMA is considered to result from a ligand-dependent, toxic gain of function of the mutant androgen receptor protein. Complete loss of its function, as seen in testicular feminization syndrome (Chapter 241), does not lead to motor neuron degeneration. The toxicity has not been fully characterized, but protein aggregation, impairment of protein degradation pathways, disruption of gene transcription, impairment of axonal transport, and neurotrophic factor signaling may all contribute.

Pathologic examination reveals mild spinal cord atrophy, with ventral horn gliosis and loss of α-motor neurons. Misfolding of the polyglutamine (Q)-expanded protein leads to the formation of nuclear inclusions that contain the amino-terminal epitopes of the mutant androgen receptor within motor neurons and certain non-neuronal tissues.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The mean age at onset of SBMA is 30 years, with a range of 15 to 60 years, and the severity of the disease and its age at onset correlate with the size of the repeat expansion. Initial symptoms consist of hand tremors, fasciculations, and muscle cramps, followed by progressive weakness and atrophy of the limb and bulbar muscles. Limb muscle weakness tends to be proximal and predominantly involves the lower limbs. There are no clinical signs of upper motor neuron dysfunction. Weakness of the lower facial and tongue muscles causes dysarthria, and jaw weakness may cause the mouth to hang open. The presence of perioral fasciculations with quivering of the chin is a characteristic feature. Pharyngeal involvement can cause dysphagia, and respiratory muscle weakness causes breathlessness. Mild distal sensory loss is frequently present in the lower limbs. Features of mild androgen insensitivity with gynecomastia, testicular atrophy, and erectile dysfunction will often be apparent. Heterozygous female carriers of SBMA may show mild clinical manifestations of the disease.

EMG and muscle biopsy, which are often performed because the creatine kinase level tends to be elevated, reveal evidence of chronic denervation. Genetic screening for the CAG repeat expansion in exon 1 of the androgen receptor gene is diagnostic.

TREATMENT AND PROGNOSIS

Rx

Current therapy consists of supportive care. The course of the disease is slowly progressive in comparison to ALS and is compatible with normal life expectancy, although a proportion of patients may die of respiratory failure. Patients may become wheelchair dependent over a period of 2 to 3 decades, but some remain ambulatory until late in life.

MULTIPLE SCLEROSIS AND DEMYELINATING CONDITIONS OF THE CENTRAL NERVOUS SYSTEM

PETER A. CALABRESI

The disorders of myelin encompass a wide range of diseases in which either myelin is not formed in a normal fashion (dysmyelinating disease) or normally formed myelin is destroyed or not maintained appropriately (demyelinating disease) (Table 419-1). Dysmyelinating diseases are uncommon and include an array of leukodystrophies that have a genetic basis. Demyelinating diseases are much more common and include multiple sclerosis (MS), which represents more than 95% of all types of disorders of central nervous system (CNS) myelin.

Some disorders of myelin actually have a distinct pathogenesis in which the disruption of myelin is secondary. Further, in many of the diseases of myelin, the axon degenerates as a result of loss of trophic support from loss of myelin or because of increased susceptibility to injury in the absence of myelin. This observation has led to the recent hypothesis that axonal loss is the underlying substrate for permanent disability in MS, adrenoleukodystrophy, and perhaps other diseases of myelin.

MULTIPLE SCLEROSIS

DEFINITION

MS is a disease characterized by multifocal areas of demyelination in the brain and spinal cord, with associated inflammatory cell infiltrates, reactive gliosis, and axonal degeneration. It typically presents in young adults with episodic neurologic dysfunction. Although the exact origin of MS remains enigmatic, evidence suggests that it is an immune-mediated attack on myelin, with secondary disruption of axons leading to progressive disability over time in most afflicted patients.

EPIDEMIOLOGY

The annual incidence of MS varies by location and ranges between 1.5 and 11 per 100,000 people. MS is second only to trauma as the most common cause of neurologic disability in young adults. More recent studies suggest that the incidence rate has increased, in part because of better recognition of more cases at an earlier stage. The prevalence is estimated at 350,000 to 400,000 in the United States and more than 1,000,000 worldwide, but these numbers may be underestimates owing to incomplete recognition of the disease even in developed countries.

MS occurs 2- to 2.5-fold more frequently in women than in men, a sex predilection that is common in autoimmune diseases. The disease most often presents in the third to fourth decades of life, but with an incidence age range from postpubertal teenagers to persons in their 50s. Rare cases occur in infants or in patients in their 60s, but extreme caution is warranted in these situations to exclude alternative processes. In many of the late-onset cases, symptoms were present in younger years and were attributed to other causes.

MS is most common in people of Northern European descent, and whites acquire multiple sclerosis at nearly twice the rate of African Americans in the United States. In many areas of the world, MS is more prevalent in temperate latitudes (approaching 1 in 500 in some locations) and becomes less common toward the equator (1 in 20,000 or rare case reports only in some locations), perhaps explained, in part, by migration patterns of people with the same gene pools. However, the absence of complete genetic penetrance in monozygotic twin studies suggests an environmental component to the disease. Indeed, an outbreak of MS was documented on the Faroe Islands following World War II, and numerous other clusters have been reported, although an environmental trigger has not been identified.

Several studies have linked cigarette smoking with risk for MS. High levels of vitamin D and early exposure to excessive sunlight (sunburns) have been linked with lower risk for MS, possibly related to the beneficial effects of cholecalciferol on regulating immune cell responses.

PATHOBIOLOGY AND GENETICS

Monozygotic twins with MS show a concordance rate of between 15 and 50%, compared with only 3 to 5% concordance in dizygotic twins, consistent with a strong but incomplete role for genes in causing MS. The lifetime risk for MS is increased to 2 to 4% in individuals with a first-degree relative with

MS, compared with the general population risk of 0.1%. In addition, between 10 and 20% of patients with MS have a first-degree relative with another autoimmune disease, commonly rheumatoid arthritis, systemic lupus erythematosus, or autoimmune thyroid disease. Hashimoto's disease and Crohn's disease also may be more common in patients with MS. Genetic modeling of the disease strongly argues against a single MS gene and suggests that many different genes predispose to MS and account for its many phenotypes. Linkage and association studies have identified the human leukocyte antigen (HLA) or major histocompatibility complex (MHC) region on chromosome 6 as one genetic determinant for MS. The MHC class II region, involved in presentation of antigen to $CD4^+$ T cells, is the most strongly associated locus. The HLA-DR2 allele and, more specifically, the molecular haplotype HLA-DRB*1501 allele have repeatedly been implicated. Two single nucleotide polymorphisms in the interleukin-2 (IL-2) receptor α gene and the IL-7 receptor gene also appear to be associated with a higher risk for MS. Other loci of interest on other chromosomes, including chromosome 1, continue to be investigated, but the associations appear less strong.

Pathology

Pathologically, most cases are characterized by multifocal areas of demyelination and gross gliotic scar in the brain and spinal cord. Classic locations of these lesions, called *plaques,* are the optic nerves, periventricular white matter, deep white matter, juxtacortical white matter, corpus callosum, cerebellar peduncles, and dorsolateral spinal cord. However, there may be a bias toward recognition of lesions in white matter because of the relative ease of detecting demyelination and inflammation in white compared with gray matter. Indeed, more recent pathologic studies have confirmed demyelination, neuritic damage, and atrophy in the cortex and deep gray matter. At the microscopic level, one usually sees multiple areas of perivenular inflammatory cell infiltrates with extravasation into the surrounding tissue parenchyma. In the acute active plaque, CD4 helper T (T_H) cells are prominent in the perivenular areas. Proinflammatory cytokines released from T_H1 (interferon-γ [IFN-γ]) and T_H17 (IL-17) cells are thought to mediate damage. Increasingly large numbers of CD8 cytotoxic T cells have been documented in brain tissue, especially in the parenchyma, and these cells may mediate direct damage to axons through release of proteases such as granzyme B. Most parenchymal inflammatory cells are $CD68^+$ macrophages and microglia. In addition to the influx of circulating immune cells, prominent astroglial activation and even oligodendrocyte precursor cell proliferation occur in response to injury. Over time, the inflammation becomes less prominent in the center of the plaque, but a chronic active rim of inflammation with microglial activation exists at a well-demarcated border between abnormal and normal unharmed myelin. This characteristic of MS is seldom seen in other disorders of myelin. Although oligodendrocytes may survive, proliferate, and result in partial remyelination (shadow plaques) in some early cases, this process is hardly ever complete in MS. Over time, remyelination is less successful, and oligodendrocyte progenitor cells appear unable to differentiate into mature myelinating oligodendrocytes.

The number of damaged axons correlates with the extent of inflammation. Further, axonal damage and even neuronal apoptosis are seen in the cortex. Atrophy of both the brain and spinal cord, which occurs more rapidly in MS than in normal aging, reflects loss of both myelin and axons.

No consistent microbial cause has been discerned from careful examination of MS tissues for known infectious pathogens. Differential expression of human herpesvirus type 6, which is acquired by most people in childhood, has been noted in oligodendrocytes of patients with MS, but whether this virus is a cofactor in demyelination or just a bystander remains unclear. Evidence suggests the possibility that the earliest event in MS may be an insult to the oligodendrocytes, with subsequent activation of resident immune cells and secondary recruitment of other immune cells only at later stages.

Some pathologists believe that four distinct subtypes of MS can be discerned, in which the pathologic characteristics are consistent in every lesion, thereby allowing classification of patients with differing pathologic categories rather than just describing evolution of lesions over time. Type I lesions are characterized by typical perivenular inflammatory infiltrates consisting mainly of T cells, with early preservation of oligodendrocytes. Type II lesions are similar to type I but have an additional humoral component with immunoglobulin G (IgG) deposition and complement activation. Type III lesions are distinguished by not being based around venules and by prominent loss of myelin-associated glycoprotein, with evidence for oligodendrocyte apoptosis. Type IV lesions have inflammatory infiltrates more similar to types I and II but also have oligodendrocyte loss as in type III. These varying pathologic features may begin to explain clinical subtypes of the disease.

TABLE 419-2 CONDITIONS THAT CAN BE MISTAKEN FOR MULTIPLE SCLEROSIS AND OTHER DISEASES OF MYELIN

VASCULAR DISEASE
Small-vessel cerebrovascular disease
Vasculitides
Arteriovenous malformation
CADASIL
Antiphospholipid antibody syndrome
STRUCTURAL LESIONS
Craniocervical junction, posterior fossa, or spinal tumors
Cervical spondylosis or disc herniation
Chiari malformation or syrinx
DEGENERATIVE DISEASES
Hereditary myelopathy
Spinocerebellar degeneration
INFECTIONS
HTLV-1 infection
HIV myelopathy or HIV-related cerebritis
Neuroborreliosis (e.g., Lyme disease)
JC virus/progressive multifocal leukoencephalopathy
Neurosyphilis
OTHER INFLAMMATORY CONDITIONS
Systemic lupus erythematosus
Sjögren's syndrome
Sarcoidosis
MONOFOCAL OR MONOPHASIC DEMYELINATING SYNDROMES
Transverse myelitis
Optic neuritis
Neuromyelitis optica/Devic's disease
Acute disseminated encephalomyelitis
OTHER CONDITIONS
Hashimoto's thyroiditis with or without encephalopathy
Nonspecific MRI abnormalities related to migraine, aging, or trauma

CADASIL = cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; HIV = human immunodeficiency virus; HTLV = human T-cell lymphotropic virus; MRI = magnetic resonance imaging.

Pathogenesis

It remains possible that the autoimmune hypothesis is wrong and that the inflammation observed in MS is secondary to an as yet uncharacterized primary degenerative process. Proponents of this theory cite evidence from pathologic features of hyperacute cases, in which the oligodendrocytes appear to die before any systemic immune response occurs, as well as recent data revealing neuronal and axonal death or demyelination in the absence of inflammation.

Macrophages and microglia, which make up the majority of cells within the parenchymal infiltrate in chronic MS plaques, are potent antigen-presenting cells and express HLA and costimulatory molecules. Activated macrophages and microglia also have effector functions, including release of cytokines that are partly (IL-6, tumor necrosis factor-α) or completely distinct from the T cells (IL-1β, IL-12, and IL-23). In high concentrations, these cytokines may damage oligodendrocytes and neurons and activate T cells.

CLINICAL MANIFESTATIONS

Presenting Symptoms

MS, which can present in many ways across a broad age range, may initially masquerade as a variety of different illnesses (Table 419-2; see Table 419-1). In a classic presentation, a young white person, more often a woman, will have the acute to subacute onset of impaired vision or sensation. Fatigue, depression, bladder urgency, weakness, impaired balance, and impaired coordination are also common symptoms. The often remarkably mild nature of the first symptoms often dissuades the patient from seeking medical attention

or is insufficiently impressive to stimulate the physician to order diagnostic tests. Furthermore, patients may initially have few objective neurologic findings, especially between attacks.

Paresthesias of a limb that are circumferential and do not follow a dermatome suggest a spinal cord lesion; these symptoms often manifest distally and then ascend to involve more proximal parts of the limb, spread to the contralateral limb, or progress from a leg to an arm. Similarly, bandlike sensations around a limb or the torso also suggest a myelopathic process.

Incomplete transverse myelitis is a focal (partial) spinal cord syndrome that is usually inflammatory and does not follow vascular territories. It is a common presentation of MS.

Lhermitte's symptom, an electrical sensation moving down the spine into the limbs on flexion of the neck, is characteristic of cervical myelitis from any cause, including MS. Frank loss of sensation is less common as an early symptom or sign but is seen in more advanced cases. Burning, electrical, or deep aching sensations are also common in MS.

Sensory Abnormalities

On examination, the most common sensory findings are loss of vibration perception, most prominent in the feet, and incomplete spinal cord levels to pin prick or vibration, which are often more notable in a graded fashion rather than at a distinct level. Such sensory levels may be asymmetrical and differ by sensory modality because of isolated demyelination in the dorsal columns compared with the spinothalamic tracts. Patchy or seemingly nonanatomic focal areas of impaired sensation can occur, and some patients describe bizarre sensations such as water dripping or bugs crawling on an area of the body.

Visual Effects

Optic neuritis (Chapter 432) is a classic presenting syndrome, typically with visual symptoms in one eye. In optic neuritis, patients often complain of pain over the lateral eyebrow and worsening on lateral eye movement. The visual impairment may be described as looking through frosted glass or a veil. The scotoma or area of greatest loss can often be mapped in a centrocecal distribution (central focal point to the blind spot laterally), which in mild cases may be evident only as desaturation to red color using the head of a pin. More severe cases may result in total loss of light perception. In most acute cases of optic neuritis, the inflammation is retrobulbar (behind the disc), so no immediate changes are visible on the optic disc, thereby leading to the aphorism "the patient sees nothing, and the doctor sees nothing." However, there should be a relative afferent papillary defect (Marcus-Gunn pupil; Chapter 432) with paradoxical dilation of the affected eye to direct light on swinging a flashlight from the unaffected eye in which consensual constriction was induced. In cases of bilateral optic neuritis (new or old), this abnormality may not be seen. Patients usually spontaneously recover substantial vision after weeks to months. Later, the optic disc may become pale, especially in the temporal region, a finding reflecting damage to the axons following inflammation and demyelination, even with recovery of normal visual acuity. Patients often have more subtle chronic visual impairment for colors, low contrast visual acuity, and contrast sensitivity. Visual testing using low contrast letter acuity charts commonly reveals substantial visual loss after clinical optic neuritis.

Visual impairment from impaired tracking of eye movements owing to brain stem or cerebellar disease most commonly occurs in the setting of an acute lesion affecting the medial longitudinal fasciculus, which is the neurologic pathway that yokes the eyes together on lateral saccades. Patients may experience frank diplopia or just blurred vision, especially when they look off to one side rapidly, such as when looking over one's shoulder while driving. The neurologic sign of this problem is called *internuclear ophthalmoplegia* (Chapter 432) and manifests as slowed or absent adduction of one eye with abducting nystagmus of the other eye. It may occur bilaterally or may exist in milder forms, such that the adduction lag is imperceptible to the human observer. Blurred vision from cerebellar damage with nystagmus is very common in MS and is often worse on extreme lateral or vertical gaze. *Oscillopsia,* the sensation that the environment is moving when it actually is not, is another symptom of impaired cerebellar coordination of the eyes. Saccadic eye movement or loss of smooth pursuit is also common in MS and also can be seen in numerous neurologic conditions or with aging.

Motor Symptoms

The most common motor symptoms of MS are weakness and impaired coordination in a leg, with ascending involvement from distal to proximal and commonly spreading to the contralateral leg or ipsilateral arm. The lesion causing these symptoms is more commonly in the cervical spinal cord rather than the thoracic spinal cord, even when the first sign is partial footdrop. It is likely that axons that must conduct impulses over the longest distance (entire length of the spinal cord) from a site of inflammatory demyelination will become symptomatic before axons delivering signals to closer synapses (adjacent anterior horn cells in the cervical cord). Clinically, the weakness may be severe and may result in an obvious paralysis or be so subtle as to be undetectable. Heat-induced fatigue and weakness, as manifested by focal symptoms (slapping of a foot or dragging a leg) occurring after 15 to 20 minutes of exercise and resolving with rest, are characteristic of early demyelinating disease. The early absence of associated hyperreflexia and plantar extensor responses (Babinski's sign) may make it difficult to document corticospinal tract involvement. Later, in more established MS, classic corticospinal tract signs are often evident and manifest clinically as spastic gait (either hemiparetic or paraparetic), muscle cramps, and clonus (sustained reflex loop), sometimes occurring with positional changes and mistaken for signs of a cerebellar tremor.

Ataxia may occur as a result of impaired delivery of sensory information up the spinal cord or from demyelination of cerebellar pathways in the brain stem or cerebellum. Often, the two are mixed and may be confounded further by visual loss and impaired ability to compensate by fixing on the environment; this combination commonly causes dizziness in crowds, in which fixation may be further obscured. Appendicular dysmetria resulting in tremor on reaching for an object is a common cause of impaired coordination and dexterity. Lower extremity and truncal ataxia may result in a wide-based (drunk) gait. Other movement disorders, such as postural tremor and titubation (head tremor), are much less common in MS. *Myokymia* (wormlike muscle movements) under the skin, especially around the face, however, is fairly common. Pseudoathetosis and parkinsonism can be seen in severe cases.

Organ Dysfunction

Bladder symptoms are extremely common, but often are not volunteered, so specific questions must be asked. A careful bladder history may reveal isolated or mixed patterns of urinary frequency, urgency, incontinence, or retention. Careful delineation of a spastic bladder (detrusor muscle spasm) causing incontinence from an atonic bladder or spasm of the external sphincter (the latter two are causes of retention) leading to overflow incontinence is critical to designing an appropriate therapeutic strategy (Chapter 25). Urinary tract infections (Chapter 292), which are commonly the result of bladder dysfunction, may aggravate the underlying symptoms of MS.

Bowel dysfunction commonly manifests as constipation (Chapter 138), which may be primary (related to spinal cord involvement) or secondary (related to self-induced dehydration to manage urinary frequency or to side effects of anticholinergic drugs). Bowel incontinence secondary to an incompetent anal sphincter is less common and most often occurs as an isolated episode of fecal urgency, sometimes related to dietary change or diarrheal illness.

Sexual dysfunction is also common and underdiscussed in MS. In men, erectile dysfunction is frequent. In women and men, loss of libido and inability to achieve orgasm can occur as a result of medication, loss of sensation, heat-induced worsening of symptoms, physical barriers to intercourse (impaired mucosal moisture, spasticity, and pain), depression, or disorders of body image.

Systemic Symptoms

Fatigue, which is common in MS, may be linked to depression but often occurs independently and can be the most disabling symptom of the disease. A sleep history is important to exclude daytime fatigue resulting from disrupted sleep secondary to pain, cramps, bladder frequency, sleep apnea, periodic limb movements, depression, or disrupted sleep-wake cycles. Daytime fatigue even after a good night of sleep may occur in midafternoon and may be described as being "unplugged" or completely drained. Many patients obtain benefit from a short daytime nap.

Sensitivity to heat, which is a classic symptom of MS, occurs only in some patients. Even minor elevations of the body temperature can dramatically worsen symptoms. Symptoms usually (but not always) improve on cooling. Cooling devices can prevent this phenomenon, but there is no persistent benefit of cooling below normal body temperature. Some patients complain of worsened symptoms in cold weather, likely related to increased dysfunction of already stiff muscles and increased pain.

Pregnancy

Many women with MS successfully have multiple children, and the activity of MS lessens during the course of pregnancy, especially by the third trimester, when the frequency of exacerbations is reduced by approximately two thirds. Relapses are more frequent in the first 6 postpartum months, but no evidence indicates that pregnancy changes the natural history of the disease. Whether breast-feeding alters the course of MS is debated, but it is contraindicated for patients who resume disease-modifying drugs following delivery.

Types of Multiple Sclerosis

The three major clinical types of MS are relapsing remitting, secondary progressive, and primary progressive. Approximately 85 to 90% of patients present with relapsing remitting MS, characterized by acute or subacute episodes of new or worsening old neurologic symptoms that increase in severity, plateau, and then partly or completely remit. Patients may have no detectable residual deficit, or they may accumulate significant permanent disability from an attack. Most patients with relapsing remitting MS convert to secondary progressive MS after 20 to 40 years. This stage of the disease, which is characterized by at least 6 months of progressive worsening without evidence of a relapse, can be diagnosed with confidence only retrospectively. Some patients with secondary progressive MS also have interposed relapses distinct from their periods of progressive worsening, although these episodes become less frequent with time. Primary progressive MS, which is characterized by progressive deterioration from the onset for at least 1 year without a history of distinct relapses, occurs in approximately 10 to 15% of patients. It is more common in middle-aged men and typically has more involvement of the spinal cord and fewer inflammatory brain lesions.

Several other uncommon types of MS also are described. Progressive relapsing MS refers to a fairly uncommon variant of MS (6%), in which a relapse ensues after an initially primary progressive course. Acute progressive MS (Marburg's disease) causes acute or subacute progressive neurologic deterioration leading to severe disability within days to a month in a patient with no prior history of MS. This rare form of the disease may progress to a quadriplegic, obtunded state with death as a result of intercurrent infection, aspiration, or respiratory failure from brain stem involvement.

DIAGNOSIS

The diagnosis of MS rests on demonstrating evidence of at least two inflammatory demyelinating lesions referable to different locations within the CNS, occurring at different times (usually ≥1 month apart), and for which no better explanation exists. Diagnostic criteria allow for the diagnosis to be made on clinical grounds alone as long as appropriate exclusionary testing is performed (Table 419-3). Clinical evidence of a lesion requires objective findings on examination, not just a symptom. Further, repeated episodes of neurologic dysfunction that could be explained based on one lesion (e.g., a cervicomedullary junction lesion causing brain stem, cerebellar, and corticospinal tract dysfunction) is not enough evidence to diagnose MS.

Laboratory Findings

Magnetic Resonance Imaging

No definitive diagnostic laboratory test exists for MS, but magnetic resonance imaging (MRI) of the brain is extremely useful and should be performed in all patients in whom MS is a diagnostic consideration. More than 95% of patients with clinically definite MS have an abnormal brain MRI, and the presence of high-signal, bright lesions is so characteristic of MS that a normal brain MRI should suggest an alternative diagnosis. Brain MRI is also useful in predicting future MS at the time of a clinically isolated demyelinating syndrome. Specific MRI findings allow for confirmation of disease disseminated in time and space (different parts of the brain or spine) as well as fulfilling evidence for dissemination in time (Table 419-4). MS plaques typically appear as high-signal (white) areas on fluid attenuation inversion recovery (FLAIR) T2-weighted images, which allow for the best discrimination of these lesions by suppressing high-signal from cerebrospinal fluid (CSF) in the ventricles (Fig. 419-1). Lesions generally range in size from 2 mm to 2 cm; larger plaques occasionally resemble a tumor. Features of an MRI lesion suggesting MS include an elliptical shape, discrete borders, lack of mass effect, and gadolinium enhancement. Typical locations include the periventricular area (perpendicular to or abutting the walls of the ventricles) (Fig. 419-2), the corpus callosum, the cerebellar peduncles, the brain stem, the juxtacortical area, and the dorsolateral spinal cord (Fig. 419-3). Cortical and deep gray matter lesions also occur but are less clearly seen on conventional MRI. Gadolinium enhancement, which suggests permeability of the blood-brain barrier, is correlated with new or active inflammation in lesions (Fig. 419-4). Lesions that enhance on a T1-weighted sequence usually have a concomitant lesion in the same location on a T2-weighted image. However,

TABLE 419-3 2010 REVISIONS TO THE MCDONALD DIAGNOSTIC CRITERIA FOR MULTIPLE SCLEROSIS

CLINICAL PRESENTATION	ADDITIONAL DATA NEEDED FOR DIAGNOSIS OF MULTIPLE SCLEROSIS
Two or more attacks; objective clinical evidence of two or more lesions; or one lesion with a prior attack	None*
Two or more attacks; objective clinical evidence of one lesion	Dissemination in space, demonstrated by: (1) MRI (see Table 419-4), or (2) Two or more MRI-detected lesions consistent with MS plus positive CSF, or (3) Await further clinical attack implicating a different site
One attack; objective clinical evidence of two or more lesions	Dissemination in time, demonstrated by: (1) MRI (see Table 419-4), or (2) Second clinical attack
One attack; objective clinical evidence of one lesion (monosymptomatic presentation; clinically isolated syndrome)	(1) Dissemination in space, demonstrated by: (a) MRI (see Table 419-4), or (b) Two or more MRI-detected lesions consistent with MS plus positive CSF, and (2) Dissemination in time, demonstrated by: (a) MRI (see Table 419-4), or (b) Second clinical attack

*Must rule out other causes (e.g., see Table 419-2).
CSF = cerebrospinal fluid; MRI = magnetic resonance imaging; MS = multiple sclerosis.

TABLE 419-4 MAGNETIC RESONANCE IMAGING CRITERIA IN MULTIPLE SCLEROSIS (INTERNATIONAL PANEL RECOMMENDATIONS: 2010)

DISSEMINATION IN TIME
Detection of a new T2 or gadolinium-enhancing lesion if it appears at any time compared with a reference scan*
Simultaneous presence of asymptomatic gadolinium-enhancing and non-enhancing lesions at any time
DISSEMINATION IN SPACE
At least one gadolinium-enhancing lesion in at least 2 of 4 areas: Periventricular Juxtacortical Infratentorial Spinal cord
DIAGNOSIS OF PRIMARY PROGRESSIVE MULTIPLE SCLEROSIS
One year of disease progression (retrospectively or prospectively determined) plus two of the following: a. Positive brain magnetic resonance imaging (≥1 T2 lesion in at least one characteristic area: periventricular, juxtacortical, or infratentorial) b. Positive spinal cord magnetic resonance imaging (two focal T2 lesions) c. Positive cerebrospinal fluid (isoelectric focusing evidence of oligoclonal immunoglobulin G bands or increased immunoglobulin G index, or both)

*Caution: Determination that a T2 lesion is indeed new can be challenging. A new T2 lesion must be of sufficient size and location to reflect one that could not have been missed previously for technical reasons of slice orientation, thickness or spacing, tissue contract, patient motion, or other artifacts. This judgment requires standardized scanning procedures, with emphasis on careful repositioning, as well as input from qualified evaluators experienced in multiple sclerosis imaging.
From Polman Ch, Reingold SC, Banwell G, et al. Diagnostic criteria for multiple sclerosis: 2010 revisions to the McDonald criteria. *Ann Neurol.* 2011;49:292-302.

FIGURE 419-3. Sagittal T2-weighted image of the brain and cervical spine from a patient with multiple sclerosis. The image shows a high-signal plaque from C3-C5 in the spinal cord.

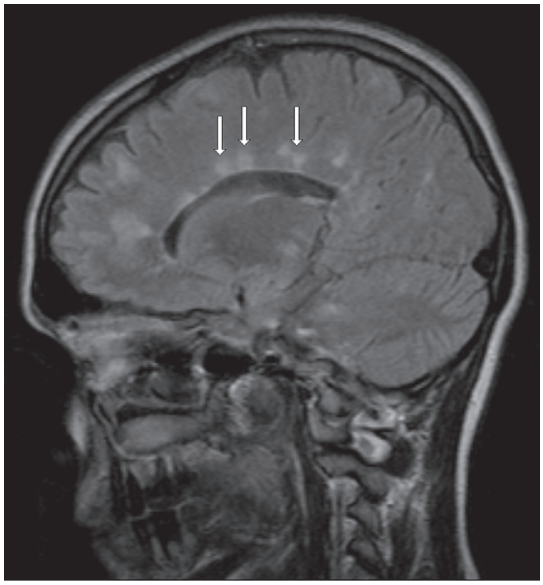

FIGURE 419-2. Sagittal fluid attenuation inversion recovery image of the brain from a patient with multiple sclerosis revealing classic periventricular lesions radiating outward from the ventricles *(arrows)*.

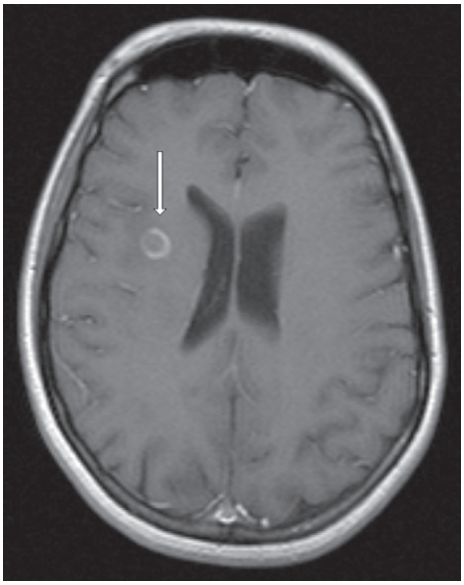

FIGURE 419-4. Axial T1-weighted image after gadolinium contrast showing an actively inflamed ring-enhancing lesion in a patient with multiple sclerosis.

T2-weighted lesions may form without evident enhancement. Gadolinium enhancement typically persists for 2 to 8 weeks and thus may be missed on intermittent scans. Persistent areas of low signal on T1-weighted images before contrast ("black holes") correlate with pathologic evidence of axonal loss and atrophy (Fig. 419-5).

Cerebrospinal Fluid

Examination of the CSF is useful in many cases but is not mandatory in patients with a typical clinical presentation and MRI evidence of disseminated disease. CSF evaluation includes cell counts, total protein, glucose, oligoclonal bands with a paired serum sample, and an IgG index. The presence of myelin basic protein is not specific for MS because it can be elevated secondary to any disruption of CNS tissue. Oligoclonal bands in the CSF or an elevated IgG index provides evidence for intrathecal production of immunoglobulins, and oligoclonal bands are common in MS but can occur with infection or other immune-mediated processes; the test lacks specificity for MS and has a sensitivity of only approximately 85 to 90% of patients with clinically definite MS. In clinically isolated demyelinating syndromes (see later), the sensitivity is even lower (~50%).

CSF evaluation is generally recommended if an alternative diagnosis is considered, especially if one suspects an infectious process (e.g., fever, sweats, unusual travel history, tick bite, or rash). CSF analysis may also be useful if clinical or MRI criteria are incomplete to provide confirmation of the diagnosis.

Evoked Potential Tests

Evoked potentials (Chapter 403) may also be useful in some situations to document objective evidence of slowed conduction owing to demyelination in locations different from those recognized clinically. However, visual evoked potentials (VEPs), brain stem auditory evoked potentials, and somatosensory

evoked potentials are less sensitive and less specific for MS than is high-resolution MRI. Multifocal VEPs may be more sensitive than global VEPs in revealing focal areas of abnormal conduction along the optic nerve.

Optical Coherence Tomography

Optical coherence tomography is an office-based device that uses the reflection of infrared light (from an exogenous source directed through the pupil) off the back of the eye to quantify the thickness of retinal tissues, including the retinal nerve fiber layer and macula. This test, which has been widely used in glaucoma, can monitor axonal damage, both in the setting of acute optic neuritis and in detecting subclinical axonal damage (Fig. 419-6). Retinal nerve fiber layer thinning correlates with brain atrophy and may be useful as a surrogate marker of more global neurodegeneration in MS.

Differential Diagnosis

The diagnosis of MS may be so clear that it is recognized by the patient and is readily confirmed by the primary physician or so obscure that even experienced specialists disagree. Many processes (see Table 419-2) can mimic the clinical, radiologic, and CSF findings associated with MS, and there is no "gold standard" diagnostic test that is 100% sensitive and specific for the disease.

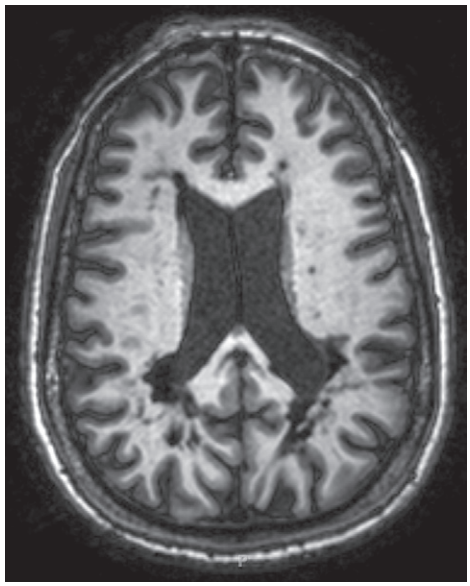

FIGURE 419-5. Axial T1-weighted image showing numerous areas of T1 low signal ("black holes"), ventricular enlargement, and diffuse atrophy.

Processes that mimic MS include structural lesions, especially of the base of the brain and of the spinal cord, in which one lesion can cause symptoms referable to many different tracts and at different perceived locations in the body. Chiari malformations with or without syrinx (Chapter 426), disc herniation (Chapter 407), cervical spondylosis, and low-grade tumors (Chapter 195) can produce symptoms of MS both in newly presenting patients and in patients who truly have MS but who also have a second process.

Various infectious diseases can mimic MS. Examples include human T-cell lymphotropic virus types I and II (virally associated myelopathy or tropical spastic paraparesis; Chapter 386), human immunodeficiency virus (neuropathy, myelopathy, cognitive impairment, CNS white matter changes; Chapter 401), neuroborreliosis (Lyme disease; Chapter 329), neurosyphilis (Chapter 327), Epstein-Barr virus (Chapter 385), cytomegalovirus (Chapter 384), herpes simplex virus (Chapter 382), varicella-zoster virus myelitis (Chapter 383), and JC virus (progressive multifocal leukoencephalopathy; Chapter 378).

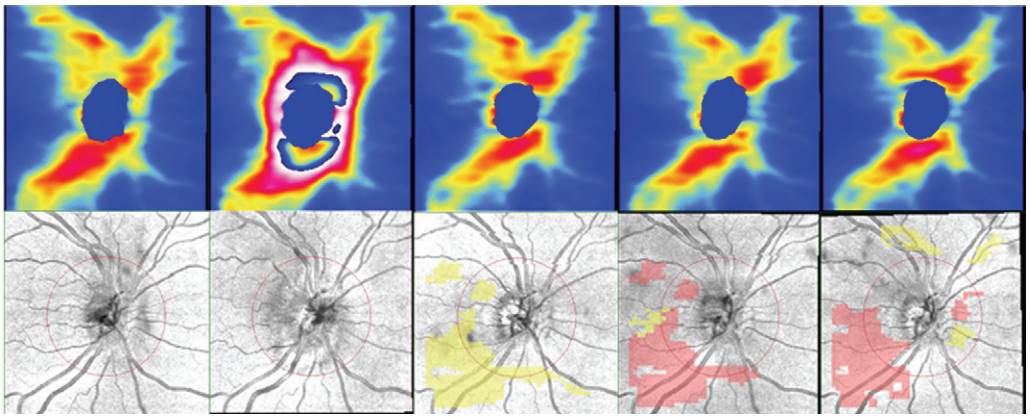
Other inflammatory diseases that usually involve other parts of the body can concomitantly affect the CNS or rarely present in the CNS. Examples include sarcoidosis (Chapter 95), systemic lupus erythematosus (Chapter 274), Sjögren's syndrome (Chapter 276), and vasculitides (Chapter 278). Ischemic vascular disease secondary to any cause also can resemble MS. Metabolic and nutritional disorders that can mimic MS include vitamin B_{12} deficiency and methylmalonic acidemia (in some cases distinct from cyanocobalamin deficiency). Central pontine myelinolysis (Chapters 118 and 425) secondary to overly rapid correction of sodium is rarely mistaken for MS. Thyroid disease (Chapter 233) may mimic the fatigue of MS and may cause dysesthesias and disorders of the optic nerve and muscles. Nutritional deficiency (Chapter 222) and malabsorption have been associated with demyelination and may mimic MS. Copper deficiency can cause dorsal column pathology, neuropathy, anemia, and optic neuropathy. Vitamin D deficiency (Chapter 252), which is becoming increasingly common, can cause proximal weakness, fatigue, and asthenia, in addition to bone loss.

Monophasic demyelinating syndromes with or without multiple other lesions often, but not always, progress to become MS (see later). Spinocerebellar atrophy and hereditary myelopathy cause slowly progressive disease but do not cause sensory and visual abnormalities.

TREATMENT

Rx

The treatment of MS can be divided into drugs designed to relieve symptoms, drugs designed to modify the course of the disease, and nondrug measures. In addition, numerous drugs can target specific aspects of MS: depression, fatigue, muscle spasticity, pain, insomnia, and bladder, bowel, and sexual dysfunction. Before considering a symptomatic therapy, the



Time from AON onset	− 3 Months	+ 2 Weeks	+ 3.5 Months	+ 8 Months	+ 10 Months
Average RNFL (microns)	108	164	98	99	97
Superior	131	197	131	123	125
Nasal	78	126	74	75	74
Inferior	141	246	118	130	126
Temporal	79	84	69	66	65

FIGURE 419-6. Serial optical coherence tomography (OCT) scans in a patient who developed unilateral optic neuritis. Immediate swelling and increased thickness of the retinal nerve fiber layer (RNFL) thinning can be seen followed by focal thinning, especially in the temporal quadrants, as depicted by the *yellow* and *red* regions. AON = acute optic neuritis.

patient should be educated about the purpose of the drug and its side-effect profile. On learning that these drugs have no long-term impact on disease activity, patients may elect not to use them for relief of symptoms alone. Symptomatic therapies are best started at low doses and frequently require titration to obtain the optimal balance between efficacy and side effects.

Treatment of Specific Symptoms

Depression and emotional lability are common symptoms of MS. In addition to appropriate supportive care and counseling, antidepressant therapy with one of the "activating" serotonergic or noradrenergic drugs (fluoxetine, sertraline, citalopram, escitalopram, venlafaxine, or bupropion) can be of benefit (see Table 404-5 in Chapter 404). If anxiety and panic symptoms predominate, a less activating drug such as paroxetine may be preferable. Patients with concomitant pain or insomnia may benefit more from a sedating antidepressant (amitriptyline, nortriptyline, or trazodone) given at bedtime.

Spasticity can be managed by physical therapy, stretching, and institution of either baclofen (5 to 160 mg in divided doses) or tizanidine (2 to 32 mg in divided doses). Either drug should be started as a single agent at a low dose, generally three to four times a day, but a larger dose at bedtime is often the best tolerated and may target nocturnal symptoms. Decreasing muscle tone can result in weakness. Baclofen should never be discontinued abruptly because of the potential for a severe withdrawal reaction.

Bladder urgency resulting from detrusor muscle spasm can be managed effectively with anticholinergics such as oxybutynin (5 to 20 mg in divided doses) or tolterodine (1 to 4 mg), but these agents can cause temporary urinary retention. Bladder ultrasonography permits accurate bedside assessment of postvoid residual volume to determine whether a patient is retaining excessive amounts of urine. Urinary retention may be improved by removing drugs known to induce it. Primary urinary retention is difficult to treat with drugs, but external sphincter spasm can be treated with α_{1a}-adrenergic receptor blockers such as tamsulosin (0.4 to 0.8 mg) and doxazosin (1 to 8 mg). Bethanechol (10 to 150 mg in divided doses) may be tried for an atonic bladder, but intermittent catheterization is often required. Alternative causes of bladder symptoms such as urinary tract infections, prostatic enlargement, or anatomic changes following pregnancy should be considered and managed separately.

Painful dysesthesias and paroxysmal dystonic spasms may be managed effectively with antiepileptic drugs (gabapentin, 300 to 5400 mg/day in divided doses; pregabalin, 75 to 600 mg/day in divided doses; or carbamazepine, 100 to 2400 mg/day in divided doses) or tricyclic antidepressants (amitriptyline, 10 to 150 mg; or nortriptyline, 10 to 50 mg). Patients with trigeminal neuralgia (Chapter 405) may respond to these drugs or to baclofen, misoprostol, botulinum toxin, or decompression surgery.

Sexual dysfunction in MS is often multifactorial. Patients with erectile dysfunction usually respond well to the phosphodiesterase inhibitors, which enhance penile vasodilation (Chapter 242). Education regarding the use of lubrication, alternative sensory stimulation, and the adverse effect of heat can improve sexual function.

Systemic Treatments

Corticosteroids (e.g., intravenous methylprednisolone, 1 g/day for 3 to 5 days) shorten the duration and severity of symptoms from an acute exacerbation but have no proven effect on long-term disability. Oral corticosteroids used in equivalent dosage are probably equally efficacious and safe. Intravenous immunoglobulin and plasma exchange have been reported occasionally to benefit steroid-refractory patients, but randomized placebo-controlled trials have failed to show consistent benefits, perhaps because only patients with type II disease (humoral component) are likely to respond.

Seven disease-modifying agents have been approved by the U.S. Food and Drug Administration (FDA): IFN-β1b (Betaseron and Extavia), IFN-β1a (Avonex), IFN-β1a (Rebif), glatiramer acetate (Copaxone), natalizumab (Tysabri), and mitoxantrone (Novantrone). The first six agents were approved for relapsing remitting MS, and mitoxantrone is indicated for worsening forms of MS and for secondary progressive MS.

The three IFN-β drugs[1-3] and glatiramer acetate[4] reduce the relapse rate by approximately one third. IFN-β1b (8 million IU, subcutaneously every other day [Betaseron and Extavia]) and IFN-β1a (30 μg intramuscularly weekly [Avonex] or 22 to 44 μg subcutaneously three times a week [Rebif]) appear to have a more rapid onset of action, perhaps based on their dosing regimen, compared with weekly IFN-β1a (30 μg weekly intramuscularly). However, weekly IFN-β1a Avonex is less immunogenic and results in only a 3% incidence of neutralizing antibodies, which reduce efficacy, compared with 20 to 30% for the other IFN-β preparations. The major side effects of IFN-β are a flulike reaction (low-grade fever, chills, and myalgias 6 to 24 hours after the injection), local reactions at the injection site (pain, erythema, and rarely necrosis), and elevated aminotransferase levels (rarely severe hepatitis). These side effects can be managed by initiating the drug slowly and by prophylaxis with acetaminophen and nonsteroidal anti-inflammatory agents, and they improve in most patients after 3 to 6 months.

Glatiramer acetate is a copolymer of four amino acids designed to mimic myelin basic protein; given as 20 mg/day subcutaneously, it also reduces relapses by about one third and is well tolerated by most patients.[4] Major side effects are local reactions at the injection site, swelling, hives, and a rare, self-limited (15 to 20 minutes) systemic reaction consisting of chest pain, palpitations, and anxiety. No monitoring of blood tests is required for this medication. The effect of glatiramer acetate on MRI T2-weighted and gadolinium-enhancing lesions is less dramatic than for the IFNs (30% reduction) perhaps because its primary effect is not at the blood-brain barrier.

Natalizumab is a monoclonal antibody directed against the α_4-integrin chain of the leukocyte adhesion molecule VLA-4. In a large phase III trial, this drug, at a dose of 300 mg intravenously every 4 weeks, reduced relapses by 68% compared with placebo and reduced gadolinium-enhancing lesions by 92%.[5] However, about 1 per 500 patients develop JC virus brain infection (Chapter 378) after 24 months of exposure, which causes progressive multifocal leukoencephalopathy.

In a randomized study, yearly courses of alemtuzumab (12 or 24 mg daily for 5 consecutive days in year 1 and for 3 days in years 2 and 3), which is a monoclonal antibody that targets CD52 in lymphocytes and monocytes, reduced relapse rates and disability by up to 75% compared with IFN-β1a given three times a week.[6] Serious side effects associated with alemtuzumab include an increased rate of autoimmune thyroid and thrombocytopenic purpura.

Mitoxantrone, which is an anthracenedione antineoplastic agent with potent immunosuppressive activity, has been approved to slow progression of neurologic disability and to reduce the relapse rate in patients with relapsing remitting MS and secondary progressive MS.[7] The recommended dose is a 5- to 12-mg/m^2 intravenous infusion every 3 months. In a phase III randomized, placebo-controlled, multicenter trial of 188 patients, the number of treated relapses was reduced by 67%. Side effects of mitoxantrone include nausea and alopecia. The lifetime use of this drug is limited to 2 to 3 years (or a cumulative dose of 120 to 140 mg/m^2) because of its cardiotoxicity. Heart failure or asymptomatic decreases in left ventricular ejection fraction (LVEF) can occur even after one to four doses, so careful monitoring of LVEF after each dose is mandatory. The risk for leukemia is increased and may be as high as 0.8%. A complete blood count, including platelets, should be done before each course of mitoxantrone therapy, and women of childbearing age should have a pregnancy test and should know the results before each dose, regardless of whether or not they are using birth control. Patients should be made aware that mitoxantrone may impart a blue-green color to the urine for 24 hours after administration. It also may cause bluish discoloration of the sclera. Rituximab (1000 mg intravenously 2 weeks apart every 6 months), which is a monoclonal antibody that depletes B-cell lymphocytes, can significantly reduce inflammatory brain lesions and relapse by about 50% for up to 48 weeks in patients with relapsing remitting MS,[8] but has not been effective in primary progressive MS. A trial of rituximab in primary progressive MS failed to show an effect on progression, although a post hoc analysis suggested that younger patients with enhancing lesions on MRI did have reduced progression after treatment compared with controls.

Fingolimod is a sphingosine-1 phosphate receptor modulator that is given orally once a day at 0.5 mg. Fingolimod reduces relapse rates and the progression of disease compared with placebo[9] and compared with IFN therapy.[10] Fingolimod's side effects include first-dose bradycardia, macular edema, and respiratory infections. Cladribine (2-chlorodeoxyadenosine, 3.5 or 5.25 mg/kg/day) given as a short course once a year reduced the annualized relapse rate by 55% and disease progression by one third compared with placebo in a phase III trial.[11] Both these drugs may have a role in treating MS but also have global immunosuppressive effects that increase the risk for serious infections and possibly other systemic complications.

In a phase 2 trial, treatment with 0.6 mg/day of laquinimod, a novel oral immunomodulatory agent, resulted in a 40% decrease in MR lesions in relapsing-remitting multiple sclerosis at 36 weeks.[12] In another phase II trial, oral fumarate, which also has anti-inflammatory effects, reduced new gadolinium-enhancing lesions by 69%.[13] In a randomized trial, sustained-release fampridine, a potassium-channel blocker at 10 mg twice daily, improved walking in 35% of patients compared with only 8% of patients receiving placebo, leading to its recent approval by the FDA.[14] Teriflunomide is an oral dihydro-orotate dehydrogenase inhibitor that reduced MRI activity in a phase II clinical trial. Other forms of immunosuppression, including methotrexate, azathioprine, mycophenolate mofetil, and cyclophosphamide, also appear to have some efficacy in MS, although no definitive clinical trials have been done with these agents, and none is as yet approved for MS by the FDA.

MS patients are at high risk of developing osteopenia or osteoporosis, so prophylaxis with vitamin D and calcium and treatment with bisphosphonates or other proven approaches should be considered. Patients with suboptimal 25-OH vitamin D levels (<30 ng/mL) on standard 1000 IU cholecalciferol replacement therapy should consider increasing to 2000 to 4000 IU/day or 50,000 IU ergocalciferol every other week or, in some cases, weekly, with appropriate monitoring of vitamin D and calcium levels. If osteoporosis has already been diagnosed, bisphosphonate therapy, such as alendronate (10 mg daily or 70 mg weekly) or similar drug is generally indicated.

Nondrug Approaches to Well-Being

Nonmedical treatment of MS is a critical part of managing the disease. Patients derive benefit from a health care team approach consisting of an experienced MS physician, nurse, social worker, therapist, and counselor, with appropriate referral to other subspecialties as needed. Alternative and complementary therapies (Chapter 38) are commonly used by patients with MS, and the risks and benefits of these approaches must be discussed with the patient.

PROGNOSIS

The average lifespan of patients with MS is about 8 years less than normal, a finding reflecting a bimodal distribution in which many patients live a normal lifespan and a few die at a significantly younger age owing to aggressive disease, severe disability, infection, or suicide. Most patients presenting with relapsing remitting MS convert to secondary progressive MS after 20 to 40 years. Only one third of patients will require use of a wheelchair, but 50% may need assistive devices, and nearly two thirds will have disability that prevents them from working. African Americans and men of all races tend to have a more aggressive course and are more likely to become disabled. Institution of immunomodulating therapy early in the course of the disease may slow progression of disability, but no long-term follow-up data are available to quantify the extent of this benefit.

OTHER DISEASES OF MYELIN

Monofocal and Monophasic Demyelinating Processes

OPTIC NEURITIS AND TRANSVERSE MYELITIS

Optic neuritis (Chapter 432) and transverse myelitis are inflammatory processes that can occur as entities distinct from MS or as part of MS (see earlier). In addition, optic neuritis and transverse myelitis can occur together in the syndrome called *neuromyelitis optica* (Devic's disease).

Optic Neuritis

Optic neuritis (Chapter 432) is an inflammatory disease that usually involves the retrobulbar portion of the optic nerve and sometimes parts of the optic chiasm. Although optic neuritis is most often associated with MS (50 to 75%), it also can be seen as an isolated idiopathic disorder (25 to 50%), as part of neuromyelitis optica, or associated with other inflammatory and infectious diseases such as systemic lupus erythematosus, Sjögren's syndrome, sarcoidosis, Lyme disease, syphilis, and human immunodeficiency virus infection. The pathobiologic features are thought to be similar to those of MS and are characterized by idiopathic inflammatory demyelination followed by secondary axonal injury.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical presentation, which typically is monocular visual loss with pain over the brow that worsens with lateral eye movement, is similar regardless of whether it presents as part of MS (see the earlier discussion of the visual effects of MS) or not. When it involves the optic nerve head, it is called *papillitis* and, in bilateral cases, can be impossible to differentiate from papilledema. Optic neuritis can also be mimicked by anterior segment, choroidal, or retinal diseases. Optic neuritis is distinguished from optic neuropathy, which is a chronic, generally noninflammatory condition of the optic nerve caused by tobacco or nutritional amblyopia, ischemia, Leber's disease, or other rare hereditary diseases (Chapter 432).

TREATMENT

Rx

Among patients with optic neuritis, the 15-year risk of developing MS is 25% in patients without lesions on their baseline brain MRI but 72% in patients with one or more baseline MRI lesions. Treatment with intravenous methylprednisolone as in MS may shorten the duration and severity of the attack, but no definitive evidence indicates that it changes the long-term outcome. Oral prednisone alone, without prior treatment with intravenous methylprednisolone, may increase the risk for recurrent optic neuritis and should be avoided. Data support the use of IFN-β drugs and glatiramer acetate in patients whose optic neuritis is at high risk for conversion to MS (one or more typical brain MRI lesions).

Transverse Myelitis

Transverse myelitis is a rare (~1 in 100,000 people) monophasic inflammatory process of the spinal cord that is usually distinct from MS in that it either involves the entire cross section or is longitudinally extensive along three vertebral body segments rostrocaudally. Transverse myelitis may be idiopathic or associated with inflammatory diseases (systemic lupus erythematosus, Sjögren's syndrome, vasculitis, or MS), infectious diseases, or vascular diseases (antiphospholipid antibody syndrome or dural venous fistula).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In its fulminant form, transverse myelitis causes complete loss of motor and sensory function below the affected level of the spinal cord and causes concomitant bowel, bladder, and sexual dysfunction. Autonomic involvement can be seen in cervical and high thoracic spine cases. Transverse myelitis may also manifest in an incomplete or partial form, which is more commonly associated with MS.

TREATMENT AND PROGNOSIS

Rx

Treatment is usually with methylprednisolone (1000 mg intravenously for 3 to 5 days), followed by specific treatment of any identifiable underlying disease process. The prognosis is worse than in MS in that significant recovery is seen in fewer than 50% of patients, and many patients remain completely paralyzed after the initial attack. Plasma exchange or cyclophosphamide may be considered in steroid-refractory cases.

NEUROMYELITIS OPTICA

Neuromyelitis optica is now recognized as a distinct entity from MS and is characterized by an optic neuritis, often bilateral and temporally associated with a fulminant multilevel transverse myelitis. A specific IgG directed against aquaporin 4 strongly predicts this process. Brain lesions may be seen on MRI and have a predilection for the brain stem. Neuromyelitis optica may be similar to what is called *opticospinal MS* in Japan. There is no proven effective treatment, but patients are usually given anti-inflammatory and immunosuppressive medications. Therapies directed against B cells or humoral factors are being explored. The prognosis is generally poor; most patients develop sustained disabling visual loss and weakness.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis and its hyperacute form, acute necrotizing hemorrhagic encephalopathy, are thought to be forms of monophasic immune-mediated inflammatory demyelination. They differ from MS in that they are typically monophasic, whereas MS is by definition multiphasic or chronically progressive. However, no reliable clinical or pathologic criteria are available to differentiate the two processes, which may represent a continuum. Patients may present with fever, headache, meningeal signs, and altered consciousness, which are exceedingly rare in MS. There is no known effective treatment. Large numbers of patients, especially children, make remarkable recoveries, but the necrotizing form can be severely disabling or fatal.

Leukodystrophies

The leukodystrophies represent a variety of diseases formerly characterized by their common clinical and pathologic characteristics of white matter and, presumably, myelin. Many of these diseases now have a defined biochemical and genetic basis, and some (e.g., Alexander's disease) are no longer considered dysmyelinating diseases.

ADRENOLEUKODYSTROPHY AND ADRENOMYELONEUROPATHY

Adrenoleukodystrophy and adrenomyeloneuropathy, which are caused by impaired ability of the peroxisomes to metabolize very long chain fatty acids, represent different phenotypes resulting from the same X-linked, incompletely recessive genetic defect. Impaired oxidation of very long chain fatty acids results from deficient function of the enzyme lignoceroyl–coenzyme A ligase. The defective gene maps to Xq28 and codes for a peroxisomal membrane protein (ALDP), which is a member of a large family of proteins referred to as the adenosine triphosphate–binding cassette (ABC) transporters, specifically *ABCD1*.

Childhood cerebral adrenoleukodystrophy, which is the most common form of the disorder, represents 45% of all cases; it is seen only in male patients, with an onset at ages 4 to 11 years. Adolescent (5%) and adult (3%) cerebral forms progress at a similar or slower rate compared with the childhood form.

CLINICAL MANIFESTATIONS

Adrenomyeloneuropathy begins in young men as slowly progressive paraparesis with hypogonadism, impotence, sphincter disturbances, variable adrenal insufficiency, and axonal neuropathy affecting mainly the lower extremities. A rare acute inflammatory form with rapid progression and dementia may occur. A similar, but usually milder, disorder can be seen in up to 20% of women who are hemizygous for the disease.

DIAGNOSIS

Diagnosis is established in male patients by finding elevated very long chain fatty acids in the plasma. DNA-based diagnosis in carriers is reliable and is recommended in women because of false-negative results using the plasma assay.

TREATMENT

Rx

Treatment is unsatisfactory. A 4:1 mixture of glyceryl trioleate and glyceryl trierucate (i.e., "Lorenzo's oil") normalizes plasma very long chain fatty acids within 4 weeks and has few side effects. Although clinical trials suggested that treatment in presymptomatic patients delayed or prevented the onset of disease, this treatment is ineffective after symptoms have begun, and the disease progresses relentlessly.

PELIZAEUS-MERZBACHER DISEASE

Pelizaeus-Merzbacher disease is an extremely rare, chronic, familial leukodystrophy usually caused by a genetic defect in the myelin proteolipid (PLP; lipophilin) protein gene. In classic Pelizaeus-Merzbacher disease, age at onset varies between 3 months and 9 years, the age at death varies between 6 years and 25 years, and the longest duration of the disease is approximately 24 years. The disease manifests as a slowly progressive myelopathy, often with cerebellar and cognitive involvement. The diagnosis is established by genetic testing for mutations in the *PLP* gene. No specific treatment exists for Pelizaeus-Merzbacher disease.

METACHROMATIC LEUKODYSTROPHY

Metachromatic leukodystrophy usually results from a recessively inherited defect in the lysosomal enzyme arylsulfatase A. Absence of arylsulfatase A results in the accumulation of sulfatide in both central and peripheral myelin and myelin-forming cells; instability of the myelin membranes results in the breakdown of myelin. Metachromatic leukodystrophy is generally divided into four subtypes: congenital, late infantile (most common), juvenile, and adult. It appears in all ethnic groups and has an overall frequency of 1 in 40,000.

The clinical manifestations are variable and may include progressive spastic paraparesis, extrapyramidal signs, seizures, and peripheral neuropathy. Brain MRI usually shows large confluent symmetrical high-signal areas in the cerebral white matter, brain stem, and cerebellum, but a more patchy appearance resembling MS is occasionally seen in adult cases. At present, no satisfactory treatment exists. Some evidence suggests that bone marrow transplantation delays the onset in presymptomatic patients and may slow progression of the disease.

GLOBOID CELL LEUKODYSTROPHY

Globoid cell leukodystrophy is characterized biochemically by accumulation of galactocerebroside in cerebral white matter as a result of deficient galactocerebroside β-galactosidase activity. The disease is transmitted as an autosomal recessive trait and affects infants in the first 2 to 3 months of life, initially manifesting with behavioral changes and failure to achieve developmental milestones. Rare late-onset cases present with progressive motor impairment and, less frequently, visual failure. Neuropathologic examination reveals marked loss of myelin throughout the brain, with the presence of round or oval macrophages and large, irregular, multinucleated cells, termed *globoid cells,* which are filled with galactocerebroside. Accumulation of galactosylsphingosine (psychosine) is thought to cause destruction of oligodendrocytes and marked reduction of myelin formation.

CANAVAN'S DISEASE

Canavan's disease is a fatal, progressive leukodystrophy with an autosomal recessive inheritance, caused by mutations in the gene for aspartoacylase, an enzyme that hydrolyzes *N*-acetylaspartate into L-aspartate and acetate. Aspartoacylase deficiency results in elevated levels of its substrate molecule, *N*-acetylaspartate, brain edema, and dysmyelination. Clinically, the disease manifests with retardation, seizures, and diffuse, symmetrical white matter degeneration in the subcortical areas, with involvement of the globus pallidum on MRI. No treatment is available.

MENINGITIS: BACTERIAL, VIRAL, AND OTHER

MORTON N. SWARTZ AND AVINDRA NATH

BACTERIAL MENINGITIS

DEFINITION

Meningitis is an inflammation of the arachnoid membrane, the pia mater, and the intervening cerebrospinal fluid (CSF). The inflammatory process extends

throughout the subarachnoid space around the brain and spinal cord and involves the ventricles. Pyogenic meningitis is usually an acute bacterial infection that evokes a polymorphonuclear response in CSF. By comparison, tuberculous meningitis (Chapter 332) is often subacute and characterized initially by a modest polymorphonuclear pleocytosis that rapidly evolves to lymphocytic predominance.

EPIDEMIOLOGY

The incidence of bacterial meningitis has dropped dramatically in developed countries since the introduction of vaccines against bacterial pathogens such as *Haemophilus influenzae* type b (Chapter 308), *Streptococcus pneumoniae* (Chapter 297), and *Neisseria meningitidis* (Chapter 306). Worldwide, however, bacterial meningitis remains a major cause of mortality and morbidity. Although all human microbes have the potential to cause meningitis, only a few organisms account for most cases of bacterial meningitis.

The clinical setting in which meningitis develops may provide a clue to the specific bacterial cause. *H. influenzae* (Chapter 308) affects primarily children, whereas *S. pneumoniae* (Chapter 297) causes meningitis in adults, especially those older than 50 years with comorbid conditions. Meningococcal meningitis (Chapter 306) most often occurs in outbreaks. In developed countries, *Listeria monocytogenes* (Chapter 301) is emerging as the most common cause of bacterial meningitis, with peak frequencies in the neonatal period and in persons 60 years of age and older. Simultaneous mixed bacterial meningitis is rare but occurs in the setting of neurosurgical procedures, penetrating head injury, head trauma with fracture of the cribriform plate, erosion of the skull or vertebrae by adjacent neoplasm, extension of osteomyelitis, or intraventricular rupture of a cerebral abscess; isolation of anaerobes should strongly suggest the latter two of these situations. Meningitis involving anaerobes may also occur very rarely as a result of an intestinal-meningeal fistula following surgery and radiation therapy for colorectal cancer. In approximately 10% of patients with pyogenic meningitis, the bacterial cause cannot be defined.

Over the past several decades, gram-negative bacillary meningitis has doubled in frequency in adults, a change reflecting more frequent and extensive neurosurgical procedures, as well as other nosocomial factors. *L. monocytogenes* has increased 8- to 10-fold as a cause of bacterial meningitis in large urban general hospitals. *Listeria* infections are most often food-borne via dairy products, processed meats, uncooked vegetables, and precut salads. Although *Listeria* meningitis may occur in immunocompetent individuals, it occurs mostly in organ transplant recipients, patients undergoing hemodialysis, patients receiving corticosteroids or cytotoxic drugs for treatment of cancer or autoimmune diseases, patients with liver disease, alcoholic patients, pregnant women, and neonates. Meningitis caused by coagulase-negative staphylococci, which represents approximately 3% of cases in large urban hospitals, occurs as a complication of neurosurgical procedures and is often caused by methicillin-resistant strains. *Streptococcus viridans*, *Pseudomonas*, and other gram-negative bacteria are the agents most often associated with meningitis that complicates diagnostic myelography and percutaneous trigeminal rhizotomy.

In large tertiary care hospitals, approximately 40% of cases of bacterial meningitis in adults are of nosocomial origin. The leading causes are gram-negative bacilli (primarily *Escherichia coli* and *Klebsiella*), which account for approximately 40% of nosocomial episodes, as well as various streptococci, *Staphylococcus aureus*, and coagulase-negative staphylococci, each responsible for approximately 10% of nosocomial cases.

Meningococcal disease, including meningitis, may occur sporadically and in cyclic outbreaks. High-risk groups include individuals who live in close quarters such as crowded classrooms, college dormitories, military barracks, or jails. The meningococcal vaccine is about 85% protective. In industrialized countries, serogroups B and C account for the majority of infections. In developing countries, serogroups A and, to a lesser extent, C are dominant. In sub-Saharan Africa, the so-called meningitis belt, recurrent yearly waves of serogroup A meningococcal infections can occur.

Predisposing factors for the development of pneumococcal meningitis include acute otitis media (Chapters 297 and 434), with or without mastoiditis, which is seen in approximately 20% of adult patients. Pneumonia is present in approximately 15% of patients with pneumococcal meningitis, a much higher frequency than in meningitis caused by *H. influenzae* or *N. meningitidis*. Acute pneumococcal sinusitis (Chapter 434) is occasionally the initial focus from which infection spreads to the meninges. A recent or remote major head injury (Chapter 406) precedes approximately 10% of episodes of pneumococcal meningitis, and CSF rhinorrhea (usually caused by a defect or fracture in the cribriform plate) is present in approximately 5% of patients. Cochlear implants, particularly those that include a positioner, have been implicated in cases of childhood bacterial meningitis, especially episodes resulting from *S. pneumoniae*. Occasionally, meningitis caused by *S. pneumoniae* develops in patients with central nervous system (CNS) shunts. Splenectomy or splenic dysfunction, as in sickle cell anemia (Chapter 166) or in cirrhosis (Chapter 156) with portal hypertension, or other defects in humoral immunity also predispose patients to pneumococcal meningitis. Alcoholism (Chapter 32) is an underlying problem in 10 to 25% of adults with pneumococcal meningitis in urban hospitals. The estimated annual incidence of bacterial meningitis (primarily pneumococcal) in patients infected with human immunodeficiency virus (HIV) is 150-fold higher than in the general population.

S. aureus meningitis is seen most commonly as a complication of a neurosurgical procedure, after penetrating skull trauma, or occasionally secondary to staphylococcal bacteremia and endocarditis. Meningitis attributable to gram-negative bacilli takes one of three forms: neonatal meningitis, meningitis after trauma or neurosurgery, or spontaneous meningitis in adults (e.g., bacteremic *Klebsiella* meningitis in a patient with diabetes mellitus). The most common causes of gram-negative bacillary meningitis in adults are *E. coli* (≈30%) and *Klebsiella-Enterobacter* (≈40%). Meningitis caused by group A streptococci is uncommon but occasionally occurs after acute otitis media, more often in children than in adults. *H. influenzae* type b meningitis in an adult should raise the question of the presence of an underlying anatomic or immunologic defect.

Patients with defects in cell-mediated immunity are susceptible to the development of CNS infections with intracellular organisms such as *L. monocytogenes*. Patients with defective humoral immunity and an inadequate antibody response are particularly vulnerable to meningitis with *S. pneumoniae* and *H. influenzae*. Patients with neutropenia are at higher risk for meningitis with *Pseudomonas aeruginosa* and members of the Enterobacteriaceae family.

PATHOBIOLOGY

Pathology

On gross examination, purulent exudate in the subarachnoid space is most abundant in the cisterns at the base of the brain and over the convexities of the rolandic and sylvian sulci, which are expansions of the subarachnoid space. Although neither the infecting organism nor the inflammatory exudate directly invades cerebral tissue, the subjacent brain becomes congested and edematous. The effectiveness of the pial barrier generally prevents bacterial meningitis from causing a cerebral abscess; when these two processes coexist, the sequence is usually that an initial abscess leaks its contents into the ventricular system and produces secondary meningitis.

The inflammatory exudate can extend around the perivascular spaces to adjacent structures, especially the arteries and veins that carry a layer of pia mater and arachnoid membrane as they enter the brain from the cortical surface. *Cortical thrombophlebitis* results from venous stasis and adjacent meningeal inflammation. Infarction of cerebral tissue may follow. *Involvement of cortical and pial arteries* by peripheral aneurysm formation and vascular occlusion or narrowing (related to spasm, arteritis, or both) of the supraclinoid portion of the internal carotid artery at the base of the brain occurs in approximately 15% of patients with meningitis. The anterior and middle cerebral arteries may have markedly increased intracerebral blood flow velocity (an index of stenosis or arterial spasm) on transcranial Doppler ultrasonography, a finding corresponding to focal cerebral signs. In fulminating cases, particularly meningococcal meningitis, *cerebral edema* may be marked even though the pleocytosis is only moderate. Rarely, temporal lobe herniation through the tentorium develops in such patients and compresses the midbrain, thereby leading to ipsilateral third nerve palsy and contralateral hemiparesis or cerebellar herniation through the foramen magnum with compression of the medulla, which results in apnea, hemodynamic instability, and coma. *Damage to cranial nerves* occurs in areas where dense exudate accumulates around the nerves; the third and sixth cranial nerves are also vulnerable to damage by increased intracranial pressure. *Ventriculitis*, which probably occurs in most cases of bacterial meningitis, rarely progresses to *ventricular empyema*. As the exudates continue to accumulate, obstruction of the flow of CSF may result in *hydrocephalus*. Obstruction of the foramina of Magendie and Luschka at the base of the fourth ventricle results in noncommunicating or obstructive hydrocephalus, whereas obstruction at the level of the arachnoid granulations in the venous sinuses results in communicating hydrocephalus. *Subdural effusions* are sterile transudates that develop over the

cerebral cortex and can be demonstrated readily by computed tomography (CT) as low-density areas about the cerebrum; rarely, such effusions become infected and produce subdural empyema.

Pathogenesis

Bacteria may gain access to the meninges by several routes: (1) hematogenous spread from a distant site, (2) direct ingress from the upper respiratory tract or skin through an anatomic defect (e.g., skull fracture, eroding sequestrum, meningocele, sequela of surgery), (3) passage intracranially through venules in the nasopharynx, or (4) spread from a contiguous focus of infection (infection of the paranasal sinuses, leakage of a brain abscess). Bacteremic spread of *H. influenzae*, *N. meningitidis*, and *S. pneumoniae* is probably the most frequent path of infection. Bacteremia is usually initiated by pharyngeal adhesion and colonization by an infecting strain. Adhesion of such strains, as well as of *S. pneumoniae*, to mucosal surfaces is abetted by their capacity to produce proteases that cleave immunoglobulin A, thus inactivating this local antibody defense. Adhesion of *N. meningitidis* to nasopharyngeal cells is affected by fimbriae or pili and promoted by previous damage to ciliated cells such as from smoking or viral infections. Meningococci invade the nasopharyngeal mucosal cells by means of endocytosis and are transported to the abluminal side in membrane-bound vacuoles. *H. influenzae*, in contrast, invades intercellularly by causing separation of the apical tight junctions between columnar epithelial cells. When these meningeal pathogens gain access to the blood stream, their intravascular survival is aided by the presence of polysaccharide capsules that inhibit phagocytosis and confer resistance to complement-mediated bactericidal activity.

The mechanism by which bacteria gain access to the subarachnoid spaces from blood appears to be related to specific adhesion molecules on brain endothelial cells. Once established in any part of the meninges, infection quickly extends throughout the subarachnoid space. Bacterial replication proceeds relatively unhindered because the low CSF levels of immunoglobulin and complement early in meningeal inflammation result in minimal or no opsonic or bactericidal activity and because surface phagocytosis of unopsonized organisms is meager in such a fluid environment. During meningitis, the concentrations of immunoglobulins in CSF increase but still remain relatively low. Secondary bacteremia may follow meningeal infection and may itself contribute to continuing further inoculation of CSF.

Bacterial meningitis following head trauma occurs because of a dural fistula from the nasal cavity, paranasal sinuses, or the middle ear to the subarachnoid space. The most frequent site is at the cribriform plate, where the bone is very thin and the dura is tightly adherent to the bone. Leakage of CSF results in CSF rhinorrhea and loss of smell.

Bacterial components (e.g., pneumococcal cell walls or lipoteichoic acid, *H. influenzae* lipopolysaccharide) are major elicitors of meningeal inflammation by causing release into the subarachnoid space of various pro-inflammatory cytokines such as interleukin-1 and tumor necrosis factor from endothelial and meningeal cells, macrophages, and microglia. Cytokines appear to enhance the passage of leukocytes by inducing several families of adhesion molecules that interact with the corresponding receptors on leukocytes. Cytokines can also increase the binding affinity of a leukocyte selectin, leukocyte adhesion molecule, for its endothelial cell receptor and may thereby further contribute to trafficking of neutrophils into the subarachnoid space.

In bacterial meningitis, neutrophils move into the subarachnoid space but are not able to control the bacterial infection because their phagocytic properties are inefficient as a result of a lack of opsonic and bactericidal activity. Within the subarachnoid space, neutrophils release products such as prostaglandins, matrix metalloproteinases, and free radicals that disrupt the endothelial intercellular tight junctions and the subendothelial basal lamina. The increased local vascular permeability of the blood-brain barrier may cause cerebral edema, which can also be caused by increased CSF pressure as a result of obstruction of CSF outflow because of interstitial inflammation at the level of the arachnoidal villi.

Cerebral blood flow, which depends on mean arterial pressure, appears to be increased in the very early stages of meningitis, but it subsequently decreases, substantially in some patients, in whom it may be responsible for ensuing neurologic injury. Localized regions of marked hypoperfusion, attributable to focal vascular inflammation or thrombosis, can occur in patients with normal blood flow. Impairment of cerebral blood flow autoregulation, as measured by transcranial Doppler ultrasonography of the middle cerebral artery, occurs in the early phase of acute bacterial meningitis and causes cerebral blood flow to correspond directly to mean arterial blood pressure, with attendant hyperperfusion or hypoperfusion of the brain. On recovery, the ability of the cerebral vasculature to maintain a constant level of perfusion despite variations in mean arterial pressure is restored.

CLINICAL MANIFESTATIONS

History

Acute-onset fever, generalized headache, vomiting, and stiff neck are common to many types of meningitis (Table 420-1). Most patients with community-acquired pyogenic meningitis have had an antecedent or accompanying upper respiratory tract infection or nonspecific febrile illness, acute otitis (or mastoiditis), or pneumonia. Myalgia, particularly in patients with meningococcal disease, backache, and generalized weakness are common symptoms. The illness usually progresses rapidly, with the development of confusion, obtundation, and loss of consciousness. Occasionally, the onset may be less acute, with meningeal signs being present for several days to a week.

General Physical Findings

Evidence of meningeal irritation is usually present as evidenced by a stiff neck, Kernig's sign, and Brudzinski's sign. Although the classic triad of fever, stiff neck, and change in mental status is present in only 44% of episodes, a combination of two of four symptoms (headache, fever, stiff neck, and altered mental status) is found in 95% of patients. The findings of meningitis may easily be overlooked in infants, obtunded patients, elderly patients with heart failure or pneumonia, or immunosuppressed individuals, who may have

TABLE 420-1 CHARACTERISTICS OF THE STUDY POPULATION*

CHARACTERISTIC	EPISODES OF MENINGITIS (*N* = 696)
Duration of symptoms <24 hr	48%
Predisposing conditions	
Otitis or sinusitis	25%
Pneumonia	12%
Immunocompromise†	16%
Symptoms at initial evaluation	
Headache	87%
Nausea	74%
Neck stiffness	83%
Triad of fever, neck stiffness, and change in mental status	44%
Focal neurologic deficits	33%
Aphasia	23%
Hemiparesis	7%
Indices of CSF inflammation	
Opening pressure (mm H_2O)‡	370 ± 130
White cell count§	
Mean (cells/mm^3)	7753 ± 14,736
<100/mm^3	7%
100-999/mm^3	14%
>999/mm^3	78%
Protein (g/L)	4.9 ± 4.5
CSF/blood glucose ratio	0.2 ± 0.2
Positive blood culture‖	66%
Blood tests	
ESR (mm/hr)¶	46 ± 37
C-reactive protein (g/L)**	225 ± 132
Platelet count (platelets/mm^3)††	198,000 ± 100,000

*The study included 671 patients who had a total of 696 episodes of community-acquired meningitis. Plus-minus values are means ± standard deviation.
†Immunocompromise was defined by the use of immunosuppressive drugs, a history of splenectomy, or the presence of diabetes mellitus or alcoholism, as well as patients infected with human immunodeficiency virus.
‡CSF pressure was measured in 216 patients.
§The CSF leukocyte count was determined in 659 patients; CSF specimens from 14 patients had too many leukocytes for an exact count to be performed.
‖Blood culture was performed in 611 patients.
¶The ESR was determined in 549 patients.
**C-reactive protein levels were determined in 394 patients.
††The thrombocyte count was determined in 653 patients.
CSF = cerebrospinal fluid; ESR = erythrocyte sedimentation rate.
Data from 696 cases reported in van de Beek D, de Gans J, Spanjaard L, et al. Clinical features and prognostic factors in adults with bacterial meningitis. *N Engl J Med*. 2004;351:1849-1859.

meningitis without prominent meningeal signs; in such patients, lethargy should be investigated carefully, meningeal signs should be sought, and examination of CSF is indicated if any doubt exists. In elderly patients, neck stiffness may be difficult to evaluate because of osteoarthritis in the neck or stiffness of neck muscles secondary to basal ganglia disorders. When neck stiffness is caused by meningitis, the neck resists flexion but can be rotated passively from side to side; with cervical spine disease, however, resistance is present in all directions of neck movement. Neck stiffness disappears during coma.

The presence of a petechial or ecchymotic rash (see Fig. 306-3 in Chapter 306) in a patient with meningeal findings almost always indicates meningococcal infection and requires prompt treatment because of the rapidity with which this infection can progress (Chapter 306). Rarely, extensive petechial and ecchymotic lesions occur in meningitis caused by *S. pneumoniae*, *H. influenzae*, or echovirus type 9. Very rarely, skin lesions almost indistinguishable from those of meningococcal bacteremia occur in patients who have acute *S. aureus* endocarditis (see Fig. 76-1) and who also have meningeal signs and pleocytosis (secondary either to staphylococcal meningitis or to embolic cerebral infarction). Usually, one or two of the lesions in such a patient represent purulent purpura; aspiration of material reveals staphylococci on Gram staining. In the summer, viral aseptic meningitis may produce meningeal signs, macular and petechial skin lesions, and a pleocytosis of several hundred cells, sometimes with neutrophils predominating initially.

Fulminant meningococcal septicemia may cause hemorrhages within the adrenal glands and result in Waterhouse-Friderichsen syndrome (Chapter 234), a condition characterized by the sudden onset of a febrile illness, large petechial hemorrhages in the mucous membranes and skin, cardiovascular collapse, and disseminated intravascular coagulation. In contrast, hyponatremia and the syndrome of inappropriate secretion of antidiuretic hormone may develop in patients with meningitis attributable to *H. influenzae*. A concurrent respiratory tract infection or acute otitis media may be present with either *H. influenzae* or *S. pneumoniae*.

In patients with a basilar skull fracture, the potential for development of a dural fistula and bacterial meningitis is indicated by the presence of CSF rhinorrhea, periorbital ecchymoses, bruising behind the ear (Battle's sign), hemotympanum, or blood in the external auditory canal. Meningitis complicating neurosurgical procedures may be insidious in onset and difficult to distinguish from the altered consciousness and signs of meningeal irritation that are expected in the postoperative period. However, fever or prolonged obtundation is an indication for evaluation of CSF.

Neurologic Findings and Complications

Neurologic complications in patients with inadequately treated bacterial meningitis can be severe and disabling. Cranial nerve abnormalities, involving principally the third, fourth, sixth, or seventh nerve, occur in 5 to 10% of adults with community-acquired meningitis and usually disappear shortly after recovery. Persistent sensorineural hearing loss occurs in 10% of children with bacterial meningitis, and another 16% have transient conductive hearing loss. The most likely sites of involvement in patients with persistent sensorineural deafness appear to be the inner ear (infection or toxic products possibly spreading from the subarachnoid space along the cochlear aqueduct) and the acoustic nerve. In children, permanent hearing impairment is more common after meningitis caused by *S. pneumoniae* than by *H. influenzae* or *N. meningitidis*.

Seizures (focal or generalized; Chapter 410) occur in 20 to 30% of patients and may result from reversible causes (high fever or hypoglycemia in infants, penicillin neurotoxicity when large doses are administered intravenously to patients with renal failure) or, more commonly, from focal cerebral injury related to arterial hypoperfusion and infarction, cortical venous thrombosis, or focal edema and cerebritis. Seizures can occur during the first few days or can appear with associated focal neurologic deficits caused by vascular inflammation some days after onset of the meningitis. In adults with seizures accompanying meningitis, *S. pneumoniae* is more commonly the cause, but alcohol withdrawal is a confounding factor.

Increased CSF pressure, which can be caused by brain swelling or hydrocephalus, is associated with seizures, vomiting, sixth and third nerve dysfunction, abnormal reflexes, reduced consciousness or coma, dilated and poorly reactive pupils, and the Cushing response of decerebrate posturing, hypertension, bradycardia, and irregular respirations. In approximately a fourth of fatal cases of community-acquired meningitis in adults, cerebral edema accompanied by temporal lobe herniation is observed at autopsy.

Papilledema (see Fig. 431-27 in Chapter 431) occurs in less than 1% of patients with bacterial meningitis, even with high CSF pressure, probably because the patient is seen early in the process before changes in the nerve head have occurred. The presence of this sign should indicate the possibility of another associated or independent suppurative intracranial process, such as subdural empyema or brain abscess. Marked central hyperpnea sometimes occurs in patients with severe bacterial meningitis; CSF acidosis, which is principally due to increased lactic acid levels, provides much of the respiratory stimulus.

Focal cerebral signs (principally hemiparesis, dysphasia, visual field defects, and gaze preference) occur in approximately a third of adults with community-acquired bacterial meningitis. These signs may develop because of arterial or venous occlusion. In addition, cerebral blood flow velocity may be decreased in patients with increased intracranial pressure and may lead to temporary or lasting neurologic dysfunction. It is important to distinguish these vascular effects from postictal changes (Todd's paralysis), which usually persist for less than a day. Meningitis may also cause the syndrome of inappropriate secretion of antidiuretic hormone.

DIAGNOSIS

Bacterial meningitis is a medical emergency that requires immediate diagnosis and rapid institution of antimicrobial therapy. Delay in treatment is the most critical factor in determining the morbidity and mortality of patients with bacterial meningitis. The diagnosis of bacterial meningitis is not difficult in a febrile patient with meningeal symptoms and signs developing in the setting of a predisposing illness. The diagnosis may be less obvious in an elderly, obtunded patient with pneumonia or a confused alcoholic patient in impending delirium tremens.

When the diagnosis of bacterial meningitis is entertained, blood cultures should be performed, CSF examined and cultured, and antimicrobial therapy instituted promptly. If a mass lesion (cerebral abscess, subdural empyema) is suspected from the history, clinical setting, or physical findings (papilledema, focal cerebral signs), CT with or without contrast enhancement or magnetic resonance imaging (MRI) should be performed because of the danger of brain herniation with lumbar puncture. Antibiotics can and commonly should be started immediately, even before performing lumbar puncture, because it takes approximately 2 hours for antibiotics to affect CSF cultures. Diagnostic lumbar puncture should not be delayed to perform CT or MRI except in patients who have focal neurologic findings suggestive of a parameningeal collection or other intracranial mass lesions; in such patients, it is critical to initiate antimicrobial therapy for meningitis of unknown origin or brain abscess before CT or MRI is performed. Patients with community-acquired meningitis rarely have important abnormalities detected on CT in the absence of focal neurologic findings.

Laboratory Findings

Cerebrospinal Fluid Examination

Initial CSF pressure is usually moderately elevated (200 to 300 mm H_2O in adults). Striking elevations (≥450 mm H_2O) occur in occasional patients with acute brain swelling complicating meningitis in the absence of an associated mass lesion. Findings on CSF analysis are strikingly abnormal in patients with meningitis, and such findings help suggest the cause even before the results of culture are available (Table 420-2). In patients with skull fractures, CSF rhinorrhea can be distinguished from nasal secretions by the presence of glucose.

Gram-Stained Smear

By the time of hospitalization, most patients with pyogenic meningitis have large numbers (≥10^5/mL) of bacteria in their CSF. Careful examination of the Gram-stained smear of the spun sediment of CSF reveals the etiologic agent in 60 to 80% of cases. In most instances when gram-positive diplococci (or short-chain cocci) are observed on a stained CSF smear, they are pneumococci. In certain clinical settings, it is important to distinguish pneumococci from the relatively penicillin-resistant *Enterococcus*, an occasional cause of nosocomial meningitis, by latex particle agglutination. Rarely, three species may morphologically mimic *Neisseria* in CSF or may suggest a mixed infection with short gram-negative rods and meningococci: *Acinetobacter baumannii*, *Moraxella* sp, and *Pasteurella multocida*. Culture of CSF reveals the etiologic agent in 80 to 90% of patients with bacterial meningitis if CSF is obtained before or within 1 to 2 hours of the initiation of antibiotics.

TABLE 420-2 COMMON CEREBROSPINAL FLUID FINDINGS IN PATIENTS WITH MENINGITIS

MICROORGANISM	CSF OPENING PRESSURE (cm H_2O)	CELL COUNT (CELLS/mm^3)	PROTEIN (mg/dL)	GLUCOSE (mg/dL)
Bacteria*	>20	>1000	>100	<10
Mycobacterium tuberculosis	>20	100-500	>100	10-45
Borrelia burgdorferi	<20	100-500	50-150	10-45
Treponema pallidum	<20	5-500	50-150	10-45
Fungi	<20	5-500	>100	10-45
Viruses	<20	5-500	50-150	Normal

*Group B streptococci, *Escherichia coli, Listeria monocytogenes, Streptococcus pneumoniae, Neisseria meningitidis*, and *Haemophilus influenzae* type b.
CSF = cerebrospinal fluid.
Adapted from Kim KS. Acute bacterial meningitis in infants and children. *Lancet Infect Dis*. 2010;10:32-42.

Special Testing Procedures

Broad-range polymerase chain reaction (PCR), which can be performed on CSF within 1.5 hours, can diagnose bacterial meningitis in patients in whom antimicrobial therapy was begun before lumbar puncture or when cultures are negative and a bacterial origin is still suspected. However, specific real-time PCR for the diagnosis of pneumococcal and meningococcal meningitis is currently available only in the research setting. The sensitivity and specificity of rapid antigen testing by latex agglutination are highest (>90%) for *H. influenzae*, lower for *S. pneumoniae*, and considerably lower for *N. meningitidis*. Gram-stained smears almost invariably show the causative microorganism when the latex agglutination test result is truly positive, so latex agglutination is not used routinely for the diagnosis of bacterial meningitis. However, latex agglutination testing may be very useful when the CSF cell count is abnormal, the Gram stain is negative, and blood and CSF cultures are unrevealing at 48 hours, at which time a stored sample of the initial CSF specimen can be tested. Occasionally, when only rare organisms of ambiguous morphology or Gram-staining properties are seen, latex agglutination may be helpful in providing a more specific diagnosis. Other promising new techniques include a nucleic acid amplification technique, which may be useful in resource-poor settings, and a rapid immunochromatographic test for *S. pneumoniae*.

Cell Count

Cells counts should be determined promptly because the cells will begin to lyse after 90 minutes. The normal CSF white blood cell count is less than 5/mm^3 (all mononuclear). The cell count in untreated meningitis usually ranges between 100 and 10,000/mm^3, with polymorphonuclear leukocytes predominating initially (>80%) and lymphocytes appearing subsequently.

The cell count in *L. monocytogenes* meningitis tends to be lower (median, 585/mm^3) than in other types of community-acquired pyogenic meningitis. Extremely high cell counts (>50,000/mm^3) should raise the possibility of intraventricular rupture of a cerebral abscess. Cell counts as low as 10 to 20/mm^3 may be observed early in bacterial meningitis, particularly that caused by *N. meningitidis* and *H. influenzae*. Occasionally, in granulocytopenic patients or in elderly persons with overwhelming pneumococcal meningitis, CSF may contain very few leukocytes and yet may appear grossly turbid because of the presence of a myriad of organisms and an elevated protein level. Meningitis caused by several bacterial species (*Mycobacterium tuberculosis*, *Borrelia burgdorferi*, *Treponema pallidum*, *Leptospira* sp, *Francisella tularensis*, *Brucella* sp) is characteristically associated with a lymphocytic pleocytosis. With *L. monocytogenes* meningitis in an adult, there is usually a polymorphonuclear response, but lymphocytes may predominate in rare instances.

Glucose

CSF glucose is reduced to values of 40 mg/dL or less (or <50% of the simultaneous blood level) in 50% of patients with bacterial meningitis; this finding can be valuable in distinguishing bacterial meningitis from most viral meningitides or parameningeal infections. However, a normal CSF glucose value does not exclude the diagnosis of bacterial meningitis. The blood glucose level should be determined simultaneously because patients with diabetes mellitus (or those who are receiving intravenous glucose infusions) have an elevated CSF glucose level that can be appreciated only by comparison with the simultaneous blood level; however, it may take 90 to 120 minutes for equilibration to occur after major shifts in the level of glucose in the circulation. The hypoglycorrhachia characteristic of pyogenic meningitis appears to result from interference with normal carrier-facilitated diffusion of glucose and increased utilization of glucose by host cells.

Protein

The level of protein in lumbar CSF is usually elevated to greater than 100 mg/dL, and higher values are more commonly observed in pneumococcal meningitis. Extreme elevations, 1000 mg/dL or greater, may indicate subarachnoid block with obstruction of CSF flow. Values higher than 15 mg/dL in ventricular CSF are considered abnormal. If the lumbar puncture is traumatic, the CSF protein level is corrected by subtracting 1 mg/dL for every 1000 red blood cells.

Other Abnormalities

Elevated levels of lactic acid occur in pyogenic meningitis, but other conditions (cerebral ischemia, metabolism of CSF neutrophils, hypoxia) may also increase CSF lactate concentrations. Although lactate dehydrogenase levels are higher in patients with bacterial meningitis than in patients with viral infections of the CNS, these alterations are not helpful in determining the specific etiologic agent.

Blood and Respiratory Tract Cultures

Bacteremia is demonstrable in approximately 80% of patients with *H. influenzae* meningitis, 50% of patients with pneumococcal meningitis, and 30 to 40% of patients with meningococcal meningitis. Hence, blood cultures should be performed routinely in patients suspected of having bacterial meningitis. Cultures of the upper respiratory tract are not helpful in establishing an etiologic diagnosis.

Determination of serum creatinine and electrolyte levels is important in view of the gravity of the illness, the occurrence of specific abnormalities secondary to the meningitis (syndrome of inappropriate secretion of antidiuretic hormone), and problems with therapy in patients with renal dysfunction (seizures and hyperkalemia with high-dose penicillin therapy). In patients with extensive petechial and purpuric skin lesions, evaluation for coagulopathy is indicated. Elevated serum procalcitonin levels have been used to distinguish bacterial meningitis from that of viral origin, but CSF examination (Gram stain, white blood cell count, glucose, culture) usually provides more direct and specific information.

Radiologic Studies

Because of the frequency with which pyogenic meningitis is associated with primary foci of infection in the chest, nasal sinuses, or mastoid, radiographs of these areas should be taken when clinically indicated at the appropriate time after antimicrobial therapy is begun. Initial head CT or MRI is not indicated in most patients with bacterial meningitis. For example, in patients who undergo head CT or MRI before lumbar puncture for suspected meningitis, only approximately 5% have a mass effect identified on CT. Baseline clinical features associated with abnormal findings on CT include age older than 60 years, history of CNS disease, seizure within the previous week, abnormal level of consciousness, abnormal visual fields, limb drift, and aphasia. In patients without any of these clinical findings, only approximately 1% have a mass effect identified on CT or MRI that would raise concern regarding lumbar puncture.

Specific changes that may be observed on CT or MRI during meningitis include cerebral edema and enlargement of the subarachnoid spaces, contrast enhancement of the leptomeninges and the ependyma, or patchy areas of diminished density as a result of associated cerebritis and necrosis. In patients

with meningitis whose clinical status deteriorates or fails to improve, CT or MRI may help demonstrate suspected complications: sterile subdural collections or empyema; ventricular enlargement secondary to communicating or obstructive hydrocephalus; prominent persisting basilar meningitis; extensive areas of cerebral infarction resulting from occlusion of major cerebral arteries, veins, or venous sinuses; or marked ventricular wall enhancement suggesting ventriculitis or ventricular empyema. MRI is superior to CT for visualizing these abnormalities. Rarely, cerebral hemorrhage identifiable on CT may complicate acute bacterial meningitis in adults. In approximately 10% of adults with bacterial meningitis, findings on cranial CT (mastoid or sinus wall defect, eroding retrobulbar mass, pneumocephalus) are indicative of disruption of the dural barrier.

Rarely, paraparesis or tetraparesis resulting from myelitis may complicate bacterial meningitis. In this situation, T2-weighted or short tau inversion recovery (STIR) sequences on MRI can be helpful to exclude spinal cord compression by an extramedullary mass.

Differential Diagnosis

Headache, fever, stiff neck, confusion, vomiting, and pleocytosis are features of meningeal inflammation and are common to many types of meningitis (e.g., bacterial, fungal, viral, chemical) and also to some parameningeal processes. The CSF findings are most helpful in distinguishing among these processes (Chapters 421 and 422). Although a lymphocyte-predominant pleocytosis without hypoglycorrhachia is characteristic of viral (usually enteroviral or herpes simplex virus type 2 [HSV-2]) meningitis or meningoencephalitis (HSV-1), the initial CSF finding may be a polymorphonuclear response (of ≤60%) that quickly becomes mononuclear. HSV-1 encephalitis is suggested by neurologic findings (dysphasia, hemiparesis, olfactory hallucinations, other temporal lobe signs, seizures), abnormalities in the orbitofrontal and medial temporal lobes on MRI, and distinctive electroencephalographic changes in the temporal lobe or lobes. The rash, fever, and headache of Rocky Mountain spotted fever (Chapter 335) may suggest meningococcal infection, but the geographic and seasonal predilections of the former can provide clues. Approximately 10% of patients hospitalized with Rocky Mountain spotted fever have CSF cell counts higher than 100/mm^3 (>70% polymorphonuclear), and thus the condition may initially be confused with bacterial meningitis. The rash associated with enteroviral infections typically consists of erythematous macules and papules on the face, neck, and trunk. Acute subarachnoid hemorrhage (Chapter 415) may be confused with bacterial meningitis because of headache, stiff neck, and vomiting. However, subarachnoid hemorrhage usually has a more abrupt onset without a prodromal fever but with evidence of subarachnoid blood on CT or CSF examination. In patients with neuroleptic malignant syndrome (Chapters 417 and 427), fever, generalized rigidity, and a fluctuating level of consciousness with autonomic instability and leukocytosis may develop. The most specific laboratory abnormality in these patients is a markedly elevated creatine kinase level.

In a patient with meningitis but whose CSF does not reveal the etiologic agent on a Gram-stained smear, particularly when the CSF glucose level is normal and the polymorphonuclear pleocytosis is atypical, certain treatable processes that can mimic bacterial meningitis should be considered in the differential diagnosis:

1. *Parameningeal infections.* The presence of infections (chronic ear or nasal accessory sinus infections, lung abscess) predisposing to brain abscess, epidural (cerebral or spinal) abscess, subdural empyema, or pyogenic venous sinus phlebitis should be sought (Chapter 421). Neurologic symptoms may appear in the course of primary bacterial meningitis, but their presence should alert the physician to the need for close scrutiny for the presence of a space-occupying infectious process in the CNS. Neurologic symptoms or findings antedating the onset of meningeal symptoms should suggest the possibility of a parameningeal infection. Isolation of an anaerobic organism should suggest the possibility of intraventricular leakage of a cerebral abscess.
2. *Bacterial endocarditis.* Bacterial meningitis may occur during bacterial endocarditis (Chapter 76) caused by pyogenic organisms such as *S. aureus* and enterococci. In subacute bacterial endocarditis, sterile embolic infarctions of the brain may produce meningeal signs and a pleocytosis consisting of several hundred cells, including polymorphonuclear leukocytes. A history of dental manipulation, fever, and anorexia antedating the meningitis should be sought; careful examination for heart murmurs and peripheral stigmata of endocarditis is indicated.
3. *"Chemical" meningitis.* The clinical and CSF findings (polymorphonuclear pleocytosis and even reduced glucose level) of bacterial meningitis may be produced by chemically induced inflammation. Acute meningitis after diagnostic lumbar puncture or spinal anesthesia may result from bacterial or chemical contamination of equipment or anesthetic agent. Chemical meningitis, characterized by polymorphonuclear pleocytosis, hypoglycorrhachia, and a latent period of 3 to 24 hours, occurs after 1% of metrizamide myelograms. Endogenous chemical meningitis resulting from material from an epidermoid tumor or a craniopharyngioma leaking into the subarachnoid space can produce polymorphonuclear pleocytosis and hypoglycorrhachia; birefringent material may be seen on polarizing microscopy of the CSF sediment.

Complications

Non-neurologic Complications

Shock

When shock occurs in patients with pyogenic meningitis, it is usually a manifestation of the accompanying intense bacteremia, as in fulminant meningococcemia, rather than a manifestation of the meningitis itself. Management is guided by the principles of septic shock therapy (Chapter 108), with appropriate modifications in patients with heart failure (Chapter 59).

Coagulation Disorders

Coagulopathies (Chapter 177) are frequently associated with the intense bacteremia (usually meningococcal, occasionally pneumococcal) and hypotension that can accompany meningitis. The changes may be mild, such as thrombocytopenia (with or without prolongation of the prothrombin and partial thromboplastin times), or more marked, with clinical evidence of disseminated intravascular coagulation (Chapter 178).

Septic Complications

Endocarditis

In patients with pneumococcal meningitis, particularly those with concomitant bacteremia and pneumonia, acute endocarditis (Chapter 76) can develop, most commonly on the aortic valve. In such patients, febrile relapse and a new cardiac murmur may appear shortly after the completion of antimicrobial therapy for meningitis.

Pyogenic Arthritis

Septic arthritis may result from the bacteremia associated with meningitis caused by *S. pneumoniae, N. meningitidis*, or *H. influenzae*.

Prolonged Fever

With appropriate antimicrobial treatment of community-acquired bacterial meningitis, patients become afebrile within 2 to 5 days. Sometimes, however, the fever persists or recurs after an afebrile period. In a patient with persisting headache, obtundation, and cerebral findings, inadequate drug therapy or neurologic sequelae (cortical venous thrombophlebitis, ventriculitis, subdural collections) are important considerations. Re-evaluation of CSF, particularly Gram-stained smear and culture, is essential in these circumstances. Drug-induced fever (Chapters 262 and 288) should be suspected in patients who continue to show clinical improvement in all other respects. Metastatic infection (septic arthritis, purulent pericarditis, thoracic empyema, endocarditis) may be the cause of continuing or recurrent fever. A syndrome, probably immunologic, consisting of fever, arthritis, and pericarditis 3 to 6 days after the initiation of effective antimicrobial therapy for meningococcal meningitis occurs in approximately 10% of patients (Chapter 306).

Recurrent Meningitis

Repeated episodes of bacterial meningitis generally indicate a host defect, either in local anatomy or in antibacterial and immunologic defenses (e.g., recurrent *N. meningitidis* infections in patients with congenital or acquired deficiencies of complement, particularly the late-acting components). Approximately 10% of episodes of pneumococcal meningitis in adults are recurrent meningitis, but only 0.5% of patients with community-acquired meningitis caused by other microorganisms have recurrent attacks. *S. pneumoniae* is the cause of a third of episodes of community-acquired recurrent meningitis; various streptococci, *H. influenzae*, and *N. meningitidis* are the cause of another third of episodes. In contrast, in nosocomial recurrent meningitis, gram-negative bacilli and *S. aureus* are the cause of approximately 60% of episodes. A history of head trauma is much more frequent in patients with recurrent meningitis. Organisms may enter the subarachnoid space directly, through a defect in the cribriform plate (the most common site),

in association with the empty sella syndrome, by means of a basilar skull fracture, through an erosive sequestrum of the mastoid, through congenital dermal defects along the craniospinal axis (usually evident before adult life), or as a consequence of penetrating cranial trauma or neurosurgical procedures. The anatomic defect may produce a frank CSF leak (rhinorrhea or, less commonly, otorrhea) or may entrap a vascular cuff of meninges that may subsequently serve as a direct route for organisms to reach the meninges. CSF rhinorrhea may be intermittent, and meningitis may occur months or years after head injury.

Any patient with bacterial meningitis, particularly if the meningitis is recurrent, should be evaluated carefully for congenital or post-traumatic defects. The presence of CSF rhinorrhea should be sought at admission and subsequently (rhinorrhea may clear during active meningitis only to recur when the inflammation has resolved). Clinical clues suggesting the presence of a CSF fistula through the cribriform plate, pericranial air sinuses, or temporal bone include (1) a salty taste in the throat, (2) positionally dependent rhinorrhea (rhinorrhea only in the lateral recumbent or prone position suggests an otic or sphenoid origin), (3) anosmia (cribriform plate leak), and (4) hearing loss or full feeling in the ear, often with a finding of fluid or bubbles behind the tympanic membrane (leakage into the middle ear). Quantitative determination of the glucose and chloride content of nasal secretions and detection of a transferrin band unique to CSF by protein electrophoresis can definitively establish the presence of CSF rhinorrhea.

Recurrent pneumococcal meningitis may develop without apparent predisposing circumstances, and cryptic CSF leaks should be sought actively in such patients by CT of the frontal and mastoid regions and by radioisotope techniques. Radioiodine-labeled albumin is introduced intrathecally, and pledgets of cotton placed in the nares are subsequently examined for the radionuclide. Intrathecal introduction of fluorescein as a visual tracer (under ultraviolet light) can similarly be used to detect active leaks. Surgical closure of CSF fistulas should be performed to prevent further episodes of meningitis. Extracranial approaches through the ethmoidal sinuses can be used to repair cribriform plate or sphenoidal sinus dural defects and avoid the higher morbidity associated with craniotomy.

In most patients with CSF otorrhea and rhinorrhea after an acute head injury, the leak ceases in 1 or 2 weeks. *Persistent rhinorrhea for more than 4 to 6 weeks is an indication for surgical repair.* Prolonged administration of penicillin does not prevent pneumococcal meningitis and may encourage infection with more drug-resistant species.

TREATMENT

Rx

Antimicrobial Agents

Antimicrobial therapy should be initiated promptly in this life-threatening emergency. Subsequent management should be undertaken with close monitoring, often in an intensive care unit. Treatment should be aimed at the most likely causes based on clinical clues, such as the age of the patient, the presence of a petechial or purpuric rash, a recent neurosurgical procedure, and CSF rhinorrhea. However, it is difficult to distinguish among the various causes of bacterial meningitis on clinical grounds alone, although patients with pneumococcal meningitis frequently have altered mental status and progress rapidly to coma, often with recurrent seizures and the rapid development of focal neurologic deficits. If the infecting organism is observed on examination of a Gram-stained smear of the CSF sediment, specific therapy is initiated. If the etiologic agent is not seen on a smear from a patient with suspected bacterial meningitis or if lumbar puncture is delayed because head CT is needed, empirical antimicrobial therapy should be initiated (Table 420-3).

Adequate CSF bactericidal activity, which is critical to cure the meningitis, depends on the ability of the antibiotic to penetrate CSF and to maintain its activity in the purulent exudate, as well as on its metabolism and rate of clearance from CSF. The ability of the antibiotic to penetrate CSF depends on its lipid solubility, protein binding in serum, molecular size, and the status of the blood-CSF barrier. For example, chloramphenicol has very high lipid solubility, whereas β-lactam antibiotics have poor solubility. With the exception of rifampin and chloramphenicol, the commonly used antimicrobial agents do not readily penetrate the normal blood-brain barrier, but the passage of penicillin and other antimicrobial agents is enhanced in the presence of meningeal inflammation (Table 420-4). Antimicrobial drugs should be administered intravenously throughout the treatment period; the dose should not be reduced as the patient improves because normalization of the blood-brain barrier during recovery reduces the achievable CSF drug levels. Bactericidal drugs (penicillin, ampicillin, third-generation cephalosporins) are preferred whenever possible, and CSF levels of antibiotics at least 10 to 20 times the minimal bactericidal concentration are needed for optimal therapy. Some antibiotics are removed from CSF by active transport into blood via the epithelium of the choroid plexus; by comparison, third-generation cephalosporin antibiotics persist in CSF for longer periods. Antimicrobial drugs (first- or second-generation cephalosporins, clindamycin) do not provide effective levels in CSF and should not be used.

Empirical Treatment

Initial treatment of presumed bacterial meningitis when the etiologic agent cannot be identified on a Gram-stained smear of CSF is based on the available clinical clues. In older children and adults, therapy with vancomycin and a third-generation cephalosporin (cefotaxime or ceftriaxone) is recommended (see Table 420-3). In adults older than 50 years and in high-risk groups, ampicillin is also added because of penicillin-resistant pneumococci, the increased frequency of aerobic gram-negative bacilli in nosocomial meningitis and meningitis in immunocompromised patients, and the possibility of *L. monocytogenes*, which is susceptible to ampicillin but not to third-generation cephalosporins. In a penicillin-allergic individual, trimethoprim-sulfamethoxazole is a suitable alternative for *Listeria* meningitis. In special settings, such as nosocomial meningitis associated with neurosurgical procedures or penetrating head trauma, more resistant species such as methicillin-resistant *S. aureus*, coagulase-negative staphylococci, and *P. aeruginosa* may be responsible; in these situations, vancomycin in addition to cefepime is indicated as initial therapy.

Meningitis of Specific Bacterial Cause

Pneumococcal Meningitis

The treatment of choice for pneumococcal meningitis in adults has historically been penicillin, with vancomycin (or chloramphenicol) being a reasonable alternative in patients allergic to penicillin (see later). However, penicillin-resistant pneumococcal strains are found worldwide, including 25% of clinical isolates in the United States. Thus, antimicrobial susceptibilities should be determined for all pneumococcal isolates from CSF, blood, or sterile body fluids (see Table 420-4). Approximately 9% of pneumococcal isolates from patients with meningitis in the United States are resistant to third-generation cephalosporins, with a minimal inhibitory concentration of 2 μg/mL or greater. If the minimal inhibitory concentration for cefotaxime or ceftriaxone (≤1.0 μg/mL) indicates a susceptible isolate, cefotaxime or ceftriaxone would be the drug of choice. If the isolate is highly penicillin resistant or is resistant to 1.0 μg/mL ceftriaxone or cefotaxime, alternative therapy (vancomycin with or without rifampin intravenously) is indicated. Because of the increasingly wide distribution of highly resistant strains, initial therapy (pending susceptibility testing) with cefotaxime (or ceftriaxone) in addition to vancomycin intravenously is recommended. When initial adjunctive therapy with dexamethasone is used (see later) along with vancomycin, it should be borne in mind that vancomycin levels in CSF may be reduced by concomitant corticosteroid use.

Although resistance to chloramphenicol is unusual in pneumococcal isolates from the United States, chloramphenicol has poor bactericidal activity against penicillin-resistant isolates from children with meningitis in South Africa. The relative chloramphenicol resistance of such strains may not be discerned on usual laboratory testing, but it is revealed when the minimum bactericidal concentration is determined. For this reason, vancomycin is preferred over chloramphenicol for the initial treatment of pneumococcal meningitis in a highly penicillin-allergic patient.

The β-lactam antibiotic meropenem is as effective as cefotaxime for meningitis caused by *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* in adults and in children. Cefepime is also similar to ceftriaxone and cefotaxime for infection with *S. pneumoniae*, *N. meningitidis*, and *H. influenzae*, and it has greater activity than these antibiotics against *Enterobacter* sp and *P. aeruginosa* (Table 420-5).

Meningococcal Meningitis

Intravenous administration of penicillin G and ampicillin, in doses used to treat meningitis caused by penicillin-susceptible pneumococci, successfully treats *N. meningitidis* meningitis resulting from susceptible strains. Meningococci resistant to penicillin have occasionally been isolated in Spain (≤50% of strains), South Africa, and Canada but rarely in the United States. Most of these isolates have been only intermediately resistant to penicillin (minimal inhibitory concentration of 0.1 to 1.0 μg/mL), although rare strains have had high-level resistance related to β-lactamase production and require third-generation cephalosporins such as ceftriaxone, which is as effective as the potentially more toxic chloramphenicol. Nevertheless, "meningitis doses" of penicillin or ampicillin may provide CSF levels that are sufficient for infections with some strains of intermediately penicillin-resistant *N. meningitidis*. Usually, a 7-day course of antibiotics is sufficient.

Haemophilus influenzae Meningitis

At present, 25 to 35% of isolates of *H. influenzae* type b in the United States are β-lactamase producers and are ampicillin resistant; cefotaxime or ceftriaxone is the initial therapy of choice (see Table 420-5). Alternatives include cefepime or the combination of chloramphenicol and ampicillin; if the isolate proves susceptible to ampicillin, chloramphenicol may be discontinued. Although more than 50% of isolates are chloramphenicol resistant in some

β-Lactamase positive	Ceftriaxone or cefotaxime	Cefepime, or chloramphenicol, or gatifloxacin, or moxifloxacin
Listeria monocytogenes	Ampicillin† or penicillin G†	Trimethoprim-sulfamethoxazole or meropenem
Streptococcus agalactiae (group B streptococci)	Ampicillin† or penicillin G†	Cefotaxime or ceftriaxone

*Addition of rifampin should be considered. Consider intrathecal (or intraventricular vancomycin, 5 to 20 mg/day) if not responding to intravenous therapy.
†Addition of intravenous gentamicin should be considered.
MIC = minimal inhibitory concentration.
From Tunkel AR, Hartman BJ, Kaplan SL, et al. IDSA practice guidelines for the management of bacterial meningitis. *Clin Infect Dis.* 2004;39:1267-1284.

areas of Spain, less than 1% of isolates have been found to be resistant in the United States. A 10-day course of antibiotics is usually sufficient.

Staphylococcal Meningitis

For the treatment of adult meningitis caused by methicillin-susceptible *S. aureus* or in a penicillin-allergic patient, vancomycin is the alternative of choice (Tables 420-6 and 420-7). Because penetration of vancomycin into CSF is limited, adjunctive intrathecal (or intraventricular) therapy with vancomycin (without preservative) is occasionally used when CSF cultures have remained positive after 48 hours of intravenous therapy alone and CSF levels can be monitored. For adult meningitis caused by methicillin-resistant *S. aureus*, intravenous vancomycin (with adjunctive intrathecal vancomycin as needed) is the treatment of choice. In severe or refractory cases, the addition of rifampin is warranted.

Listeria Meningitis

Ampicillin is the drug of choice for *Listeria* meningitis. When combined with gentamicin, it can have a synergistic bactericidal effect. Third-generation cephalosporins and vancomycin are not effective. In patients allergic to

TABLE 420-6 THERAPY FOR NOSOCOMIAL MENINGITIS OF KNOWN BACTERIAL CAUSE IN ADULTS

ORGANISM	THERAPY OF CHOICE	ALTERNATIVE THERAPY
Staphylococcus aureus		
Methicillin susceptible	Nafcillin or oxacillin; in difficult cases may add rifampin	Vancomycin or meropenem
Methicillin resistant	Vancomycin; in difficult cases may add rifampin	Linezolid or trimethoprim-sulfamethoxazole
Coagulase negative	Vancomycin; may consider addition of rifampin	Linezolid
Enterococcus sp		
Ampicillin susceptible	Ampicillin plus gentamicin	Vancomycin plus gentamicin
Ampicillin resistant	Vancomycin plus gentamicin	Linezolid
Ampicillin and vancomycin resistant	Linezolid	
Escherichia coli and other	Cefotaxime or ceftazidime	Meropenem or aztreonam or ampicillin or trimethoprim-sulfamethoxazole
Enterobacteriaceae*		
*Pseudomonas aeruginosa**	Cefepime or ceftazidime	Meropenem or aztreonam or ciprofloxacin

*Selection of specific antimicrobial drug should be based on in vitro susceptibility results, with consideration given to the addition of an aminoglycoside (e.g., tobramycin, gentamicin, or amikacin).

TABLE 420-7 DOSES OF ANTIMICROBIAL DRUGS FOR TREATMENT OF BACTERIAL MENINGITIS*

ANTIMICROBIAL DRUG	ADULTS (24-HR DOSE)	INFANTS AND CHILDREN (24-HR DOSE)
β-LACTAMS		
Penicillin G	24 million U, q4h aliquots	300,000 U/kg, q4h aliquots
Ampicillin	12 g, q4h aliquots	300 mg/kg, q4h aliquots
Nafcillin	10-12 g, q4h aliquots	200 mg/kg, q4h aliquots
Oxacillin	10-12 g, q4h aliquots	200 mg/kg, q4h aliquots
Aztreonam (a monobactam)	6-8 g, q6-8h aliquots	
Meropenem (a carbapenem†)	6 g, q8h aliquots	120 mg/kg, q8h aliquots
CEPHALOSPORINS		
Cefotaxime	12 g, q4h aliquots	200-300 mg/kg, q6h aliquots
Ceftriaxone‡	4 g, q12h aliquots	80-100 mg/kg, q12h aliquots
Ceftazidime	6 g, q8h aliquots	150 mg/kg, q8h aliquots
Cefepime	6 g, q6-8h aliquots	150 mg/kg, q8h aliquots
AMINOGLYCOSIDES		
Gentamicin§	5 mg/kg, q8h aliquots	7.5 mg/kg, q8h aliquots
Tobramycin§	5 mg/kg, q8h aliquots	7.5 mg/kg, q8h aliquots
Amikacin§	15 mg/kg, q8h aliquots	20-25 mg/kg, q8h aliquots
FLUOROQUINOLONES		
Ciprofloxacin	800-1200 mg, q8-12h aliquots	—
Gatifloxacin‖	400 mg, q24h dosing	—
Moxifloxacin‖	400 mg, q24h dosing	—
OTHERS		
Chloramphenicol	4-6 g, q6h aliquots	75-100 mg/kg, q6h aliquots
Vancomycin¶	2-3 g, q6-8h aliquots	50-60 mg/kg, q6h aliquots
Rifampin	600 mg, q24h dosing	10-20 mg/kg, q12-24h aliquots
Trimethoprim-sulfamethoxazole**	20 mg/kg, q6h aliquots	20 mg/kg, q6h aliquots
Linezolid	1200 mg, q12h aliquots	30 mg/kg, q8h aliquots

*Dosages are intravenous and for patients with normal renal and hepatic function.
†Use may be associated with seizures, but much less so than with imipenem.
‡Four-gram maximum daily dose.
§Peak and trough serum levels should be monitored.
‖No data are available on the optimal dosage required for bacterial meningitis.
¶Monitoring of trough serum levels is advisable; they should be maintained at concentrations of 15 to 20 μg/mL. If the patient is not responding well, one may need to monitor cerebrospinal fluid levels and, if low, temporarily increase the daily dose accordingly or add adjuvant intrathecal vancomycin (5 to 20 mg), as for the treatment of methicillin-resistant *Staphylococcus aureus* meningitis.
**Dosage based on the trimethoprim component of the combination.

ampicillin, intravenous trimethoprim-sulfamethoxazole may be used, followed by oral trimethoprim alone.

Gram-Negative Bacillary Meningitis

Cefotaxime or ceftriaxone (see Tabless 420-6 and 420-7) is used to treat meningitis known to be caused by susceptible gram-negative bacilli (e.g., *E. coli*, *Klebsiella*, *Proteus*), but they should not be used to treat meningitis caused by less susceptible species such as *P. aeruginosa* and *Acinetobacter*. After identifying the specific pathogen and determining its drug susceptibilities, alterations in antimicrobial therapy may be indicated. Although experience is limited, fluoroquinolones can also be used. If the organism is *P. aeruginosa*, ceftazidime or cefepime is recommended and may be combined with vancomycin (see Tables 420-6 and 420-7).

Zoonotic Meningitis

Uncommonly, systemic or bacteremic zoonotic infections are complicated by bacterial meningitis. *F. tularensis* (Chapter 319) meningitis, a rare complication of tularemia, develops approximately a week after the onset of infection. Illness is acquired from direct (or airborne) contact with wild rabbits or squirrels, with domestic animals, or through tick bites. Tularemia occurs throughout the United States, particularly in the Southeast and Midwest. CSF usually exhibits a lymphocytic pleocytosis (several hundred to 2000 cells/mm^3), hypoglycorrhachia, and increased protein concentration. Treatment of adults consists of chloramphenicol (4 g/day intravenously in 6-hour aliquots) in addition to either gentamicin (3 to 5 mg/kg/day intravenously in 8-hour aliquots) or streptomycin (15 mg/kg intramuscularly every 12 hours for 3 days followed by 7.5 mg/kg every 12 hours for the remainder of treatment). The duration of therapy is 14 days or longer.

Brucella meningitis (Chapter 318) is a subacute or chronic process that is often accompanied by other manifestations of neurobrucellosis (encephalitis, polyradiculitis, myelitis). Infection is transmitted to humans in endemic areas (Central and South America, Mediterranean littoral, Arabian peninsula) from the ingestion of unpasteurized milk or cheese or direct contact with domestic animals. Neurobrucellosis occurs in 2 to 5% of patients with brucellosis. CSF findings consist of a lymphocytic pleocytosis (<500 cells/mm^3), hypoglycorrhachia, and an elevated protein level, findings that could mistakenly suggest tuberculous meningitis. The diagnosis is based on demonstration of antibody in serum and CSF or by isolation of *Brucella* from blood; the microorganism is isolated from CSF in only a minority of cases. Treatment of adults involves the three-drug combination of doxycycline (200 mg/day), rifampin (600 mg/day), and trimethoprim-sulfamethoxazole (20 mg/kg/day, based on trimethoprim component, in 6-hour aliquots) intravenously for several months, depending on the clinical and CSF responses.

Streptococcus suis is an uncommon cause of meningitis seen in pig breeders, butchers, and abattoir workers in Europe, Canada, and China. *S. suis* meningitis, which is an acute illness with a brisk neutrophilic pleocytosis, is often initially mistaken for pneumococcal meningitis on the basis of Gram stain of CSF. Treatment of adults consists of penicillin (12 to 24 million U/day in 4-hour aliquots) or ampicillin (12 g/day in 4-hour aliquots) intravenously for 10 to 14 days.

Bacillus anthracis (Chapter 302) is a rare cause of meningitis that most often develops as a complication of inhalation anthrax following exposure to aerosols of anthrax spores in the setting of large-scale processing of wool and hides or a bioterrorism attack (Chapter 20). Anthrax meningitis is an acute process characterized by hemorrhagic or serohemorrhagic CSF with a neutrophilic predominance (several thousand cells per cubic millimeter), hypoglycorrhachia, an elevated protein level, and prominent large gram-positive bacilli on stained smear. Treatment of adults initially includes ciprofloxacin (400 mg at 12-hour intervals) in addition to penicillin (24 million U/day in 4-hour aliquots) and chloramphenicol (4 g/day in 6-hour aliquots) intravenously. Whether all drugs are continued (or treatment is narrowed to one or two antimicrobials) and the duration of treatment depend on whether the meningitis is of suspected bioterrorist origin (Chapter 20) or caused by cutaneous anthrax resulting from animal (or animal product) exposure (Chapter 302). Consultation with infectious disease and public health authorities should be sought.

Duration of Therapy

The frequency of CSF examination depends on the clinical course, but examination should be repeated in 24 to 48 hours if there has not been satisfactory improvement or if the causative microorganism is a more resistant gram-negative bacillus or a highly penicillin-resistant (or cephalosporin-resistant) *S. pneumoniae* strain, especially in patients who are receiving adjunctive dexamethasone therapy. Routine "end-of-treatment" CSF examination is unnecessary in most patients with the common types of community-acquired bacterial meningitis. Meningococci are rapidly eliminated from the circulation and CSF with appropriate antimicrobial therapy, which should be continued for 4 to 7 days after the patient becomes afebrile. If the patient has responded well, a follow-up lumbar puncture is not necessary. *H. influenzae* meningitis should be treated for 7 to 10 days. Follow-up CSF examination may be omitted in patients who have responded with rapid clinical resolution of the meningitis. In pneumococcal meningitis, antimicrobial treatment should be continued for 10 to 14 days and follow-up examination of CSF should be performed, particularly when the patient has coexistent mastoiditis. More prolonged therapy is indicated with concomitant parameningeal infection. Meningitis caused by *L. monocytogenes* should be treated for 21 days. Treatment of gram-negative bacillary meningitis with parenteral antimicrobials is prolonged, usually for a minimum of 3 weeks (particularly in patients after a recent neurosurgical procedure) to prevent relapse. Repeated examinations of CSF are necessary both during and at the conclusion of treatment to determine whether bacteriologic cure has been achieved. When treating meningitis resulting from vancomycin-resistant *Enterococcus faecium* with linezolid, an antibiotic that is bacteriostatic, approximately 4 weeks of therapy is indicated.

Other Aspects of Treatment

Adjunctive Corticosteroids

In children, the routine use of dexamethasone administered intravenously (either 0.15 mg/kg every 6 hours for 4 days or 0.4 mg/kg every 12 hours for 2 days), either at the time of or 10 to 20 minutes before initiating antimicrobial therapy (third-generation cephalosporin), has no effect on mortality but reduces the incidence of neurologic sequelae (primarily bilateral sensorineural hearing loss). However, the benefits are seen predominantly in *H. influenzae* type b meningitis, the incidence of which has been sharply reduced by the use of protein-conjugate vaccines. In a randomized double-blind study in adults with community-acquired bacterial meningitis, adjunctive dexamethasone therapy (10 mg every 6 hours intravenously for 4 days) significantly reduced the proportion of patients with an unfavorable neurologic outcome from 25 to 15% or a fatal outcome from 15 to 7%.■ Adverse events were not increased in those receiving dexamethasone. Notably, the risk for gastrointestinal bleeding was not increased in the dexamethasone-treated group. The beneficial effect of dexamethasone was most evident in the subgroup of patients with pneumococcal meningitis, in whom the rate of unfavorable outcomes was reduced from 52 to 26% and deaths from 34 to 14%. In this trial, adjuvant dexamethasone was not beneficial in patients with meningococcal meningitis, but the number of patients in this subgroup was small. In a study of adolescents and adults with bacterial meningitis in Vietnam, dexamethasone significantly reduced death and disability by approximately 54% at 6 months in patients with confirmed disease but not in those with suspected disease.■ By comparison, adjunctive corticosteroids were not effective in treating bacterial meningitis in a large trial of predominantly HIV-positive patients in sub-Saharan Africa.■ Based on these data, adjunctive dexamethasone (0.15 mg/kg every 6 hours for 2 to 4 days, with the initial dose given 10 to 20 minutes before or simultaneously with the initial dose of antimicrobial therapy) is recommended in adults with suspected or demonstrated pneumococcal meningitis and perhaps routinely in all cases of bacterial meningitis,■ at least in non–HIV-infected patients in high-income countries.■ Continuation of dexamethasone requires demonstration of gram-positive diplococci on the CSF Gram stain or positive blood or CSF cultures for *S. pneumoniae*. When vancomycin is used for treatment of meningitis resulting from highly cephalosporin-resistant *S. pneumoniae*, as is recommended in the United States, the addition of rifampin should be considered because dexamethasone may reduce the CSF concentration of vancomycin (see Table 420-4).

Elevated Cerebrospinal Fluid Pressure (Brain Swelling)

Occasional patients with acute bacterial meningitis experience marked brain swelling (CSF pressure >450 mm H_2O), which may lead to temporal lobe or cerebellar herniation after lumbar puncture. To decrease the possibility of this complication when the pressure is found to be this high, only a small amount of CSF should be removed for analysis (the amount present in the manometer), and a 20% solution of mannitol (0.25 to 0.5 g/kg) should be infused intravenously over a period of 20 to 30 minutes while monitoring (if possible) for a decline in CSF pressure to a lower level before the spinal needle is removed. Continued control of increased intracranial pressure, if needed thereafter, may be effected with additional mannitol; dexamethasone (10 mg intravenously, followed by 0.15 mg/kg every 6 hours) should be used in patients with brain swelling regardless of the suspected bacteriologic cause of meningitis.

In a stuporous patient or one with respiratory insufficiency and markedly increased intracranial pressure, use of a ventilator to reduce the arterial carbon dioxide pressure to between 25 and 32 mm Hg is reasonable, and the patient's head should be elevated 30 to 45 degrees. Intubation should be performed with minimal stimulation to avoid an appreciable further rise in pressure; pharmacologic aids to intubation are recommended, such as succinylcholine and opioids, with the possible use of adjunctive intravenous lidocaine. Subsequently, transient increases in intracranial pressure associated with hyperactive airway reflexes can be mitigated by intratracheal instillation of lidocaine before vigorous suctioning. With continued marked and fluctuating elevations in intracranial pressure, use of a continuous intracranial monitoring device may be warranted.

Hypotension

Initial hypovolemia or hypotension, if present, should be treated with fluid to prevent significantly decreased cerebral blood flow. Over the next 24 to 48 hours, inappropriate secretion of antidiuretic hormone may contribute to

further brain swelling; in such cases, fluid should be restricted to 1200 to 1500 mL daily in adults if possible, although a study in children suggests that routine fluid restriction does not improve outcome and that the resulting decrease in extracellular water may increase the likelihood of hypovolemia and an adverse outcome.

Supportive Care

Patients with acute bacterial meningitis should receive constant nursing attention in an intensive care unit to ensure prompt recognition of seizures and to prevent aspiration. If seizures occur, they should be treated acutely in adults with diazepam (administered slowly intravenously at a dose of 5 to 10 mg) or lorazepam (4 to 8 mg). Maintenance anticonvulsant therapy can be continued thereafter with intravenous phenytoin (Chapter 410) until the medication can be administered orally. Sedation should be avoided because of the danger of respiratory depression and aspiration.

Surgery

Surgical treatment of an accompanying pyogenic focus such as mastoiditis should be undertaken when recovery from the meningitis is as complete as possible but under continuing antibiotic administration. Rarely, the mastoid infection (e.g., Bezold's abscess) is so hyperacute that early drainage may be required after 48 hours or so of antibiotic therapy when the acute meningeal process has subsided somewhat.

PROGNOSIS

Prompt treatment of bacterial meningitis usually results in rapid recovery of neurologic function. Persistent or late-onset obtundation and coma without focal findings suggest brain swelling, subdural effusion, hydrocephalus, loculated ventriculitis, cortical thrombophlebitis, or sagittal sinus thrombosis. The last three conditions are commonly associated with fever and continuing pleocytosis.

The mortality rate for community-acquired bacterial meningitis in adults varies with the etiologic agent and the clinical circumstances. With current antimicrobial therapy, the mortality rate for *H. influenzae* meningitis is less than 5% and that for meningococcal meningitis is approximately 10%. The highest mortality is seen with pneumococcal and *L. monocytogenes* meningitis, for which the rates are approximately 20% and 20 to 30%, respectively.

The mortality rate for gram-negative bacillary meningitis, commonly nosocomial in origin, has been 20 to 30% in adults, but it appears to be decreasing. The mortality rate for recurrent community-acquired meningitis in adults (≈5%) is strikingly lower than the 20% rate for nonrecurrent episodes. Poor prognostic factors include advanced age, the presence of other foci of infection, underlying diseases (leukemia, alcoholism), obtundation, seizures within the first 24 hours, and delay in instituting appropriate therapy.

Residual neurologic damage is seen in 10 to 20% of patients who recover from bacterial meningitis. Approximately 25% of adults considered clinically well recovered (expected to function independently and to resume activities of daily life, including work) from pneumococcal meningitis show neuropsychological abnormalities, mainly loss of cognitive speed, when they are examined 6 to 24 months after hospital discharge. Developmental delay and speech defects are each observed in approximately 5% of children. In infants surviving neonatal meningitis, significant sequelae are much more frequent (15 to 50%).

PREVENTION

Vaccination

Effective vaccines are now available for many subtypes of *H. influenzae* type b (Chapter 308) and many meningococcal (Chapter 306) infections that cause meningitis. Adherence to recommended vaccination (Chapter 17) substantially reduces meningitis from each of these organisms.

Chemoprophylaxis

Prompt prophylaxis of close contacts (individuals who frequently slept and ate in the same household with the patient, girlfriend, or boyfriend) is warranted because up to a third of secondary cases of meningococcal disease develop within 2 to 5 days of illness in the initial case. Only hospital personnel who were in close contact with a patient (mouth-to-mouth resuscitation, initial examination before institution of respiratory precautions) are at special risk. Commonly, rifampin orally is used for prophylaxis: for adults (other than pregnant women), 600 mg twice daily for 2 days; for children, 10 mg/kg twice daily for 2 days. Alternatively, for adults, ciprofloxacin (500 mg), ofloxacin (400 mg), or azithromycin (500 mg), each given orally as a single dose, may be used. Another choice is ceftriaxone intramuscularly as a single dose in adults (250 mg) or children (125 mg).

Widespread use of *H. influenzae* type b polysaccharide protein-conjugate vaccine in developed countries has largely eliminated the need for chemoprophylaxis of close childhood contacts of patients with *H. influenzae* meningitis or invasive infection. However, prophylaxis would be indicated for unimmunized close household contacts of an index patient (e.g., recent immigrant) younger than 6 years. If two or more cases of invasive *H. influenzae* type b disease occur in children at a daycare center, prophylaxis of other unimmunized attendees is warranted. Rifampin (20 mg/kg orally) once daily for 4 days is recommended for such children.

VIRAL MENINGITIS

DEFINITION

The nonspecific term *aseptic meningitis* describes an inflammatory process involving the meninges, usually accompanied by a mononuclear pleocytosis, without evidence of pyogenic bacterial infection on Gram stain or culture. The definition encompasses various processes that produce similar clinical pictures and inflammatory responses: *viral meningitis, atypical and nonpyogenic bacterial and fungal meningitis, chemically induced meningitis, drug-induced meningitis, neoplastic meningitis, meningeal inflammation caused by adjacent pyogenic infections,* and *meningitis associated with autoimmune hypersensitivity diseases.* Aseptic meningitis, which is usually an acute or subacute process, can be further divided into types by the duration of illness (*chronic versus chronic-intermittent*) and by distinctive cellular responses in CSF (e.g., *eosinophilic meningitis*).

Many of the viruses causing meningitis may also cause infection of the brain parenchyma (encephalitis; Chapter 422) or spinal cord. Sometimes, parenchymatous involvement and meningeal involvement occur simultaneously in the same patient and are referred to as meningoencephalitis and meningomyelitis, respectively.

EPIDEMIOLOGY

Most cases of community-acquired aseptic meningitis are the result of viruses, principally enteroviruses, which account for more than 60% of viral meningitides and for 90% of those for which an etiologic agent is identified (Table 420-8). Enteroviruses are members of the Picornaviridae (small RNA) family, which consists of more than 60 serotypes: 28 echoviruses, 23 group A and 6 group B coxsackieviruses, 4 numbered enteroviruses (68 to 71), and 3 polioviruses. The most common serotypes implicated in viral meningitis from year to year have been echoviruses 4, 6, 9, 11, 16, and 30 (most recently 13 and 33) and coxsackie B serotypes 2 to 5. Currently, poliovirus infections (Chapter 423) are limited to parts of Asia and Africa, although rare cases occur secondary to attenuated vaccine strains.

Many viruses that produce the clinical picture of aseptic meningitis, such as arthropod-borne viruses, HSV-1, enterovirus 71, lymphocytic choriomeningitis virus, mumps virus, HIV-1, cytomegalovirus, and Epstein-Barr virus, can also produce the clinical picture of meningoencephalitis and encephalitis (Chapter 422). In addition, some viruses involve the spinal cord, including the anterior horn cells (poliovirus, West Nile virus) or the dorsal root ganglia (HSV-2).

Enterovirus

An estimated 10 to 15 million clinical enteroviral infections (Chapter 387) occur annually in the United States, and these include an estimated 50,000 to 75,000 cases of enteroviral meningitis. In temperate climates, enteroviral meningitis peaks during the summer and fall, especially in children. Serotypes tend to cycle with varying periodicity, and outbreaks are related to lack of previous exposure to a particular serotype. Serotype-specific protective antibodies develop following infection, so subsequent episodes of enteroviral meningitis are uncommon and are caused by a different serotype.

Humans are the only known reservoir of enteroviruses. Enteroviral infection is spread predominantly by the fecal-oral route and occasionally by the respiratory route.

Herpes Simplex Virus

HSV (Chapter 382) accounts for 1 to 3% of all episodes of aseptic meningitis and occurs most commonly in sexually active adults or adolescents. In individuals with primary genital herpes (HSV-2) infection, up to 36% of women

TABLE 420-8 AGENTS OF VIRAL MENINGITIS

COMMON
Nonarthropod Viruses
Picornavirus (RNA)
Enterovirus
Echovirus
Coxsackie A
Coxsackie B
Enterovirus 70, 71
Poliovirus
Herpes simplex virus type 2 (HSV-2) (DNA)
Arthropod-Borne Viruses (Arboviruses)
Togavirus (alphavirus, RNA)
Eastern equine encephalitis (EEE)
Western equine encephalitis (WEE)
Venezuelan equine encephalitis (VEE)
Flavivirus (RNA)
St. Louis encephalitis (SLE)
West Nile virus (WNV)
Bunyavirus (RNA)
California encephalitis
UNCOMMON

Adenovirus (DNA)
Coltivirus (RNA)
Colorado tick fever
Bunyavirus (RNA)
Toscana virus (a Phlebovirus)

and 13% of men have symptoms of aseptic meningitis. Recurrences of genital herpes are common and are sometimes accompanied by aseptic meningitis. More than 80% of cases of benign recurrent aseptic meningitis are caused by HSV-2. In contrast, HSV-1 CNS infection is almost always manifested as encephalitis rather than aseptic meningitis. Herpesviruses may also be reactivated in patients taking immunomodulatory drugs, which are often used to treat autoimmune diseases.

Arboviruses

Although the most common form of CNS infection caused by arboviruses (Chapters 391 and 422) is encephalitis, aseptic meningitis may also occur. These vector-borne viruses are introduced subcutaneously by a mosquito (e.g., West Nile virus), tick (e.g., Colorado tick fever), or sandfly (e.g., Toscana virus). Birds, which are vectors of mosquito-borne arboviruses, may not be obviously sick, although West Nile virus may cause prominent die-offs of corvine species, especially crows and blue jays, which can provide clues to an outbreak affecting humans.

The geographic spread of alphavirus infections (Eastern equine encephalitis, Western equine encephalitis, Venezuela equine encephalitis) in the United States is determined by the range of their individual mosquito vectors. Eastern equine encephalitis occurs sporadically or as focal outbreaks in the summer in the eastern and Gulf coasts, most frequently in children and elderly persons. Western equine encephalitis occurs predominantly in the western states, and Venezuela equine encephalitis is found in Florida. St. Louis encephalitis infections were originally recognized in the Midwest, but sporadic cases and outbreaks have occurred more recently in most parts of the United States; it is the most common arbovirus causing aseptic meningitis in the United States. West Nile virus infections first appeared in the United States in 1999 and now account for approximately 3000 cases of meningitis and another 3000 cases of encephalitis annually.

Mumps

Mumps virus (Chapter 377) was the leading identifiable cause of viral meningitis before widespread immunization in the 1960s. Episodes occurred most frequently in the winter and spring. It is now an uncommon cause of viral meningitis in the United States.

Lymphocytic Choriomeningitis

Lymphocytic choriomeningitis virus is transmitted to humans by rodents through direct contact, through ingestion of animal-contaminated food, or via aerosol or an animal bite. Cases tend to occur in early winter when mice seek shelter in homes. Outbreaks have occurred following exposure to pet or laboratory hamsters. Currently, lymphocytic choriomeningitis virus is infrequently a cause of aseptic meningitis.

PATHOBIOLOGY

The two basic routes for virus to gain access to the CNS are hematogenous (enteroviral infection) or neuronal (HSV infection). Enteroviruses pass through the stomach, where they resist the acid pH, and proceed to the lower gastrointestinal tract. Some virus also undergoes replication in the nasopharynx and spreads to regional lymphatics. After presumably binding to specific enterocyte receptors, the virus breaches the epithelial lining and undergoes primary replication in a permissive cell. From there, the virus progresses to Peyer's patches, where further replication occurs. A minor enterovirus viremia then seeds the CNS, heart, liver, and reticuloendothelial system. Following extensive replication at the latter sites, a major viremia ensues, often accompanying the onset of clinical illness. The mechanism by which enterovirus enters the CNS is presumed to involve crossing the blood-CSF barrier's tight endothelial junctions and then entering CSF, probably at the choroid plexus.

In contrast, HSV infections may reach the CNS via the neuronal route: in HSV-1 encephalitis, from oral sites via the trigeminal and olfactory nerve; in HSV-2 (and the rare HSV-1) aseptic meningitis, by spread from a primary genital lesion and ascent along the sacral nerve roots to the meninges. After subsidence of the primary infection, HSV-1 may remain dormant in the trigeminal or olfactory root ganglia only to reactivate at a later date, enter the temporal lobe, and produce encephalitis. Similarly, HSV-2 may remain latent in the sacral root ganglia until subsequent reactivation causes later episodes of aseptic meningitis.

CLINICAL MANIFESTATIONS

Enteroviral Meningitis

The clinical features of enteroviral meningitis (Chapter 387) in older children and adults often begin abruptly with headache (85 to 100%), fever (80 to 100%), and stiff neck (50 to 80%). In some patients the course is biphasic, with the initial prodromal phase being characterized by low-grade fever and nonspecific symptoms (malaise, sore throat, diarrhea), followed by a second phase at which time the meninges are seeded, with the development of higher fever, nausea, vomiting, myalgia, photophobia, and stiff neck. Other enteroviral syndromes may coexist, particularly pleurodynia or pericarditis resulting from coxsackieviruses. Rash may be a manifestation of infections caused by echoviruses, particularly echovirus type 9, coxsackieviruses A9 and A16, and enterovirus 71; the latter three cause hand-foot-and-mouth disease, which may occur alone or accompany aseptic meningitis. Echovirus 9 epidemics often produce syndromes of exanthem, enanthem (small, grayish white lesions resembling Koplik's spots on the buccal mucosa), and aseptic meningitis, either alone or in combination; a macular and petechial rash in the presence of a meningitic syndrome must be differentiated from meningococcal meningitis.

Neurologic abnormalities affecting the cerebrum are rarely observed because such cases would be defined as encephalitis or meningoencephalitis rather than enteroviral meningitis. In agammaglobulinemic individuals in whom enteroviral CNS infection develops, meningitis may progress to a chronic meningoencephalitis with multiple neurologic features, including headache, seizures, ataxia, weakness, hearing loss, obtundation, and coma.

The clinical course of enteroviral meningitis is benign, even in the minority of patients in whom the onset is acute and even fulminant. Symptoms subside within a week in children but may continue for several weeks in adults.

Herpes Simplex Virus Type 2 Meningitis

Aseptic meningitis is a common complication of primary genital HSV-2 infection (Chapter 382); up to 36% of women and 13% of men have

headache (developing over a period of 2 to 3 days), stiff neck, and photophobia. Clinical features of meningitis occur 3 to 12 days after the appearance of genital lesions and usually last for 4 to 7 days. Neurologic complications occur in up to 37% of patients and include dysesthesia or paresthesia in the perineum or sacral area, urinary retention, and constipation; evidence of transverse myelitis with motor weakness in the lower extremities, hyporeflexia, and paraparesis occasionally ensues. Recurrent episodes of HSV-2 meningitis may occur at intervals of months or years in 20% of patients. In recurrent HSV-2 meningitis, fever may develop but is not as prominent as in bacterial or acute enteroviral meningitis. Recurrent vesicular lesions, paresthesia, or dysesthesia in areas of previous genital herpes may or may not precede individual recurrences of meningitis. Between recurrences, CSF findings and clinical manifestations return to normal. In patients who have had neurologic complications with a first episode of HSV-2 meningitis, the findings subside within 6 months.

Mumps Meningitis

Symptomatic CNS disease, principally meningitis or meningoencephalitis, occurs in 1 to 10% of patients with mumps parotitis (Chapter 377), but pleocytosis occurs in more than 50% of patients with mumps, most of whom lack CNS symptoms. When meningitis occurs in patients with mumps, it usually follows parotitis by 4 to 10 days, but it may precede parotitis by up to 1 week. The typical features of viral meningitis (headache, fever, vomiting) are each present in 50 to 100% of patients. Stiff neck (40 to 90%) is common, and abdominal pain (perhaps complicating pancreatitis or oophoritis) or orchitis (in ≤20% of men with mumps) may be present. Other complications of mumps may involve the nervous system (eighth nerve damage, transient facial nerve paralysis, and rarely, fifth nerve palsy) but are usually independent of mumps meningitis or meningoencephalitis. The incubation period for mumps is 18 to 21 days. When mumps meningitis occurs in the absence of clinical parotitis, it is difficult to distinguish it from other forms of viral meningitis.

When meningitis complicates mumps, fever, which had been low grade, rises to 103° F or higher and persists at this level for 3 or 4 days. Most cases are uncomplicated, with approximately a 10-day duration of illness and then complete recovery. However, symptomatic mumps meningitis may persist for more than 14 days in some patients.

Meningitis Caused by Lymphocytic Choriomeningitis Virus

Lymphocytic choriomeningitis virus infections are uncommon, and clinical illness occurs after an incubation period of 1 to 3 weeks. Illness begins with a grippe-like syndrome of fever, rigors, malaise, myalgia, anorexia, and photophobia. Sore throat and arthralgia or arthritis of the digits are noted by some patients. Orchitis or parotitis occurs rarely. This grippe-like illness lasts 1 to 3 weeks in humans, but 15% of patients have a biphasic illness consisting of transient improvement and then recrudescence, 1 to 2 days later, of fever, photophobia, and more prominent headache. Meningeal signs are observed during the second phase. The duration of meningitis caused by lymphocytic choriomeningitis virus, like that of mumps meningitis, tends to be longer than the 7 to 10 days for enteroviral meningitis.

Meningitis Caused by Human Immunodeficiency Virus

Initial infection with HIV-1 (Chapter 392) is symptomatic in 40 to 90% of patients but is frequently overlooked. The interval between exposure and onset of symptoms is 2 to 4 weeks. This acute illness resembles mononucleosis, with fever, malaise, lymphadenopathy, arthralgia, myalgia, anorexia, nausea, headache, and morbilliform rash. A few patients with this initial syndrome have manifestations of aseptic meningitis (headache, photophobia, nausea, vomiting, and stiff neck). Occasionally, encephalopathy or cranial nerve palsies (seventh, eighth, and fifth) develop. Symptoms of the initial HIV-1 aseptic meningitis syndrome last several weeks and then subside. Occasionally, manifestations similar to those of the initial infection may appear later in the course of untreated infection.

DIAGNOSIS

Cerebrospinal Fluid Examination

CSF findings in all types of viral meningitis are similar and consist of a predominantly lymphocytic pleocytosis, usually 50 to 1000/mm^3 but occasionally up to several thousand per cubic millimeter, a normal glucose concentration, and a mildly elevated protein level, usually less than 150 mg/dL. During the first 24 to 48 hours of enteroviral meningitis, a predominance of neutrophils (55 to ≤90%) is observed in approximately 50% of patients; subsequently, the principal cells in CSF change to lymphocytes. Occasionally, no pleocytosis is noted in patients proved by culture or PCR to have early enteroviral meningitis. Rarely, hypoglycorrhachia occurs in meningitis resulting from mumps or lymphocytic choriomeningitis virus or in infants with enterovirus.

Polymerase Chain Reaction versus Culture or Antibody Detection

The recent development of reverse-transcription PCR for enteroviruses can reduce detection time to as little as 5 hours, thereby shortening hospital stay and minimizing the unnecessary use of antimicrobial agents. Its sensitivity in CSF is 85 to 100%, with a specificity of 90 to 100%, depending on the laboratory. The test is available in research settings, large hospitals, and commercial laboratories. By comparison, viral culture of enterovirus from CSF has a sensitivity of only 65 to 75% and takes 4 to 8 days.

HSV-2 can be cultured from CSF in approximately 75% of patients with aseptic meningitis during an initial episode of genital HSV-2 infection, but it is rarely isolated from CSF during meningitis associated with recurrent genital herpes. PCR for HSV-2 DNA is usually positive in the CSF of patients with initial episodes of meningitis and is positive in approximately 80% of patients with benign recurrent meningitis caused by lymphocytic choriomeningitis virus.

The diagnosis can be made retrospectively by demonstrating seroconversion in antibody to gG-2 antigen in HSV-2 meningitis. A four-fold rise in titer to mumps or lymphocytic choriomeningitis virus between acute and convalescent sera is also diagnostic. Serodiagnosis is not practical for sporadic enteroviral meningitis because of the specificity of antibodies to individual serotypes.

Differential Diagnosis

The most important process to distinguish from viral meningitis is bacterial meningitis. A predominance of CSF neutrophils, hypoglycorrhachia, and bacteria on Gram-stained smear or culture indicate bacterial meningitis. An early neutrophilic predominance in CSF combined with a macular and petechial rash in enteroviral meningitis may mimic meningococcemia with meningitis. Occasional bacteria and fungi cause meningitis with a predominantly lymphocytic pleocytosis similar to that of most viral meningitides (Table 420-9). Epidemiologic considerations and clinical findings aid in distinguishing leptospiral, Lyme *Borrelia*, and syphilitic meningitis, whereas hypoglycorrhachia suggests tuberculous and cryptococcal meningitis.

TABLE 420-9 NONVIRAL INFECTIOUS CAUSES OF ASEPTIC MENINGITIS

UNCOMMON	RARE
Bacterial	
Leptospira interrogans serovars	*Mycoplasma pneumoniae*
Borrelia burgdorferi	*Ehrlichia chaffeensis*
Treponema pallidum	*Listeria monocytogenes*
Mycobacterium tuberculosis	*Borrelia recurrentis* and *Borrelia hermsii*
Brucella sp	*Chlamydia psittaci*
Parameningeal infections	Staphylococcal enterotoxin or TSST-1
Subacute bacterial endocarditis	*Rickettsia rickettsii* and *Rickettsia prowazekii*
Partially treated bacterial (pyogenic) meningitis	
Fungal	
Cryptococcus neoformans	*Blastomyces dermatitidis*
Coccidioides immitis	*Sporothrix schenckii*
Histoplasma capsulatum	*Candida* sp
Protozoan	
	Trypanosoma brucei sp
	Toxoplasma gondii
	Acanthamoeba sp

TSST-1 = toxic shock syndrome toxin 1.

PREVENTION AND TREATMENT

Rx

The introduction of live attenuated mumps vaccine in the United States reduced mumps from the leading cause of aseptic meningitis and meningoencephalitis to the point at which it occurs only rarely. Chronic enteroviral meningitis and meningoencephalitis in agammaglobulinemic patients have been controlled by parenteral (even intrathecal) administration of immune globulin.

No approved antiviral chemotherapy is available for enteroviral meningitis. Pleconaril, a drug that prevents attachment of virus to host cells, can produce clinical improvement in agammaglobulinemic patients with chronic enteroviral meningoencephalitis.

Intravenous acyclovir (5 to 10 mg/kg every 8 hours) is used to treat hospitalized, symptomatic patients with HSV-2 meningitis, particularly when the disease is associated with primary genital herpes, although it has not been shown in clinical trials to alter the course of illness. In patients with frequent recurrences of HSV meningitis, it is reasonable to attempt prophylaxis with oral antivirals: valacyclovir (500 mg once daily), famciclovir (250 mg twice daily), or acyclovir (400 mg twice daily).

PROGNOSIS

The course and outcome in patients with enteroviral meningitis are almost always benign, although approximately 1% of patients have subsequent abnormalities, probably reflecting a meningoencephalitic process. Most viral meningitides are self-limited, but some cause chronic or recurrent illness. Persistent meningitis or meningoencephalitis, sometimes fatal, can occur in individuals with hereditary (usually X-linked agammaglobulinemia or common variable immunodeficiency) deficiencies in B-lymphocyte function. HIV-1 may produce a prolonged meningeal inflammation. HSV-2 infection is the most common viral cause of recurrent episodes of aseptic meningitis.

OTHER MENINGITIDES

Nonviral Infectious Causes of Aseptic Meningitis

Categories of aseptic meningitis other than the viral meningitides include nonviral infectious processes (see Table 420-9), noninfectious processes (Table 420-10), chronic meningitides (Table 420-11), recurrent meningitis (Table 420-12), and eosinophilic meningitis (Table 420-13). Nonviral infectious causes are uncommon or rare in comparison to viral or acute suppurative meningitis. Some of the bacterial causes (e.g., *Leptospira* serovars, *B. burgdorferi*, *Brucella* sp, *T. pallidum*) produce a lymphocytic pleocytosis; others (partially treated bacterial meningitis, subacute bacterial endocarditis with embolic cerebral infarcts) produce a mixed neutrophilic-mononuclear pleocytosis; and *M. tuberculosis*, though producing a lymphocytic response with developing hypoglycorrhachia, may show a predominantly neutrophilic response in a minority of patients early in the disease. Although patients with *L. monocytogenes* infection usually have neutrophilic pleocytosis, this infection may suggest aseptic meningitis because of its sometimes indolent onset and, occasionally, an early predominantly lymphocytic response in young children. Fungal (e.g., *Cryptococcus neoformans*, *Coccidioides immitis*, *Histoplasma capsulatum*) meningitides are associated with a predominantly mononuclear response, sometimes with a small percentage of eosinophils, particularly in coccidioidal meningitis (Chapter 341). Patients with Rocky Mountain spotted fever (Chapter 335), an acute disease with a macular and petechial rash, may exhibit confusion. When examined, the CSF in

Drug hypersensitivity
Systemic disease
Systemic lupus erythematosus
Familial Mediterranean fever
Behçet's syndrome
Wegener's granulomatosis
Cogan's syndrome
Sarcoidosis
Still's disease
Kawasaki disease
Lead poisoning
Neoplastic disease
Metastatic carcinomatous meningitis
Central nervous system tumors (meningeal gliomatosis, dysgerminomas, ependymomas)
Tumors that leak inflammatory material into cerebrospinal fluid (squamous cells in epidermoid tumors of the posterior fossa, cholesteatomas)
Inflammatory processes involving central nervous system structures primarily
Chemical meningitis following myelography (water-soluble nonionic contrast material)
Continuous spinal and epidural anesthesia, inflammation after neurosurgery
Granulomatous cerebral vasculitis
Vogt-Koyanagi-Harada syndrome

TABLE 420-11 INFECTIOUS CAUSES OF CHRONIC (PERSISTENT) LYMPHOCYTIC MENINGITIS

CAUSATIVE CONDITIONS	OTHER CSF FINDINGS
Bacterial	
Mycobacterium tuberculosis	Usually <500 white blood cells/mm^3, low glucose, high protein
Borrelia burgdorferi (Lyme disease)	Normal glucose, elevated protein
Treponema pallidum (secondary syphilitic meningitis, tertiary meningovascular syphilis)	Elevated protein; Venereal Disease Research Laboratory positive in CSF and serum
Brucella sp (uncommon)	Often low glucose; elevated protein
Tropheryma whippelii (rare)	Periodic acid–Schiff–positive cells on meningeal biopsy
Partially treated bacterial meningitis	Mixture of PMNs and lymphocytes, bacteria on Gram stain and culture
Parameningeal infections	Lymphocytes or mixed lymphocytic-PMN response, normal glucose
Fungal	
Cryptococcus neoformans	Low glucose, elevated protein, budding yeast on India ink or fungal wet mount, antigen detectable
Coccidioides immitis	Often low glucose, may have 10-20% eosinophils, elevated protein, presence of complement-fixing antibody
Histoplasma capsulatum	Low glucose; complement-fixing antibodies in CSF; antigen detectable in urine, CSF, serum
Blastomyces dermatitidis	Low glucose
Candida sp	Low glucose, may have PMN or lymphocyte predominance, fungal stain may be positive
Aspergillus sp	Lymphocytes or PMNs predominate
Sporothrix schenckii (sporotrichosis)	Low glucose; protein, 200-800 mg/dL
Protozoal	
Toxoplasma gondii	Usually, picture is that of an encephalitis; often in patients with AIDS; pleocytosis is mild (<60 cells/mm^3) and protein is mildly elevated
Trypanosoma gambiense or *Trypanosoma rhodesiense*	Meningoencephalitis is stage II of disease, elevated protein and immunoglobulin M, trypanosomes on Giemsa-stained smear
Viral	
Mumps	Rarely, low glucose
Lymphocytic choriomeningitis	Rarely, low glucose
Echovirus (in patients with congenital agammaglobulinemia)	Occasionally, low glucose
HIV-1	Cell counts lower (10-20/mm^3) than in acute self-limited meningitis at clinical onset of HIV infection or may develop during course of AIDS

AIDS = acquired immunodeficiency syndrome; CSF = cerebrospinal fluid; HIV = human immunodeficiency virus; PMN = polymorphonuclear leukocyte.

Presence of foreign body in the central nervous system	

*The percentage of eosinophils varies from as little as 6% to the majority of cells.

approximately 20% of such patients shows a pleocytosis of 10 to 100 or more cells/mm^3, with either a neutrophilic or lymphocytic predominance. The clinical picture may suggest either enteroviral or meningococcal disease.

Epidemiologic factors are important in raising suspicion for nonviral aseptic meningitis. Leptospirosis (Chapter 331) may be suggested by a history of recent direct or indirect exposure to animals (e.g., dogs, rodents, dairy cattle) and their urine. Neurobrucellosis (Chapter 318) is suggested by the recent ingestion of unpasteurized cheese from the Mediterranean littoral, Middle East, or Mexico or by work as a veterinarian or in an abattoir. Specific endemic mycoses may be a consideration with residence in the southwestern United States (coccidioidomycosis; Chapter 341) and the Mississippi River valley (histoplasmosis; Chapter 340). The setting of immunosuppression by drugs or illness such as acquired immunodeficiency syndrome would raise the possibility of *C. neoformans* (Chapter 344) or *L. monocytogenes* (Chapter 301). Sexual promiscuity and the macular rash of secondary syphilis could suggest *T. pallidum* (Chapter 327) as the cause in a patient with lymphocytic meningitis.

Noninfectious Causes of Aseptic Meningitis

Noninfectious causes fall into four principal categories (see Table 420-10): drug hypersensitivity; systemic processes such as systemic lupus erythematosus and other collagen-vascular diseases; neoplastic disease, primary or metastatic, infiltrating the leptomeninges; and inflammatory processes primarily involving the CNS. Although a mononuclear cell predominance is found in the CSF in most noninfectious aseptic meningitides, there are several important exceptions. Drug hypersensitivity meningitis usually causes a neutrophilic response, although occasionally mononuclear cells or eosinophils predominate. In systemic lupus erythematosus (Chapter 274), the pleocytosis may be predominantly lymphocytic or neutrophilic (sometimes several thousand per cubic millimeter) with a normal CSF glucose level. Hypoglycorrhachia is a feature of few noninfectious aseptic meningitides and suggests malignant disease or sarcoidosis. Various drugs, most commonly the nonsteroidal anti-inflammatory drugs, have also been implicated in aseptic meningitis.

Chronic (Persistent) Meningitis

Chronic meningitis is defined by the clinical syndrome of headache, stiff neck, altered mental status, nausea and vomiting, evidence of myelopathy or radiculopathy with or without cranial nerve palsies (e.g., III, IV, VI, VII, VIII), and an inflammatory response in the CSF for 4 weeks or longer. Obstruction of CSF flow may produce hydrocephalus and papilledema.

Infectious Causes

Among the more common bacterial causes of chronic meningitis, *M. tuberculosis* (Chapter 332) is the most important to identify because if untreated, it is almost always fatal within 4 to 8 weeks (see Table 420-11). Similarly, parameningeal infections (Chapter 421) must be recognized and treated promptly because surgery is often necessary to provide a specific bacteriologic diagnosis and prevent neurologic residua. Tuberculosis should be suspected in patients with a previous history of a tuberculous illness, a history of recent exposure, HIV infection or another immunosuppressed state, fever and night sweats, sixth cranial nerve palsies, stroke related to arteritis, or lesions on the chest radiograph. The purified protein derivative skin test may be negative in patients with recently acquired or overwhelming disease. Acid-fast smear and culture of concentrated CSF can provide the diagnosis, and PCR can be very helpful. When clinical and CSF findings suggest the diagnosis, treatment (Chapter 332) should be initiated while one awaits the results of culture.

Parameningeal infections (Chapter 421) should be suspected when chronic meningitis with focal neurologic signs develops in the setting of chronic otitis media or sinusitis, pleuropulmonary infection, or right-to-left cardiopulmonary shunting. Contrast-enhanced CT or MRI of the head is important to delineate brain abscess, sinus infection, and epidural or subdural infections.

Meningitis may accompany the skin, mucous membrane, and lymph node features of secondary syphilis (Chapter 327), or it may occur alone. Individual cranial nerves (II to VII) may be involved; visual abnormalities, hearing loss, and facial palsy are most frequent. The fluorescent treponema antibody absorption test or microhemagglutination *T. pallidum* serologic studies are helpful in distinguishing the process from biologic false-positive Venereal Disease Research Laboratory (or rapid plasma reagent) results in serum.

Lyme disease meningitis (Chapter 329) should be suspected on the basis of epidemiologic grounds (geographic location, season, tick exposure) and associated clinical features (erythema chronicum migrans rash, Bell's palsy, radiculopathy). The diagnosis is made by enzyme-linked immunosorbent assay with Western blot confirmation.

Noninfectious Causes

Noninfectious causes of meningitis include malignant disease, chemical meningitis, and primary inflammatory conditions (Table 420-14). Malignant disease may be diagnosed by cytologic examination of large volumes of CSF. Contrast-enhanced MRI may disclose thickening of the meninges and nerve roots, but meningeal biopsy may be required for diagnosis. Chemical meningitis from previous subarachnoid injection may persist, with xanthochromia noted in CSF; meningeal inflammation may be identified on contrast-enhanced CT or MRI.

Meningeal or CNS sarcoid (Chapter 95) may be isolated or occur with other organ involvement, such as pulmonary granulomas, lymphadenopathy, or myopathy. Neurologic findings can include diabetes insipidus and cranial nerve palsies. Wegener's granulomatosis (Chapter 278) may produce

TABLE 420-14 NONINFECTIOUS CAUSES OF CHRONIC (PERSISTENT) LYMPHOCYTIC MENINGITIS

CAUSATIVE CONDITIONS	OTHER CSF FINDINGS
Neoplasms	
Metastatic: lung, breast, stomach, pancreas, lymphoma, melanoma, leukemia	Low glucose; elevated protein, cytologic examination; polarizing microscopy; clonal lymphocyte markers
Central nervous system: meningeal gliomatosis, meningeal sarcoma, cerebral dysgerminoma; epidermoid tumors/cysts	
Chemical Inflammation	
Endogenous: epidermoid tumor, craniopharyngioma	Low glucose, elevated protein
Exogenous: recent injection into the subarachnoid space	Low glucose, elevated protein
Primary Inflammatory Processes	
Central nervous system sarcoid	Often low glucose, elevated protein, elevated angiotensin-converting enzyme levels in CSF (and serum)
Wegener's granulomatosis	Elevated protein
Behçet's syndrome	Elevated protein
Isolated granulomatous angiitis of the central nervous system	Elevated protein
Systemic lupus erythematosus	Elevated protein
?Chronic idiopathic benign meningitis	Elevated protein

CSF = cerebrospinal fluid.

TABLE 420-15 CAUSES OF CHRONIC (PERSISTENT) MENINGITIS WITH NEUTROPHIL PREDOMINANCE

UNCOMMON	OTHER CSF FINDINGS
Bacterial	
Nocardia asteroides	Low glucose, markedly elevated protein, culture positive
Actinomyces israelii	Low glucose, elevated protein, anaerobic culture positive
Arachnia propionica	Low glucose, elevated protein, anaerobic culture positive
Fungal	
Candida sp	Low glucose, elevated protein, culture positive
Aspergillus sp	Low glucose, elevated protein, enzyme immunoassay or enzyme-linked immunosorbent assay for *Aspergillus* galactomannan
Zygomycetes	Low glucose, elevated protein
Dematiaceous fungi	Low glucose, protein may be markedly elevated
Noninfectious	
Systemic lupus erythematosus	Low glucose, elevated protein
Chemical meningitis	Low glucose, protein may be markedly elevated
VERY RARE	
Bacterial	
Brucella sp	Low glucose, elevated protein
Mycobacterium tuberculosis	Low glucose, elevated protein, polymerase chain reaction positive for *M. tuberculosis* DNA
Fungal	
Pseudoallescheria boydii	Low glucose, protein may be markedly elevated
Coccidioides immitis	Low glucose, elevated protein, presence of complement-fixing antibody
Blastomyces dermatitidis	Low glucose, protein elevated, antigen detection possible in CSF and urine
Histoplasma capsulatum	Low glucose; protein mildly elevated; complement-fixing antibodies in CSF; antigen detectable in CSF, urine, serum

CSF = cerebrospinal fluid.

meningeal inflammation and cranial nerve palsies, often in association with air sinus disease. The diagnosis is suggested by lesions on the chest radiograph, microscopic hematuria, skin lesions, peripheral neuropathy, and serum antineutrophil cytoplasmic antibodies. Aseptic meningitis associated with systemic lupus erythematosus (Chapter 274) may be accompanied by other neurologic manifestations (seizures, encephalopathy, stroke, transverse myelopathy), systemic manifestations (rash, arthritis), and antinuclear and anti-DNA antibodies.

Chronic (Intermittent) Meningitis

In chronic intermittent meningitis, all clinical and CSF abnormalities resolve completely between episodes without antimicrobial therapy (see Table 420-11). Uncommonly, a patient may have several episodes resulting from different viral agents. The major causes of recurrent aseptic meningitis are infections (almost always viral and resulting from HSV-2), endogenous chemical meningitis, drug hypersensitivity with meningitis following each use, and inflammatory and autoimmune diseases.

In HSV-2 recurrent meningitis, lymphocytes predominate, with the cell numbers being approximately 40% higher in the initial episode than in recurrences. Leakage of material from intracranial epidermoid cysts produces 1000 to 5000 cells/mm^3 (≈80% polymorphonuclear leukocytes) initially, with a subsequent mononuclear cell predominance. Occasionally, polarizing microscopy may demonstrate keratin and cholesterol crystals in the CSF of patients with endogenous chemical meningitis. In Behçet's syndrome (Chapter 278), the CSF may have predominantly mononuclear cells or polymorphonuclear leukocytes. Mollaret's meningitis, a syndrome of benign recurrent meningitis usually caused by HSV-2, is initially associated with neutrophils and monocytes in the CSF without hypoglycorrhachia but subsequently transitions to a predominantly lymphocytic pleocytosis. Vogt-Koyanagi-Harada syndrome, a rare uveomeningoencephalitis, consists of recurrent meningitis/meningoencephalitis and anterior or posterior uveitis, followed by vitiligo, poliosis, alopecia, and dysacousia; the CSF cellular response is mononuclear, and an autoimmune origin, directed against a melanocyte antigen, has been suggested.

Chronic Meningitis with Predominantly Neutrophilic Pleocytosis

Chronic persistent neutrophilic meningitis (Table 420-15) is defined by the following combination: (1) clinical features consistent with meningitis; (2) initial CSF examination showing greater than 50% neutrophils, hypoglycorrhachia, and elevated protein concentration; (3) antimicrobial therapy that would be appropriate for the usual causes of bacterial meningitis; (4) negative smears and cultures for bacteria on the initial CSF specimen; and (5) repeated CSF examination 7 days or more after initial analysis showing 50% or greater neutrophils, hypoglycorrhachia, and elevated protein concentration.

Among the bacterial causes (see Table 420-15) are organisms (*Actinomyces israelii* and *Arachnia propionica* [Chapter 337]) that can be isolated by culture only under anaerobic conditions. Coexisting pulmonary lesions may suggest *Nocardia* (Chapter 338) or *M. tuberculosis* (Chapter 332) as the cause, although the initial polymorphonuclear pleocytosis present in some cases uncommonly persists much beyond a week before changing to a lymphocytic predominance. *Brucella* (Chapter 318) and endemic invasive mycotic infections would be suggested by epidemiologic considerations. Other fungal causes may be diagnosed, particularly in immunocompromised patients, by antigen testing with enzyme-linked immunosorbent assay (*Aspergillus* sp galactomannan; Chapter 347), or meningeal biopsy may be required.

Occasionally, exogenous chemical meningitis secondary to intrathecal injection of antimicrobials, chemotherapeutic agents, or contrast media may produce persisting pleocytosis and hypoglycorrhachia resulting from sclerosing arachnoiditis well after the inciting medication has been withdrawn. Systemic lupus erythematosus (Chapter 274) can produce a variety of meningitides, including acute lymphocytic or neutrophilic aseptic meningitis, as well as chronic persistent lymphocytic or neutrophilic CSF responses.

Eosinophilic Meningitis

The presence of 5% or greater eosinophils in CSF is uncommon and suggests parasitic disease, certain fungal infections such as coccidioidal or candidal meningitis, neoplastic diseases, or a few inflammatory processes (see Table 420-13). In most cases, eosinophils are mixed with lymphocytes, which predominate; the highest percentage of eosinophils is seen with meningitis caused by migrating larvae of the raccoon ascarid *Baylisascaris procyonis* (Chapter 365) and the rat lung worm *Angiostrongylus cantonensis* (Chapter 365). In fungal meningitides, particularly those resulting from *C. immitis* (Chapter 341), the CSF response is primarily mononuclear with 6 to 20% eosinophils; hypoglycorrhachia may be a feature of *C. immitis* and *Candida* meningitis (Chapter 346) and of neoplastic processes and sarcoid.

Most patients with eosinophilic meningitis, except those with cases resulting from trichinosis (Chapter 365) or drug hypersensitivity, have prolonged symptoms suggesting chronic meningitis. Most patients with meningitis of parasitic or neoplastic origin have evidence of cerebral involvement as well.

BRAIN ABSCESS AND PARAMENINGEAL INFECTIONS

AVINDRA NATH AND JOSEPH BERGER

Brain abscess affects the brain's parenchyma directly, whereas parameningeal infections produce suppuration in potential spaces covering the brain and spinal cord (epidural abscess and subdural empyema) or produce occlusion of the contiguous venous sinuses and cerebral veins (cerebral venous sinus thrombosis).

BRAIN ABSCESS

EPIDEMIOLOGY

The frequency of various causes of brain abscess (Table 421-1) in the population has been difficult to ascertain because of wide variations among case series, in part as a result of referral patterns. In addition, case series of children with brain abscesses contain a sizable contingent of cases related to cyanotic congenital heart disease or otogenic infection. Cryptogenic abscesses account for a greater percentage of cases in more recent series, perhaps related to the presence of a patent foramen ovale. On average, 90% of brain abscesses occur as a consequence of a focus of suppuration elsewhere in the body, with the remainder due to introduction of the infection from head wounds or neurosurgical procedures. Males predominate in virtually all series of brain abscess. Terminally ill patients in whom medical care may be withdrawn may be found to have abscesses at autopsy, but these abscesses are of little clinical importance.

Immunosuppression
Unknown mechanism

PATHOBIOLOGY

Brain abscesses are collections of purulent material (neutrophils and necrotic tissue) caused by infection with a variety of bacterial, fungal, and parasitic organisms. Infection arising from other sites typically seeds the brain hematogenously. When contiguous to the brain, infection enters the brain by direct extension or by traveling along veins with associated thrombophlebitis of pial veins and sinuses. Within the brain, the infection begins as a cerebritis with perivascular infiltrates and infiltration of neutrophils into the brain parenchyma. With time, the developing abscess is characterized by a purulent exudate that includes necrotic brain tissue as well as viable and necrotic neutrophils. Granulation tissue develops at the interface between necrotic and viable tissue, and eventually, the abscess is walled off by a fibrous capsule. Formation of the capsule depends on the virulence of the organism and the immune status of the individual. More virulent organisms are associated with larger lesions, more necrosis, earlier ependymitis, and more frequent areas of inflammatory escaping outside the collagen capsule. Immunocompromised patients, such as human immunodeficiency virus (HIV)-infected patients with *Toxoplasma* species abscesses, are unable to mount an immune response to form a capsule and hence respond well to antibiotic therapy alone.

CLINICAL MANIFESTATIONS

The clinical picture reflects a triad of the infectious nature of the lesion, focal brain involvement, and an increasing intracranial mass effect (Table 421-2). One or two elements may be absent in a given case, particularly early in the course. Among infectious symptoms, fever is present at onset or early in the course in only about 60% of cases. Neck stiffness is an infrequent complaint, and meningeal signs are elicited in about 30% of cases.

Focal neurologic deficits depend on the site of the lesion, which in turn will be determined by the causal or predisposing condition. In some patients, seizures precede the diagnosis. The early deficits in patients with temporal lobe lesions, which are typically caused by spread of an otogenic abscess, are contralateral homonymous superior quadrantic visual field defects and, if in the dominant hemisphere, aphasia. Motor deficits eventually occur in 40 to 50% of supratentorial abscesses. Cerebellar abscesses, which are often caused

TABLE 421-2 BRAIN ABSCESS: INITIAL FEATURES IN 123 CASES

Headache	55%
Disturbed consciousness	48%
Fever	58%

Nausea, vomiting	32%
Seizures	19%
Visual disturbance	15%
Dysarthria	20%
Hemiparesis	48%
Sepsis	17%

by aural-mastoid infections, are characterized by ipsilateral limb ataxia; there may also be abnormal head positioning, forward and away from the side of the lesion, and nystagmus that is slow and coarse on gaze to the side of the abscess and rapid in the opposite direction. Patients with multiple brain abscesses may have multifocal signs or encephalopathy. Patients with *Toxoplasma* species (Chapter 357) brain abscesses often have movement disorders because these abscesses frequently localize to the basal ganglia. In fact, nearly all patients with HIV infection in whom hemiballism or hemichorea is present have *Toxoplasma* species brain abscesses.

Headache is an important initial symptom in 80 to 90% of patients with bacterial abscess but is less frequent (approximately 20%) in patients with fungal abscesses. Symptoms of increased intracranial pressure, such as nausea, depressed level of consciousness, and papilledema, occur less often. The development of headache in a patient with a known chronic anaerobic infection, such as aural-mastoid, paranasal sinus, or pulmonary suppuration, suggests the possibility of brain abscess. Similarly, the development of headache in a child with cyanotic congenital heart disease is often related to a brain abscess. Tetralogy of Fallot (Chapter 69) is the most common congenital heart anomaly associated with brain abscess.

DIAGNOSIS

Examination of the cranium, ears, paranasal sinuses, oral cavity, heart, and lungs may provide important clues to the etiology, as may overt signs of infection at other sites. Cultures of blood and sputum may identify the organism and its antimicrobial sensitivity. In patients with signs of raised intracranial pressure, lumbar puncture may be contraindicated.

Magnetic resonance imaging (MRI) can detect early changes, such as brain edema, and is preferable to computed tomography (CT). In the early cerebritis stage, T2-weighted MRI shows abnormally high signal intensity corresponding to low signal intensity on the T1-weighted images. The fluid-attenuated inversion recovery (FLAIR) sequence provides superior visualization of brain edema. On T1-weighted images, the area of cerebritis that is seen initially as a low-signal-intensity, ill-defined area later progresses to a central cavity with slightly higher signal intensity than cerebrospinal fluid (CSF), surrounded by edema that is slightly hypointense in comparison to brain parenchyma. Later stages of infection show central necrosis and formation of a rim of slightly high signal intensity on T1-weighted images (Fig. 421-1). Gadolinium administration shows a ring-enhancing lesion. Diffusion-weighted imaging helps differentiate abscesses from brain tumors; an abscess cavity demonstrates high signal with decreased apparent diffusion coefficient values, whereas necrotic tumor cavities demonstrate the opposite.

Surgical aspiration or excision of the lesion may be necessary to establish a microbial diagnosis. Gram stain and culture from abscess fluid, with proper handling, have high yield, with or without previous antibiotic therapy. If immediate surgery is planned, antibiotics can be deferred until culture material has been acquired. Multiplex polymerase chain reaction testing is being developed for rapid identification of bacterial organisms and detection of antibiotic resistance genes.

TREATMENT

Rx

Brain abscess requires urgent intervention. Because of the risk for cerebral herniation with large lesions, treatment of cerebral edema (intravenous dexamethasone, 16 to 24 mg/day in four divided doses) may be needed even while initiating surgical intervention. Corticosteroids often decrease edema within 8 hours but may retard the formation of a capsule around the brain abscess, may suppress the immune response to the infection, and may decrease penetration of antibiotics; hence, they should be used for short periods, usually only until surgical decompression by needle drainage or surgical removal is possible. A trial of nonsurgical treatment may be considered in patients with (1) small lesion size; (2) an already identified pathogen; (3) no symptoms or signs of increased intracranial pressure requiring neurosurgical intervention; (4) a deep or inaccessible lesion; (5) multiple abscesses; (6) a contraindication to surgery (e.g., a bleeding diathesis); (7) a short duration of symptoms, which suggests that the lesion is in the cerebritis stage; and (8) availability of monitoring with MRI. Patients with acquired immunodeficiency syndrome and suspected cerebral toxoplasmosis (Chapter 357) should receive antimicrobial therapy initially. In patients who are suspected of having a brain stem abscess, the possibility of listerial infection (Chapter 301) should be considered (Fig. 421-2), even in the absence of a clear immunodeficiency. Empirical parenteral antibiotics to cover *Listeria* species should be started (Chapter 301).

Successful antibiotic management of brain abscess is based on knowledge of proved or suspected pathogens as well as familiarity with a drug's spectrum of activity and penetration into the central nervous system. When surgery cannot be performed, empirical antibiotic therapy must be initiated even if the organism cannot be isolated from the abscess (Table 421-3).

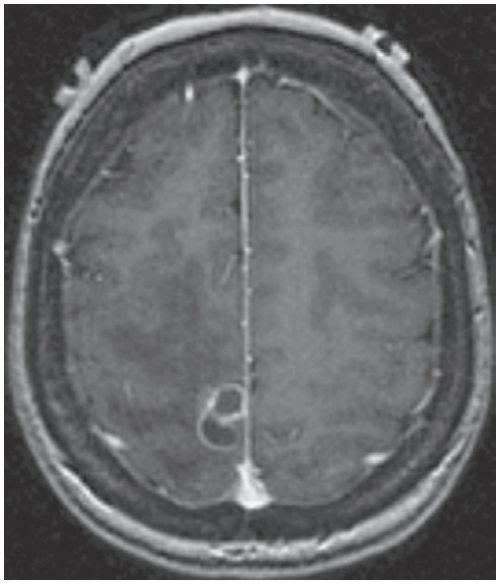

FIGURE 421-1. Brain abscess. Magnetic resonance imaging with gadolinium shows a multiloculated ring-enhancing lesion caused by *Nocardia* species infection.

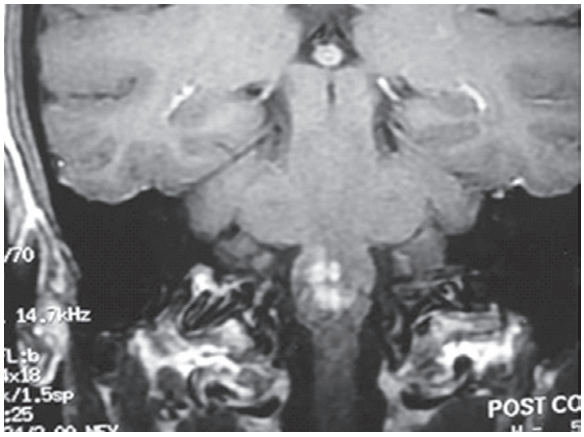

FIGURE 421-2. Brain stem abscess. Magnetic resonance imaging with gadolinium shows an enhancing lesion in the brain stem caused by *Listeria* species infection.

PROGNOSIS

Before the CT scan era, the mortality of brain abscesses ranged from 40 to 60%, and even with the drastic reduction in mortality in the era of modern neuroimaging, the mortality rate remains about 15%. In post-transplantation patients and those with deep hemispheric or brain stem abscesses, mortality

TABLE 421-3 COMMON PATHOGENS AND EMPIRICAL THERAPY FOR BRAIN ABSCESS

PREDISPOSING CONDITION	COMMON PATHOGENS	ANTIMICROBIAL AGENTS
Dental abscess	Streptococci, *Bacteroides fragilis*	Penicillin + metronidazole
Chronic otitis	*Bacteroides fragilis; Pseudomonas, Proteus, Klebsiella* species	Cefotaxime or ceftriaxone + metronidazole; ceftazidime or cefepime for *Pseudomonas* species
Sinusitis	Streptococci; *Haemophilus, Staphylococcus* species	Cefotaxime, ceftriaxone, or nafcillin + metronidazole
Penetrating trauma or postsurgical	*Staphylococcus, Pseudomonas, Enterobacter* species; streptococci	Nafcillin or vancomycin + ceftriaxone or cefotaxime + metronidazole
Bacterial endocarditis or drug use	Mixed flora, streptococci, *Staphylococcus* species	Nafcillin or vancomycin + ceftriaxone or cefotaxime + metronidazole
Congenital heart disease	Streptococci	Cefotaxime or ceftriaxone
Pulmonary infection	*Nocardia* species, *Bacteroides fragilis*, streptococci, mixed flora	Penicillin + metronidazole + trimethoprim-sulfamethoxazole
HIV infection	*Toxoplasma gondii*	Pyrimethamine + sulfadiazine + folinic acid

rates may exceed 80%. Other factors associated with a poor prognosis include extremes of age, multiple abscesses, and diagnostic delay in the absence of systemic signs of infection. Impaired level of consciousness is a poor prognostic sign even with early hospitalization and rapid diagnosis. Anaerobic and gram-negative organisms and culture-negative cases also have a poor prognosis. Seizure (Chapter 410) is a long-term risk that develops in up to 50% of patients, sometimes after latencies as long as 5 years.

SPINAL EPIDURAL ABSCESS

DEFINITION

Infection within the epidural space around the spinal cord is an uncommon but readily treatable potential cause of paralysis and death. The epidural space surrounds the dural sac and is limited by the posterior longitudinal ligament anteriorly, the ligamenta flava and the periosteum of the laminae posteriorly, and the pedicles of the spinal column and the intervertebral foramina containing their neural elements laterally. The space communicates with the paravertebral space through the intervertebral foramina. Superiorly, the space is closed at the foramen magnum. Caudally, the space is closed by the sacrococcygeal ligament. The epidural space contains loose areolar connective tissue, semiliquid fat, lymphatics, arteries, an extensive plexus of veins, and the spinal nerve roots.

EPIDEMIOLOGY

Spinal epidural abscesses can result from hematogenous spread of infection; risk factors include intravenous drug use, organ transplantation, chronic steroid use, malignancy, and diabetes. Local infection after acupuncture for back pain or epidural analgesia can also cause epidural abscesses. Cutaneous sites of infection are the most common remote sources, especially in intravenous drug users. Abdominal, respiratory tract, and urinary sources are also common. Osteomyelitis may be a cause of either direct extension or hematogenous spread, particularly when associated with sepsis. Contiguous spread may occur from epidurally placed catheters, psoas abscesses, decubitus ulceration, perinephric and retropharyngeal abscesses, or surgical sites. Minor back trauma has been implicated in causing a paraspinal hematoma, which may subsequently be seeded hematogenously. *Staphylococcus aureus* is the most common organism isolated from spinal epidural abscesses.

PATHOBIOLOGY

Because the dura mater around the cord is adherent to the vertebral column anteriorly, more epidural abscesses lie posteriorly, and because no anatomic barriers separate the spinal segments in the posterior epidural space, such abscesses usually extend over several vertebral segments. Spinal cord dysfunction probably reflects toxic processes secondary to inflammation, as well as venous thrombosis, thrombophlebitis, ischemia secondary to compression of the spinal arteries, and edema.

CLINICAL MANIFESTATIONS

The presence of a risk factor (>80% of patients) in the setting of neurologic deficits or back or radicular pain should suggest a spinal epidural abscess. The clinical manifestations can be divided into four stages (Table 421-4). Back pain (71%), fever (66%), tenderness of the spine with focal percussion (17%), spinal irritation (20%), and headache (3%) are common. Radicular pain can be mistaken for sciatica, a visceral abdominal process, chest wall pain, or cervical disc disease. Clinical signs are often substantially greater than would be predicted from the anatomic extent of pus or granulation tissue.

Unfortunately, the diagnosis often is missed initially. If the condition goes unrecognized at an early stage, the symptoms can evolve, over a period of hours to days, to paralysis below the spinal level of infection.

DIAGNOSIS

The differential diagnosis includes compressive and inflammatory processes involving the spinal cord: transverse myelitis (Chapter 419), herniation of an intervertebral disc (Chapter 407), epidural hemorrhage (Chapter 407), or metastatic tumor (Chapter 195), none of which are associated with evidence of systemic infection. Blood leukocytosis may not be present, but the sedimentation rate is often elevated. Other infectious processes that may produce back or neck pain or tenderness must be excluded: bacterial meningitis (Chapter 420), perinephric abscess, disc space infection (Chapter 407), and bacterial endocarditis (Chapter 76).

Lumbar puncture should be avoided in patients suspected of having a spinal epidural abscess for fear of spreading the infection to the subarachnoid space and causing meningitis. Gadolinium-enhanced MRI (Fig. 421-3) is the method of choice for diagnosis, but MRI findings in patients undergoing epidural analgesia can resemble those of epidural spinal abscess, even when no infection is present.

TREATMENT

Rx

Patients with a progressing neurologic deficit should undergo urgent surgical drainage; CT-guided aspiration may be useful, and antibiotics plus percutaneously guided needle aspiration may be as therapeutically effective as antibiotics plus surgery. Unless culture results and sensitivities dictate otherwise, empirical therapy should cover *S. aureus* (nafcillin, 2 g every 6 hours; vancomycin, 1 g every 12 hours for methicillin-resistant strains). Additional gram-negative coverage with a third-generation cephalosporin (e.g.,

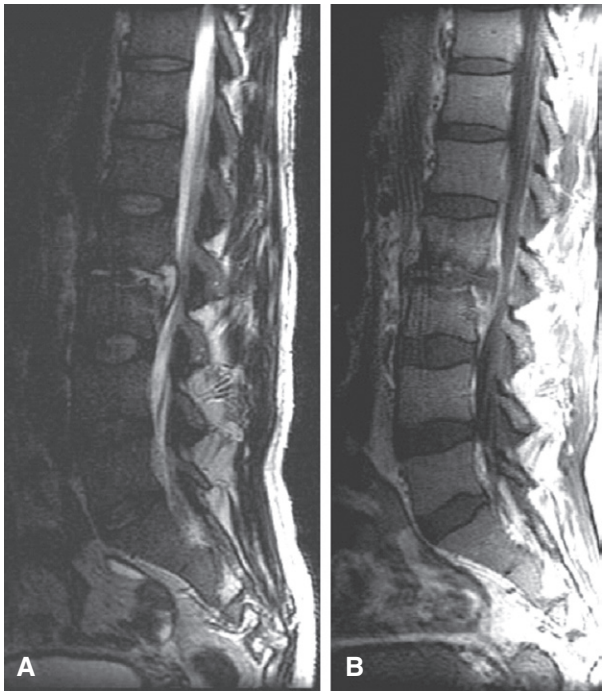

FIGURE 421-3. Epidural abscess. A and **B,** Magnetic resonance images of the lumbosacral spine show a lesion in the epidural space compressing the thecal sac. (Courtesy of Drs. Martin Pomper and Dima Hammoud, Johns Hopkins University.)

cefotaxime, 2 g every 6 hours, or ceftriaxone, 2 g every 12 hours) or a quinolone (e.g., ciprofloxacin, 400 mg every 12 hours) should be considered for severe disease. Rifampin (300 mg every 12 hours) may be added because of its ability to penetrate the abscess cavity. Intravenous therapy should be continued for 3 to 4 weeks, except in the presence of osteomyelitis (6 to 8 weeks).

PROGNOSIS

The mortality rate associated with spinal epidural abscess is about 15%. Approximately 50% of survivors have residual neurologic deficits. More severe preoperative neurologic deficits and deficits of longer duration are associated with a worse prognosis. In general, patients who develop paralysis that persists for longer than 36 hours do not recover function.

SUBDURAL EMPYEMA

Subdural empyema is an infection in the space between the dura and the arachnoid. It usually results from infected paranasal sinuses and rarely from infected mastoid sinuses by extension of thrombophlebitis from the sinuses into the subdural space. The infection is most commonly unilateral because bilateral spread is prevented by the falx. The empyema may evolve to cause cortical vein thrombosis, cerebral abscesses, or purulent meningitis.

CLINICAL FEATURES AND DIAGNOSIS

The most common symptoms are headache, fever, a neurologic deficit, and a stiff neck. However, subdural empyema may progress and cause signs of raised intracranial pressure, such as vomiting, altered level of consciousness, seizures, and papilledema. A high degree of suspicion is needed to establish the diagnosis early in the course of the illness. In patients with sinusitis (Chapter 434), the symptoms of subdural empyema may be incorrectly attributed to the sinusitis.

MRI with gadolinium enhancement and diffusion-weighted images is particularly useful in visualizing the subdural infection as a crescent-shaped mass with an enhancing rim over the cerebral convexities and below the inner table of the skull. CSF evaluation is useful only if there is accompanying meningitis. In a patient with signs of raised intracranial pressure, lumbar puncture should be avoided because of the risk for herniation.

TREATMENT Rx

Surgical drainage of the empyema is mandatory. Intravenous antibiotic therapy is also necessary and is based on the organisms isolated at the time of craniotomy.

PROGNOSIS

Mortality rates in most series are about 25%, with severe neurologic sequelae remaining in 20% of survivors. Accompanying venous sinus thrombosis or brain abscess carries a poor prognosis.

VENOUS SINUS THROMBOSIS SECONDARY TO INFECTION

The venous sinus system lacks valves, thereby permitting retrograde propagation of clots or infections that emanate from structures located in the central portion of the face or the middle ear.

Septic Cavernous Sinus Thrombosis

DEFINITION

The cavernous sinuses are the most caudal dural venous chambers at the base of the skull. The paired structures lie on either side of the pituitary fossa immediately above the midline sphenoid sinus. The cavernous sinus encloses the "cavernous portion" of the internal carotid artery as well as the third, fourth, and sixth cranial nerves en route to the apex of the orbit.

EPIDEMIOLOGY AND PATHOBIOLOGY

The infection usually spreads from the paranasal sinuses, dental abscesses, or other infections affecting the orbit or middle third of the face. *S. aureus* is the most common organism. Streptococci, pneumococci, and gram-negative bacilli are less common; anaerobic infection has also been reported. Many cases of idiopathic intracranial hypertension (Chapter 195) are due to thrombosis in the lateral sinuses.

CLINICAL MANIFESTATIONS

Cavernous sinus thrombosis may be manifested as an acute, fulminant disease or have an indolent, subacute manifestation. Fever and other systemic symptoms from sepsis may be present. Clinical symptoms and signs are related to anatomic structures within the cavernous sinuses or drained by them: unilateral periorbital edema, headache, photophobia, proptosis, ophthalmoplegia, pupillary dilation, decreased corneal reflex, and periorbital sensory loss. Obstruction of venous drainage from the retina can result in papilledema, retinal hemorrhages, and visual loss. The infection can spread rapidly (24 to 48 hours) through the intercavernous sinuses to the contralateral cavernous sinus. Thrombus can extend to other dural venous sinuses, adjacent vascular structures, or the brain parenchyma.

DIAGNOSIS

The diagnosis is made on clinical grounds and confirmed by radiographic studies. Radiologic evaluation includes sinus imaging, particularly the sphenoid and ethmoid sinuses. MRI using flow parameters and a magnetic resonance (MR) venogram is very sensitive and may reveal deformity of the cavernous portion of the internal carotid artery, a heterogeneous signal from the abnormal cavernous sinus, and an obvious hyperintense signal of thrombosed vascular sinuses. MRI with intravenous gadolinium can demonstrate venous thrombosis by illustrating a lack of the normal "flow void" within vascular structures. Cranial CT scans are less helpful but may show a subtle increase in the size and enhancement of the thrombosed sinus. MR angiography may demonstrate extrinsic narrowing of the intracavernous portion of the internal carotid artery.

TREATMENT AND PROGNOSIS Rx

Blood cultures are often negative, so delays in diagnosis are common. Even when the diagnosis is established, empirical antimicrobial treatment may not provide full coverage.

Treatment consists of prompt drainage of infected paranasal sinuses or other identifiable source of infection as well as specific antistaphylococcal agents (Chapter 296). Heparin anticoagulation without a loading dose is sometimes initiated to reduce morbidity from associated brain ischemia, but experience in septic venous thrombosis is limited compared with the more frequent use of anticoagulation in nonseptic venous thromboses. Hemorrhage caused by anticoagulation is rare in this setting. Despite modern therapy, mortality rates remains as high as 44%.

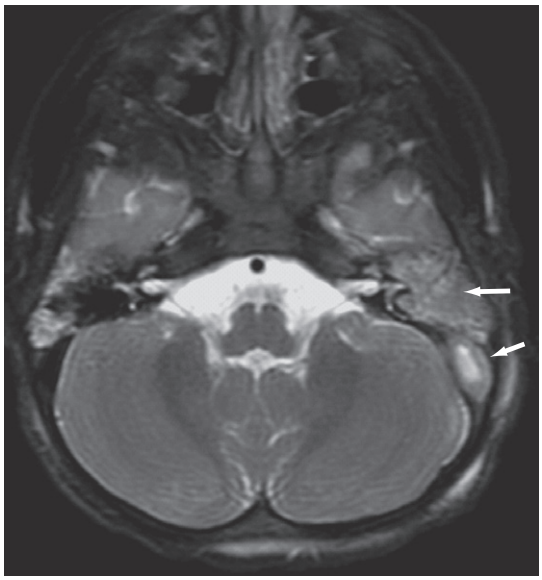

FIGURE 421-4. Lateral sinus thrombosis. Magnetic resonance imaging shows a thrombus in the lateral sinus *(short arrow)* with accompanying mastoiditis *(long arrow)*. (Courtesy of Drs. Martin Pomper and Dima Hammoud, Johns Hopkins University.)

Lateral Sinus Thrombosis

Septic thrombosis of the lateral sinus results from acute or chronic infections of the middle ear.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms consist of ear pain and fever followed by headache, nausea, vomiting, loss of hearing, and vertigo, usually evolving over a period of several weeks. Symptoms or signs suggestive of otitis media (Chapter 434), including mastoid swelling, may be seen. Sixth cranial nerve palsies can occur, but other focal neurologic signs are rare. In some patients with nonseptic lateral sinus thrombosis, headache may be the only symptom. Papilledema occurs in 50% of cases, and elevated CSF pressure is present in most, especially with occlusion of the right lateral sinus, which is the major venous conduit from the superior sagittal sinus (Fig. 421-4).

CSF is usually normal, although a parameningeal inflammatory profile (mild pleocytosis, slight elevation in protein level, and a normal glucose level) may be seen. The diagnosis is confirmed by MR venography.

TREATMENT Rx

Treatment includes intravenous antibiotics to cover staphylococci, anaerobes, and gram-negative bacilli such as *Proteus* species and *Escherichia coli* (nafcillin, 2 g every 6 hours, or vancomycin, 1 g every 12 hours; plus cefotaxime, 2 g every 6 hours, or ceftriaxone, 2 g every 12 hours; plus metronidazole, 7.5 mg/kg every 6 hours, or clindamycin, 300 mg every 6 hours; plus ciprofloxacin, 400 mg every 12 hours). Surgical drainage (mastoidectomy or tympanoplasty) may be required to eradicate the nidus of infection and to determine the antibiotic susceptibility of the organism. If the sinus contains pus, it must be opened so that the septic thrombus can be removed. Unless vision is compromised, increased intracranial pressure seldom requires specific treatment such as drainage or placement of a shunt.

PROGNOSIS

Broad intravenous antibiotic coverage and eradication of the perisinus infection, which may require surgical drainage, early in the course of the illness lead to a good prognosis. Neurologic sequelae may include a sixth nerve palsy, ataxia, and hearing loss.

Septic Sagittal Sinus Thrombosis

Although superior sagittal sinus thrombosis is the most common form of venous sinus thrombosis and is frequently associated with the use of oral contraceptives, septic sagittal sinus thrombosis is an uncommon condition that occurs as a consequence of purulent meningitis, infections of the ethmoid or maxillary sinuses spreading through venous channels, compound infected skull fractures, or rarely, neurosurgical wound infections.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms are primarily related to the elevated intracranial pressure and can evolve rapidly to stupor and coma. Seizures and hemiparesis may result from cortical infarction. Early recognition and treatment are necessary because septic sagittal sinus thrombosis carries a high mortality rate. The rate of progression, severity of symptoms, and prognosis are all related to the location of thrombosis. Obstruction of the anterior third of the sinus produces less intense symptoms and evolves more slowly.

CSF abnormalities are frequent, including enough red blood cells that the CSF can sometimes be mistaken for a subarachnoid hemorrhage; the opening pressure is increased in proportion to the extent of sagittal sinus involvement. A septic sagittal sinus is best visualized during the venous phase of cerebral angiography or MR venography. The diagnosis can also be made by MRI, which demonstrates an abnormal increase in signal intensity (absent flow void) within the affected venous sinus. Contrast-enhanced CT scanning may reveal a contrast void lying at the junction of the transverse and sagittal sinuses (the region of the torcular); this so-called delta sign is an intraluminal clot surrounded by contrast material.

TREATMENT Rx

Intravenous antibiotics should be directed at organisms recovered from the meningeal process or the meningeal site. *S. aureus* (Chapter 296), β-hemolytic streptococci (Chapter 298), pneumococci (Chapter 297), and gram-negative aerobes such as *Klebsiella* species (Chapter 314) are the most common organisms. Associated paranasal sinusitis should be drained surgically.

PROGNOSIS

If the thrombosis progresses to involve the middle and posterior thirds of the sinus, deterioration progresses rapidly. The prognosis is poor, with a mortality rate of nearly 30%.

NEUROLOGIC COMPLICATIONS OF INFECTIOUS ENDOCARDITIS

Neurologic complications develop in nearly one third of patients with infective endocarditis (Chapter 76), and neurologic manifestations are the initial symptom in 20% of patients with infective endocarditis. In nearly 30% of patients, the neurologic complications occur within 2 weeks after the initiation of treatment. Stroke is the most common manifestation; most strokes are due to cerebral emboli, and others are due to intracerebral hemorrhage. Infective endocarditis should always be considered in a patient with a fever and stroke.

PATHOBIOLOGY

Cerebral embolization occurs as a result of dislodgement or disruption of the cardiac vegetations that frequently cause occlusion of cerebral blood vessels. Emboli occurring before the initiation or completion of treatment with antibiotics may contain microorganisms capable of causing metastatic infections such as abscesses, arteritis, meningitis, or mycotic aneurysms. Most cerebral emboli involve small or moderate-sized blood vessels, and multiple cerebral emboli are common. Intracranial hemorrhage is usually due to rupture of a mycotic aneurysm (Chapter 415), septic erosion of the arterial wall without the formation of an aneurysm, or hemorrhagic transformation of a large cerebral infarct. About 20% of patients with mycotic aneurysms have multiple aneurysms; involvement of the middle cerebral artery and its branches occurs in more than 75% of patients, unlike congenital aneurysms, which occur predominantly in the circle of Willis. Mycotic aneurysms develop as a result of either septic embolization into the vasa vasorum or direct penetration of the microorganism into the wall of the artery. Streptococci and staphylococci account for nearly 90% of all mycotic aneurysms.

CLINICAL MANIFESTATIONS

The nature of the clinical manifestations depends on the underlying pathophysiology. Embolic stroke typically causes the acute onset of a focal neurologic deficit. Seizures may also occur. Multiple microemboli result in an altered or fluctuating level of consciousness not adequately explained by other abnormalities.

Most patients with mycotic aneurysms have a sudden, often fatal subarachnoid or intracerebral hemorrhage without warning signs. Warning signs, if present, include severe localized headache, ischemic events, seizures, and cranial nerve abnormalities. In some patients, mycotic aneurysms may be asymptomatic and resolve with antibiotic therapy. Clinical features of brain abscess and meningitis (Chapter 420) may also be observed in the setting of bacterial endocarditis.

DIAGNOSIS

MRI is the modality of choice for the diagnosis of cerebral infarcts and brain abscesses related to endocarditis, a CT scan is the best test for intracranial hemorrhage, and an MR angiogram is preferred for diagnosing an aneurysm. CSF evaluation is useful if accompanying meningitis or a slow leak from an aneurysm is suspected but not visualized with these imaging tests.

TREATMENT

Rx

Treatment of patients with infective endocarditis and cerebral emboli requires prevention of embolization with appropriate antibiotic therapy and sometimes cardiac surgery (Chapter 76). Anticoagulation is contraindicated in patients with cerebral infarcts and septic emboli because of the high risk for complications from intracerebral bleeding.

Patients with unruptured aneurysms smaller than 7 mm in diameter, proximal aneurysms, multiple aneurysms, ruptured aneurysms without an intracerebral hematoma, and aneurysms for which excision is likely to cause a neurologic deficit can be monitored conservatively with serial MRI and MR angiography. All other aneurysms require surgical excision of the aneurysm and the adjacent septic vessel wall. Patients who cannot undergo surgery may be candidates for endovascular embolization of the aneurysmal vessel.

PROGNOSIS

Mortality rates in patients with infective endocarditis and cerebral emboli range from 30 to 80%. Mortality is high if there is hemorrhagic transformation of the infarct. Mortality in patients with ruptured mycotic aneurysms is 80%, and even patients with unruptured aneurysms have a mortality rate of 30%.

TABLE 422-1 COMMON CAUSES OF ENCEPHALITIS IN THE UNITED STATES

I. Causes of viral encephalitis
- A. Nonseasonal
  - Herpes simplex virus type 1 (herpes simplex encephalitis)
  - Herpes simplex virus type 2 (neonatal encephalitis)
- B. Seasonal—summer and fall—arboviruses (arthropod borne)
  - West Nile virus
  - St. Louis encephalitis virus
  - Eastern equine encephalitis virus
  - Western equine encephalitis virus
  - LaCrosse/California encephalitis virus
- C. Seasonal—non–arthropod borne
  - Summer and fall: enteroviruses (including coxsackieviruses, ECHO viruses, polioviruses, and enterovirus 71)
  - Winter: influenza virus
- D. Immunosuppressed patients
  - Human immunodeficiency virus (chronic HIV encephalitis)
  - Varicella-zoster virus (subacute encephalitis)
  - JC virus (progressive multifocal leukoencephalopathy)
  - Cytomegalovirus (ventriculitis or encephalitis)
  - Human herpesvirus 6 (possible subacute encephalitis)
  - Epstein-Barr virus (subacute encephalitis)

II. Uncommon causes in the United States
- Lymphotrophic choriomeningitis virus
- Rabies
- Measles (subacute sclerosing panencephalitis)
- Mumps
- Adenovirus
- Herpes B virus (of monkeys)
- Rubella (progressive rubella panencephalitis)

III. Causes outside the United States
- Tick-borne encephalitis virus (Russia, Asia)
- Japanese encephalitis virus (Japan, Southeast Asia, Malaysia)
- Venezuelan equine encephalitis virus (Central and South America)
- Dengue virus (Southern Asia, Africa, South America)
- Rift Valley fever virus (east central Africa)
- Murray Valley encephalitis virus (Australia)
- Powassan fever encephalitis virus (Canada)
- Nipah virus (Malaysia and Bangladesh)

ACUTE VIRAL ENCEPHALITIS

ALLEN J. AKSAMIT, JR.

DEFINITION

Encephalitis is an inflammatory process that affects the parenchyma of the brain, usually in a diffuse manner. The term *encephalitis* indicates that the predominant clinical syndrome arises from infection and inflammatory reaction in the parenchyma of the brain rather than in the leptomeninges. When both the leptomeninges and brain parenchyma are involved, the term *meningoencephalitis* is used.

EPIDEMIOLOGY
